(Received 22 December 2008; published 16 March 2009)

We demonstrate the existence of a novel superconducting state in high quality two-component MgB2 single crystalline superconductors where a unique combination of both type-1 (λ1/ξ1 < 1/√2) and type-2 (λ2/ξ2 > 1/√2) superconductor conditions is realized for the two components of the order parameter. This condition leads to a vortex-vortex interaction attractive at long distances and repulsive at short distances, which stabilizes unconventional stripe- and gossamerlike vortex patterns that we have visualized in this type-1.5 superconductor using Bitter decoration and also reproduced in numerical simulations.

Vortices in superconductors consist of a normal core with size ξ (coherence length) and supercurrents flowing over a distance λ (penetration depth). If two vortices are generated in a type-1 superconductor the normal cores would overlap first, due to the larger value of ξ with respect to λ, thus leading to a gain in the condensation energy and, consequently, to vortex-vortex attraction [1,2]. Two vortices in a type-2 material would have their supercurrents overlapping first, in view of the bigger λ, leading to vortex-vortex repulsion. An attractive vortex-vortex interaction results in the formation of macroscopic normal domains in the intermediate state [3], while vortex-vortex repulsion leads to the appearance of the Abrikosov lattice [4].

The recent discovery of the two-component superconductor MgB2 [5], with two weakly coupled coexisting order parameters, Ψ1 = Ψπ and Ψ2 = Ψσ, has opened remarkable new possibilities both for fundamental research and applications. Among the new research topics, we find the semi-Meissner state [6], the violation of the London law and Onsager-Feynman quantization [7], noncomposite vortices [8], intrinsic Josephson effect [9], two-condensate Bose systems [10], superfluidity in liquid metallic hydrogen [11], etc. The two-component character of MgB2 [12–15] is related with two different types of electronic bondings, π and σ, giving rise to two superconducting gaps with energies Δπ(0) = 2.2 meV [16,17] and Δσ(0) = 7.1 meV [18–20], respectively. Using the BCS expression \( \xi(0) = h v_F / \pi \Delta \) (where \( v_F \) is the Fermi velocity (5.35 × 10^5 m/s for the π band and 4.40 × 10^5 m/s for the σ band) [21], we obtain the two coherence lengths: \( \xi_\pi(0) = 51 \text{ nm} \) and \( \xi_\sigma(0) = 13 \text{ nm} \). The calculated \( \xi_\pi(0) \) value is in agreement with \( \xi_\sigma(0) = 49.6 ± 0.9 \text{ nm} \) obtained from the fit of the vortex profile measured by scanning tunneling spectroscopy [17]. The London penetration depths λπ and λσ can be found from the respective plasma frequencies \( \omega_{p\pi} \) and \( \omega_{p\sigma} \) [22]: λπ(0) = 33.6 nm and λσ(0) = 47.8 nm. As a result, at least in the clean limit, the π and σ components of the order parameter in MgB2 are in different regimes: \( \kappa_\pi = \lambda_\pi(0) / \xi_\pi(0) = 0.66 ± 0.02 < 1/\sqrt{2} = 0.707 \) (type-1) and \( \kappa_\sigma = \lambda_\sigma(0) / \xi_\sigma(0) = 3.68 > 1/\sqrt{2} \) (type-2). Therefore, clean MgB2 represents an excellent candidate to search for a new type of superconductivity, neither of the type-1 nor type-2 character, which we coined as type-1.5 superconductivity. In type-1.5 superconductors the vortex-vortex interaction is the result of the competition between short-range repulsion and long-range attraction and it is expected that vortices could form unusual patterns at low applied fields [6].

In this Letter, we present experimental observation of vortex patterns at low vortex densities in high quality MgB2 single crystals. The vortex patterns are compared with the results of molecular dynamics simulations based on a two-gap Ginzburg-Landau (GL) theory which results in peculiar equilibrium vortex structure (VS) such as gossamerlike vortex patterns and vortex stripes.

The MgB2 single crystals were grown using a high pressure method as described elsewhere [23]. The critical temperature of the samples is 38.6 K as determined from the ac-susceptibility response at zero field. The temperature dependence of the lower and upper critical fields \( H_{c1} \) and \( H_{c2} \) were determined by means of magnetization measurements [24,25] and by ac-susceptibility measurements, respectively. From the extrapolated value \( H_{c2}(0) = 5.1 \text{ T} \), we obtain \( \xi_{ab}(0) = 8.0 \text{ nm} \) close to the value found from the BCS theory for \( \xi_{ab}(0) \). In order to estimate the penetration depth of the σ band, we use the theoretical expression for the field at which the first vortex will penetrate a two component superconductor [Eq. (4) in Ref. [6]]. Considering \( \lambda_\sigma(0) = 33.6 \text{ nm} \) for the type-1 component and taking into account \( \xi_{ab}(0) = \xi_{\sigma}(0) = 8.0 \text{ nm} \) and \( H_{c1}(0) = 0.241 \text{ T} \) from our measurements, we obtain \( \lambda_{ab} = \lambda_\sigma = 38.2 \text{ nm} \) for our samples.

For coexisting two interpenetrating weakly coupled order parameters, vortex-vortex interaction can be derived...
from the GL theory by numerically minimizing the free energy of two vortices with a variational procedure [26]. We use the two-band GL functional:

\[
F_{\text{GL}}[\Psi_\sigma, \Psi_\pi, A] = F_\sigma + F_\pi + \int d^3r \left[ \frac{E_s}{2} (\Psi_\sigma^* \Psi_\pi + \Psi_\pi^* \Psi_\sigma) + \frac{1}{2\mu_0} (\nabla \times A)^2 \right].
\]

where

\[
F_\sigma = \int d^3r \left[ 2E_{ca} \left| \Psi_\sigma \right|^2 + \left| E_{ca} \right| \left| \Psi_\sigma \right|^4 + \frac{\Phi_0}{2\pi \sqrt{\mu_0 \kappa_\sigma^3}} \left| \nabla \Psi_\sigma \right|^2 \right].
\]

where \( \sigma = \sigma, \pi \) and \( \Phi_0 \) is the flux quantum. The estimations for the intrinsic condensation energies \( E_{ca} \) and the coupling energy \( E_s \) are taken from Ref. [27] and we use the values of \( \kappa_\sigma \) and \( \kappa_\pi \) obtained for our samples. The result of the minimization shows that the interaction between vortices is short-range repulsive and weakly long-range attractive, similarly to Ref. [6]. We model a system of overdamped vortices by molecular dynamics simulations. The equation of motion for a vortex \( i \) is

\[
F^v_i = \eta \Psi_i + \Phi_0 \frac{\left| E_{ca} \right|}{\mu_0 \kappa_\sigma} \left| \nabla \Psi_i \right|,
\]

where \( F^v_i \) represents the vortex-vortex interaction and \( F^T_i \) the thermal stochastic force satisfying \( \langle F^T_i(t) \rangle = 0 \) and \( \langle F^T_i(t) F^T_j(t') \rangle = 2\eta \delta_{ij} \delta(t - t')k_B T \). \( \eta = \Phi_0 k_B T \) is the viscosity, \( k_B T = 5.1 \text{ K} \) is the upper critical field, and \( \rho_n = 0.7 \mu \Omega \text{ cm} \) is the normal state resistivity. The system size used in our simulations is \( 2000 \times 2000 \lambda^2(0) \). Two systems with the number of vortices \( N_v = 150 \) and 400 are initially prepared in a high temperature molten state and then slowly annealed to \( T = 4.2 \text{ K} \) with 1000 temperature steps. We let the system stabilize during 2000 time steps in each step of temperature.

Bitter decoration experiments on MgB\(_2\) single crystals were performed at 4.2 K after cooling down in the presence of an applied field perpendicular to the sample surface (field cooling). In this way, a homogeneous vortex distribution all over the sample is expected. A Bitter decoration image at \( H = 1 \text{ Oe} \) shows clear evidence of an inhomogeneous distribution of vortices [Fig. 1(a)] reminding gossamer patterns: local groups of vortices with intervortex distances shorter than the average vortex distance \( (2\Phi_0/\sqrt{3B})^{1/2} = 5 \mu \text{m} \) are separated by randomly distributed vortex voids with the size of a few micrometers. This is in striking contrast with the conventional homogeneous vortex pattern formed in NbSe\(_2\) single crystals [see Fig. 1(b)]. The observed clustering of vortices in MgB\(_2\) samples is consistent with the theoretical modeling [6] for a two-component superconductor in the semi-Meissner state. In Fig. 2(a), the vortex positions in a selected region of the image shown in Fig. 1(a) are indicated as white dots, while in Fig. 2(b) the results from the numerical simulations for a two-component superconductor are shown. We also calculate the vortex configuration for a reference conventional type-2 superconductor. The obtained VS, considering \( \lambda = 69 \) nm and \( \xi = 7.7 \) nm [28], is similar to the one observed in NbSe\(_2\) samples [see Figs. 2(c) and 2(d)].

In order to characterize the VS inhomogeneity, we calculate the distribution of first neighbor distance, \( P_a \) [Figs. 2(e) and 2(f)]. The first neighbor distance, \( a \), is calculated by means of the Delaunay triangulation of the VS. For the VS of NbSe\(_2\), the distribution is Gaussian with a relative standard deviation \( \delta = SD/\langle a \rangle = 0.224 \), where SD is the standard deviation of the Gaussian fit to the experimental data and \( \langle a \rangle \) is the average first neighbor distance. On the other hand, in MgB\(_2\) samples, \( P_a \) is quite broad as a consequence of the inhomogeneous arrangement of vortices and has additional peaks at distances shorter and longer than the most probable separation [see

FIG. 1 (color). Magnetic decoration images of the vortex structure at \( T = 4.2 \text{ K} \) and \( H = 1 \text{ Oe} \) in (a) MgB\(_2\) and (b) NbSe\(_2\) single crystals. The scale bars in the images correspond to 10 \( \mu \text{m} \). Notice that the density of vortices in the decoration experiments represents the internal field \( B \) rather than the applied field \( H \). This leads to a different number of decorated vortices for NbSe\(_2\) and MgB\(_2\), even at the same applied field.
the red and green arrows in Fig. 2(e)]. The distribution of the first neighbor separation of the VS obtained by simulations of a two-component material has also a three-peak structure which is fairly broader when compared to the one obtained in the case of a one-component conventional type-2 superconductor [Fig. 2(f)]. The peaks at short distances in Figs. 2(e) and 2(f) correspond to an average minimum separation between vortices.

Figure 3(a) shows a Bitter decoration image of the VS in MgB$_2$ crystals at $H = 5$ Oe and $T = 4.2$ K. The vortex distribution also appears to be inhomogeneous at this field but in a rather different manner than in the experiment described above. In some regions of the sample, vortices agglomerate forming stripes while voids are formed on considerably larger areas [29]. The present experimental results seem to be in contradiction with previous reports of the VS at low fields in MgB$_2$ samples [30]. However, it is important to note that in Ref. [30] the authors show an image of the VS at 4 Oe in a very small region of the sample (approximately $10 \times 10 \ \mu m^2$). Therefore, it is not possible to determine whether the vortex distribution in the samples studied in Ref. [30] is uniform all over the sample or not.

Although the vortex stripe pattern is rather disordered, it is still possible to determine an average direction of vortex stripes as the one defined by the dashed yellow lines in Fig. 3(a), and to calculate the vortex density in lines parallel to the vortex stripes as a function of the distance measured along the direction of the yellow arrow in Fig. 3(a). In the inset of Fig. 3(b) we plot the linear vortex density normalized by the average value for both the MgB$_2$ and NbSe$_2$ VS at 5 Oe. In the case of MgB$_2$, fluctuations of the vortex density of the order of 50% are observed. A similar calculation along lines perpendicular to the stripes shows that the standard deviation of the mean value is of the order of 30%. The large fluctuations of the vortex density in MgB$_2$ are in contrast to what is observed in NbSe$_2$ crystals where the standard deviation of the vortex density is approximately 1% of the average value. A remarkable similarity is found between experiments and simulations at still low density but higher than the one shown in Fig. 2. Disordered vortex stripes are formed in the two-component superconductor while a homogeneous distribution is apparent in the case of a conventional type-2 material [Figs. 3(c) and 3(d), respectively]. Consistently, the vortex density is seen to fluctuate in the direction perpendicular to the vortex stripes in the type-1.5 material, as shown in the inset of Fig. 3(d).

Composition analysis (via an electron microprobe in a field emission scanning electron microscope) in an area across the stripes [in the direction of the yellow arrow in Fig. 3(a)] shows no significant variations in Mg or B content, thus ruling out the possibility to attribute the stripe formation to inhomogeneous surface pinning distribution. There is also no observed correlation between the vortex positions and localization of microdefects.

At $H = 10$ Oe, the VS in MgB$_2$ samples is similar to the one in NbSe$_2$ crystals indicating that this novel superconducting phase in two-component type-1.5 superconductors is only accessible at very low applied fields as predicted in Ref. [6].

In conclusion, the type-1.5 superconductivity is a totally new state which combines two regimes (type-1 and type-2)
in the same single material (clean MgB$_2$ and possibly also other two-gap materials such as Ba$_{1-x}$K$_x$Fe$_2$As$_2$ [31]). The vortex matter in type-1.5 superconductors behaves in an extremely unusual way. The combination of the vortex-vortex repulsion and attraction in the same material leads to the appearance of novel vortex patterns: gossamerlike vortex arrays and vortex stripes. Both novel patterns have been directly visualized by Bitter decorations on high quality single crystals. Moreover, analytical modeling of exotic vortex-vortex interaction (attractive mixed with repulsive) and extensive molecular dynamic simulations are in good agreement with our experimental data.

We would like to thank P. L’Hoe¨ st from the MTM Department in K. U. Leuven for performing the electron probe microanalysis experiments on the MgB$_2$ crystals. This work was supported by Methusalem Funding of the Flemish government, FWO-Vlaanderen, the Belgian Inter-University Attraction Poles IAP, and the ESF-INES Programmes.

[29] It is important to note that this agglomeration in the form of vortex stripes is not related to the presence of steps or surface defects in the crystal. In fact, there are regions where steps can be observed (not shown) but at those locations the vortex configuration revealed by Bitter decoration is unaffected by them.
