LATEST DEVONIAN AND EARLY CARBONIFEROUS PALYNOSTRATIGRAPHY OF NORTHERN BRAZIL AND NORTH AFRICA – A PROPOSED INTEGRATION OF WESTERN EUROPEAN AND GONDWANAN MIOSPORE BIOZONATIONS

PALYNOSTRATIGRAPHIE DU DÉVONIEN LE PLUS RÉCENT ET DU CARBONIFÈRE ANCIEN DU BRÉSIL ET D'AFRIQUE DU NORD – UNE PROPOSITION D'INTÉGRATION DES BIZONES DE MIOSPORES D'EUROPE OCCIDENTALE ET DU GONDWANA

Stanislas LOBOZIAK, José Henrique G. MELO and Maurice STREEL

LOBOZIAK, S., MELO, J.H.G. & STREEL, M. (1999). — Latest Devonian and Early Carboniferous palynostratigraphy of northern Brazil and North Africa – A proposed integration of western European and Gondwanan miospore biozonations. *Palynostratigraphie du Dévonien le plus récent et du Carbonifère ancien du Brésil et d'Afrique du Nord – Une proposition d'intégration des bizones de miospores d'Europe occidentale et du Gondwana*. — *Bull. Centre Rech. Elf Explor. Prod.* 22, 2: 241-259. 3 fig.; Pau, May 29, (1998) 2000. — ISSN : 1279-8215. CODEN : BCREDP.

Des successions de miospores du Dévonien le plus récent au Viséen du nord du Brésil et de bassins sélectionnés d'Afrique du Nord sont comparées, et leur remarquable similitude une fois encore confirmée. Elles attirent l'attention sur l'unité de la Microflore à *Aratrisporites saharensis*, une province palynofloristique distincte du Gondwana occidental, dans laquelle plusieurs formes endémiques, d'intérêt biostratigraphique régional, sont présentées en même temps que des espèces de miospores-guides d'affinité eur-américaine.

L'absence apparente de palynofloras du Tournaisien le plus récent et du Viséen ancien sur de vastes étendues de cette province peut être attribuée en partie à la condensation sédimentaire et en partie à des lacunes résultant de l'érosion.

Des réinterprétations de données faunistiques publiées sur les bassins algériens et libyens occidentaux semblent confirmer nos corrélations basées sur les miospores. Cependant des révisions taxonomiques et stratigraphiques de certaines faunes marines sont encore nécessaires dans les bassins carbonifères d'Afrique du Nord. Des contrôles par les faunes au Tournaisien et Viséen manquent dans les bassins du nord du Brésil.

ABSTRACT

Latest Devonian through Viséan miospore successions from northern Brazilian and selected North African basins are compared, and their remarkable similarities once again confirmed. They point out to the unity of the so-called *Aratrisporites saharensis* Microflore, a distinctive palynofloral province of western Gondwana where several endemic forms of regional biostratigraphic usefulness occur along with some age-diagnostic miospore species of Euramerican affinity.

Latest Tournaisian and Early Viséan palynofloras apparently remain unproven in extensive portions of that province, which can be attributed partly to sedimentary condensation, partly to erosional truncations.

Reinterpretations of published faunal data from Algerian Sahara and western Libyan basins seem to support our miospore-based correlations. However, taxonomic and stratigraphic updates of some marine faunas are still needed in Carboniferous basins of North Africa. Tournaisian - Viséan faunal controls are missing in northern Brazilian basins.

INTRODUCTION

According to the paleophytogeographic terminology currently in use for the Lower Carboniferous (CLAYTON, 1985; RAWN *et al.*, 1994), the Middle East, North Africa and northern Brazil were parts of the same palynofloral province. This is the so-called *Aratrisporites saharænsis* Microflora, which was supposedly restricted to temperate and possibly subpolar Southern belts in Gondwana during the Tournaïsiens and Viséan. As it contains several endemic miospore species, the *Aratrisporites saharænsis* Microflora is well differentiated from coeval, equatorial to southern subequatorial provinces (*Lophozonotriletes/Moniliospora* and *Vallatisporites/Grandispora* Microfloras in Euramerica; *Granulatisporites frustulentus* Microflora in Australia). RAWN *et al.* (1994, p. 5, 6, 9, 10) remark that accuracies in miospore taxonomy, troublesome stratigraphic data from North Africa, and apparently disparate ranges of some of the few miospore species shared with contemporary Euramerican provinces.

Mixed western European and Gondwanan miospore assemblages occur in Carboniferous strata of the Amazon, Solimões and Parnaíba Basins of northern Brazil (Loboziak *et al.*, 1998; MELO *et al.*, 1999). Elements with Euramerican affinity can be directly calibrated in terms of standard miospore successions in Britain and continental Europe (Naves *et al.*, 1972, 1973; CLAYTON *et al.*, 1977, 1978; HIGGS *et al.*, 1988a-b). In their turn, Early Carboniferous miospores of Gondwanan (*Aratrisporites saharænsis* Microflora) affinity were also used in tracing Petrobras' regional palynozozes of northern Brazil (DAEMON & CONTRERAS, 1971; DAEMON, 1974, 1976; ANDRADE & DAEMON, 1974). These permit correlation with similar biozonal schemes in North Africa, where some marine faunal data are available (LANZONI & MAGLOIRE, 1969; MASSA & VACHARD, 1979; LEMOSQUET *et al.*, 1985; WEVANT, 1985, etc.). Unfortunately, Late Carboniferous miospore successions of northern Brazil (not focused in this paper) remain poorly understood. As they are apparently less easily compared to Euramerican equivalents, correlations must partly rely on faunal datings provided by conodonts or foraminifera (LEWIS, 1992a-b; LEMOS & MEDEROS, 1989; ALTMER & SAVINI, 1995). These faunas are restricted to carbonate facies, and are mostly consistent with Westphalian or younger ages (Loboziak *et al.*, 1997b; MELO *et al.*, 1998, 1999).

Newly obtained results from the palynostratigraphic study of Tournaïsiens and Viséan sections from northern Brazilian basins give new insights into the age and succession of similar miospore assemblages in other sites of the *Aratrisporites saharænsis* Microflora. In this contribution, the correlation of Petrobras' earlier palynozozation with biozonal schemes of Algeria and western Libya, recently updated by Loboziak *et al.* (1998) for the Viséan section, is now extended to older intervals. Comparisons will focus particularly on those few North African regions where formal palynozozations have been established. These are the Algerian Sahara (Grand Erg Occidental) zonal scheme of LANZONI & MAGLOIRE (1969), based on which the Lower Carboniferous part of PETROBRAS biozonation was largely constructed, and the controversial palynozozes from Illizi and Hammadah (Ghadamis) Basins (ATTAR *et al.*, 1980; MASSA *et al.*, 1980; COQUEL *et al.*, 1988; COQUEL & LATRECHE, 1989; COQUEL & MASSA, 1993; STEEL & LOBOZIAK, 1994; ABDESSELAM-ROUGHI & COQUEL, 1997). Obviously, some implications of this review may eventually apply to other occurrences of the same microflora in North Africa and the Middle East, not considered herein, such as those in Iran, Niger, northeast Libya, Morocco and Syria (COQUEL *et al.*, 1977; LOBOZIAK & AL-FAHNI, 1978; CLAYTON & LOBOZIAK, 1985; LOBOZIAK & CLAYTON, 1988; LOBOZIAK *et al.*, 1990; RAWN *et al.*, 1994; COQUEL *et al.*, 1995).

1. — CORRELATION OF PETROBRAS' REGIONAL PALYNOZONES

The correlation of northern Brazilian palynozozes ("biostratigraphic intervals") VII to XIII (DAEMON & CONTRERAS, 1971; DAEMON, 1974, 1976; ANDRADE & DAEMON, 1974) with their latest Devonian - early Late Carboniferous equivalents from western Europe was already discussed to a great extent in previous papers (Loboziak *et al.*, 1997b, 1998; MELO & LOBOZIAK, 1997; MELO *et al.*, 1999). The most conclusive results are from the Amazon Basin, but valuable palynological information was also obtained from adjacent basins (Solimões, Parnaíba). A brief

summary of their main conclusions is provided below. Brazilian biozones younger than interval XII will not be considered in this paper.

Intervals VII (upper part) and VIII are of latest Famennian, or "Strunian", age, for they contain *Peltispora lepidophyta*. Usually, it is found in association with other distinctive species which are likewise restricted to the Devonian (e.g., *Flugospora radia-ta*, *Leiotriletes strunienis*, *Grandispora facilis*, *Speleotriletes granulatus* and *Vallatisporites hystricosus*), or still, persist into the Early Carboniferous (*Cordylosporites marciae*, *C. spathulatus*, *Indotriadites explanatus*, *Verrucosisporites nitidus*, *Vallatisporites vallatus*, *V. verrucosus*, *Tumulispora malevken-sis*, etc.). In western Europe, such miospore assemblages characterize the *R. lepidophyta* - *I. explanatus* (LE) - *R. lepidophyta* - *V. nitidus* (LN) zonal range and correspond to the *praesulcata* conodont Zone (Higgs & Street, 1984, 1994). As pointed out by Melo et al. (1999), even occurrences of the LE Zone are questionable in Brazil, and thus, a more restricted assignment of at least interval VIII to the LN Zone is locally possible. Though demonstrated for some Amazon Basin wells (e.g., 1-Fx-1-AM; cf. Loboziak et al., 1997a, Fig. 3), such equivalence may not apply to other areas, like the Paranaíba Basin. There, unpublished miospore data suggest that pre-"Strunian" and even Tournaisian strata may have been lumped together with LN-age beds into interval VIII, e.g., in well 1-TM-1-MA (ANDRADE & DAEMON, 1974, text-fig. p. 132; DAEMON, 1976, annex to p. 190).

In well 1-RX-1-AM, according to Loboziak et al. (1997a) data, the whole biozone VII corresponds to the upper part of the *D. versabilis* - *G. cornuta* (VCo) Opper Zone, of Late Famennian age (Fa2c to earliest Fa2d in Belgium according to Loboziak et al., 1997c). We have noticed the same equivalence in some other Amazon Basin wells, where the "Strunian" section had been entirely assigned by PETROBRAS biostratigraphers to interval VIII. Except for the top of this latter, which in at least the Amazon Basin closely parallels the Devonian/Carboniferous boundary, it appears that biozonal boundaries of intervals VII through XI can be variably diachronous with relation to Euramerican zonal markers.

Intervals IX to XI are all of Tournaisian age. However, distinction between them remains difficult (Melo et al., 1999, Fig. 3) because recent studies fail to recognize the same stratigraphic succession or ranges of their zonal miospore species as proposed in earlier works (DAEMON & CONTRERAS, 1971, Fig. 4; DAEMON, 1974, Tab. 1).

In the Amazon Basin, intervals IX and X correspond altogether to the *V. verrucosus* - *R. incohatus* (VI) to *S. balteatus* - *R. polyphycha* (BP) zonal range of western Europe, which corresponds to the *sulcata* through lowermost upper *crenulata* conodont Zones of Early to early Middle Tournaisian age (Higgs & Street, 1984, 1994; Higgs et al., 1992). Several Late Devonian holdovers and the Gondwanan species *Waltzispora lanzonii* characterize the oldest Tournaisian sections of northern Brazilian basins. Those taxa are joined, in late Early to early Middle Tournaisian sections, by such newcomers as *Speleotriletes balteatus*, *Neotristrickia loganii* and *Faisticrickia strumosa*, which first appear in the BP Zone. In the Amazon Basin, the succeeding *S. pretiosus* - *R. clavata* (PC) Zone seems to fall consistently within the range of intervals X-XI, whereas in the Paranaíba Basin (e.g., wells 1-TM-1-MA and 2-LZ-1-MA) it may include sections previously assigned to interval IX (ANDRADE & DAEMON, 1974, text-fig. p. 132; DAEMON, 1976, annex to p. 190). In addition to species shared with older strata, diagnostic PC assemblages in northern Brazil usually inclu-

de *Speleotriletes pretiosus*, *Colatisporites decorus*, *Indotriadites mitratus* and only occasionally *Faisticrickia clavata*. In western Europe, the PC Zone is known to extend from the upper *crenulata* Zone in the deep water conodont succession to the lower part of the *communis carina* Zone in the shelf conodont succession of late Middle to early Late Tournaisian age (Higgs et al., 1992; Dreesen et al., 1993). Following the latest palynological review of well 2-LF-1-AM (Amazon Basin) by Loboziak et al. (1998), younger Tournaisian or Early Viséan biozones are no longer recognized above the PC Zone in northern Brazil, despite our former belief to the contrary (Loboziak et al., 1991).

Interval XII is now admitted as entirely restricted to the Late Viséan (Melo & Loboziak, 1997; Loboziak et al., 1998; Melo et al., 1999), thus confirming the previous viewpoint of PETROBRAS workers (DAEMON & CONTRERAS, 1971; DAEMON, 1974, 1976). This unit correlates with a yet undefined, but possibly the youngest, portion of the *P. tessellatus* - *S. campyloptera* through *T. vetustus* - *R. fracta* (TC - VF) zonal range. In the British Isles, these biozones are known to extend altogether from Late Holkerian through Early Brigantian (CLARROD, 1985; Higgs et al., 1988b).

Diagnostic miospore assemblages of interval XII include *Petrirites tessellatus*, *Dicytriletes* sp. cf. *Peticulatisporites magnidicytus*, *Foveosporites appositus*, *Radizonates* sp. cf. *Hymenozonotriletes dolianii*, *Cirratriletes rarus*, *Diatomozonotriletes fragilis*, *Speleotriletes arenaceus* and *S. triangulus*. Regionally, miospores of the genera *Lycospora*, *Granulatisporites*, *Waltzispora* (*sensu stricto*) and *Schopffipolienites* are also first recorded within this interval. In the Paranaíba Basin, additional forms have been identified (Melo et al., 1999), such as *Speleotriletes benghaziensis*, *S. owensii*, *Vallatisporites agadesi*, *V. ciliaris*, and scarce *Rotaspora ergonulii*. Also verified in sections assigned to interval XII is the occasional presence of mixed assemblages with Tournaisian "look", containing taxa like *Vallatisporites val-latus*, *V. verrucosus*, *Verrucosisporites nitidus*, *Speleotriletes balteatus* and *S. pretiosus*, amongst others. This may reflect either reworking from Tournaisian sediments or disparate Gondwanan ranges with respect to Euramerican occurrences of the same species, as argued by others (PLAYFORD, 1990; RAVN et al., 1994). Interval XII unconformably overlies rocks of Late Devonian to early Late Tournaisian age throughout northern Brazilian basins (Melo & Loboziak, 1997; Loboziak et al., 1998; Melo et al., 1999).

Another regional unconformity separates biozone XII from the succeeding unit, interval XIII. The latter contains pollen grains (both taeniate and non-taeniate) in addition to numerous pseudosaccates and trilete spores. In at least the Amazon Basin, interval XIII is entirely assignable to the Westphalian on the basis of combined miospore and marine faunal evidence (Loboziak et al., 1997b; Melo et al., 1998, 1999). However, in the Solimões Basin, where thick, possibly older siliciclastic sections of interval XIII lack any taeniate pollen, Late Carboniferous sedimentation could have started slightly earlier, possibly still in Late Namurian time (Melo et al., 1999).

2. — LOWER CARBONIFEROUS FAUNAL CONTROLS IN SOME ALGERIAN SAHARAN BASINS: BRIEF COMMENTS

In view of the relative shortage of Euramerican elements in Carboniferous microfossils of western Gondwana, chronocorre-

lation of regional miospore successions with those from outside areas must rely to a great extent on marine faunal datings. Unfortunately, in the Carboniferous of northern Brazil, reliable faunal data are only available from the Baskirian upwards. On the other hand, several elements of the rich Early Carboniferous microfunas and invertebrate assemblages from North Africa are shared with coeval Euramerican and eastern European marine basins. Because faunal successions in the former largely mirror those of the latter, it is reasonable to assume that F.A.D.'s (first appearance datum) of most key species are approximately synchronous all over those regions. In particular as concerns the pelagic elements (e.g. conodonts and ammonoids). In addition, certain benthic groups have been also successfully used in long-distance correlations of the North African Carboniferous, like foraminifera, brachiopods, bivalves and corals.

As already stated, of all North African regions, the most important ones for palynostratigraphic correlations with the Lower Carboniferous of Brazil are the Illizi and Hammadah Basins and especially the Grand Erg Occidental. Faunal controls are potentially more conclusive for the latter two. However, their usefulness is greatly hampered by the imprecise way in which data have been presented in the literature (LANZONI & MAGLOIRE, 1969; MASSA & VACHARD, 1979; MASSA *et al.*, 1980). Generalized faunal lists in those papers refer indistinctly to different sections pre-assigned to a same palynozone or lithostratigraphic interval, but no range charts or precise faunal successions have been presented for individual sections probably due to the scarcity of the carbonate beds. Disentangling the original data into a neat sequence of faunal F.A.D.'s or vertical ranges is practically impossible. In the case of Hammadah Basin (western Libya), the situation is further complicated by poor correlations involving composite sections with possibly distinct ages. For the moment, little can be done, except to compare information available for the Grand Erg Occidental and Illizi Basin with better known faunal successions from other Lower Carboniferous sections of the Algerian Sahara.

Varied, reasonably precise faunal data from North African basins have been compiled by the several collaborators in MARTINEZ DIAZ *et al.* (1985, p. 299-447). As shown in Figure 1, the area covered by the palynological study of LANZONI & MAGLOIRE (1969) in the Grand Erg Occidental comprises parts of what is nowadays considered the Béchar - Timimoun - Ahnet basin complex plus an adjoining portion of the Reggan Basin in the southwest. Another area of interest is the Mouydir outlier east of Ahnet, due to its intermediate location between the Grand Erg Occidental and the Illizi Basin. Maximum thicknesses of Carboniferous marine successions are attained towards the Tethyan margin of the African Platform (up to 5500 m in the Béchar Basin, near the South Atlas Flexure) and, to a lesser extent, in basins adjacent to the Ougartan Aulacogen, which was inverted into a structural high during post-Paleozoic times. They become considerably thinner southwards in pericratonic and intracratonic areas, where shallower marine sedimentation alternated with erosional cycles and continental progradations (CONRAD, 1985f, p. 333). Due to their remarkable sedimentary development and more accurate faunal controls, the Zousfana - Saoura Valley outcrops of the Béchar Basin constitute a reference section for all other Carboniferous Saharan basins (CONRAD, 1985a, p. 306).

Figure 2 demonstrates our interpretative correlation of selected Lower Carboniferous sections from the Algerian Sahara, based on lithological and faunal criteria, with referen-

ce to corresponding bio- and chronostratigraphic units in western Europe. Approximate synchronism is assumed for F.A.D.'s of pelagic zonal species, whose entries in North Africa are supposedly related to maximum flooding events. The illustrated Timimoun Basin outcrop section (after CONRAD, 1985c, p. 319) is believed to correspond reasonably to that of the nearby Timimoun core-drill in the Gourara area. The Bahmer core-drill (litho-log after LANZONI & MAGLOIRE, 1969, p. 444) is from the Touat area, on the northeastern margin of the Reggan Basin. In spite of the Grand Erg Occidental lithostratigraphic terminology used by LANZONI & MAGLOIRE (1969), the Bahmer core-drill seems to correlate best with Carboniferous successions from the adjoining Reggan and Timimoun-Ahnet-Mouydir Basins.

Subsurface sections from the Grand Erg Occidental proper tend to be more incomplete, particularly to the northeast, due to multiple erosional truncations (LANZONI & MAGLOIRE, 1969, Fig. 2, 3). Therefore, only the Bahmer and Timimoun "type sections" are sufficiently continuous to allow tentative faunal comparisons with Lower Carboniferous successions in nearby basins. This will be the subject of a separate discussion.

3. — REINTERPRETED FAUNAL SUCCESSIONS IN LANZONI & MAGLOIRE'S ZONAL REFERENCE SECTIONS

Algerian Saharan Carboniferous faunal/lithological successions and their age implications, compiled by the several collaborators in MARTINEZ DIAZ *et al.* (1985, p. 299-447), provide background information for tentative stratigraphic reinterpretations of LANZONI & MAGLOIRE'S (1969, p. 449-451) faunal lists, used by them to date Palynozones M2 to M7 in at least two reference sections. These are the Timimoun core-drill in the Gourara area of the Timimoun Basin, and the Bahmer core-drill in the Touat area, on the northeastern border of the Reggan Basin (Fig. 1, 2). Some deep wells (UT-1, UT-2, BJ-1, KE-1) have also provided faunal evidence for dating Palynozones M4, M6 and M7. Unfortunately, LANZONI & MAGLOIRE'S (1969) faunal lists have been mostly compiled from more than one section, and the old taxonomic nomenclature used in them also poses serious limitations to subsequent reinterpretations. Therefore, only those faunal elements with more or less obvious identity will be considered.

In respect of the Bahmer core-drill, our correlations follow the scheme shown in Figure 2, which is based on the following assumptions.

(a) As pointed out by CONRAD (1985b, p. 315), the Kahla Sandstone, originally defined by oil companies (B.R.P., 1959), does not correspond exactly to that of LANZONI & MAGLOIRE (1969, Fig. 2), who excluded younger Tournaïstian strata from its upper part.

(b) Therefore, we interpret that the lower part of LANZONI & MAGLOIRE'S "Argiles de Timimoun" (Palynozone M3) is coeval with shaly sections in the upper Kahla Formation *sensu* CONRAD (1985b), of Middle to early Late Tournaïstian age. In this respect, due to the vicinity of the strongly subsident Ougartan Aulacogen (CONRAD, 1985a, p. 305), Tournaïstian sections of the Touat area seem to display a shaly lithofacies development intermediate between those from the shallower Timimoun Basin, in the east, and the deeper Tindouf Basin, to the west. In the latter, much as in Touat, the Tournaïstian/Wiséan boundary is within a dominantly shaly sequence making up a part of

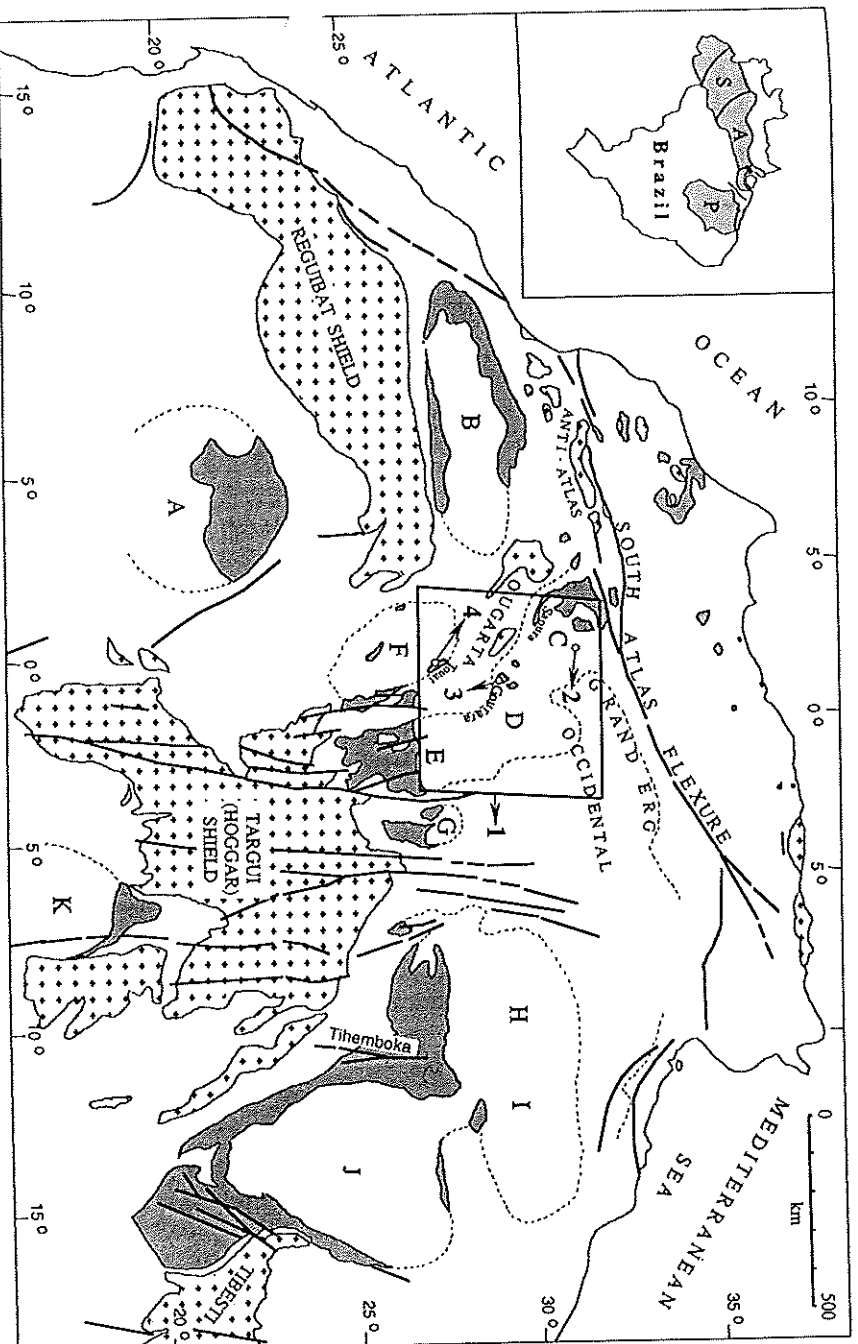

Figure 1

Geologic-structural map of northwestern Africa showing the sedimentary basins mentioned in text (modified from CONRAD, 1985a), and simplified location map of northern Brazilian Paleozoic basins (inset). In the former, shaded patterns denote the present-day configuration of Carboniferous basins (dark gray = outcrop areas; light gray = known subsurface distribution). Crosses refer to pre-Carboniferous rocks exposed on Saharan shields or within Hercynian zones to the north of the South Atlas Flexure.

Carte structurale de la partie nord-occidentale de l'Afrique montrant les bassins sédimentaires mentionnés dans le texte (modifiée d'après CONRAD, 1985a) et carte simplifiée de la localisation des bassins Paléozoïques du nord du Brésil (en médaillon). En Afrique, les figures indiquent la configuration actuelle des bassins carbonifères (gris sombre = aires en affleurement; gris clair = distribution connue en sous-sol). Les croix représentent les roches pré-Carbonifères dans les boucliers sahariens ou à l'intérieur des zones hercyniennes au nord de la flexure sud atlasique.

Northern Brazilian Paleozoic basins (inset):

Carboniferous basins of northwestern Africa:

A = Taoudeni; B = Tindouf; C = Béchar; D = Timimoun; E = Ahnet; F = Reggan;
 G = Mouydir; H = Illizi; I = Hammadah (Ghadamis); J = Mourzouk-Djado; K = Iulimeddén.

Special notations for the Grand Erg Occidental region

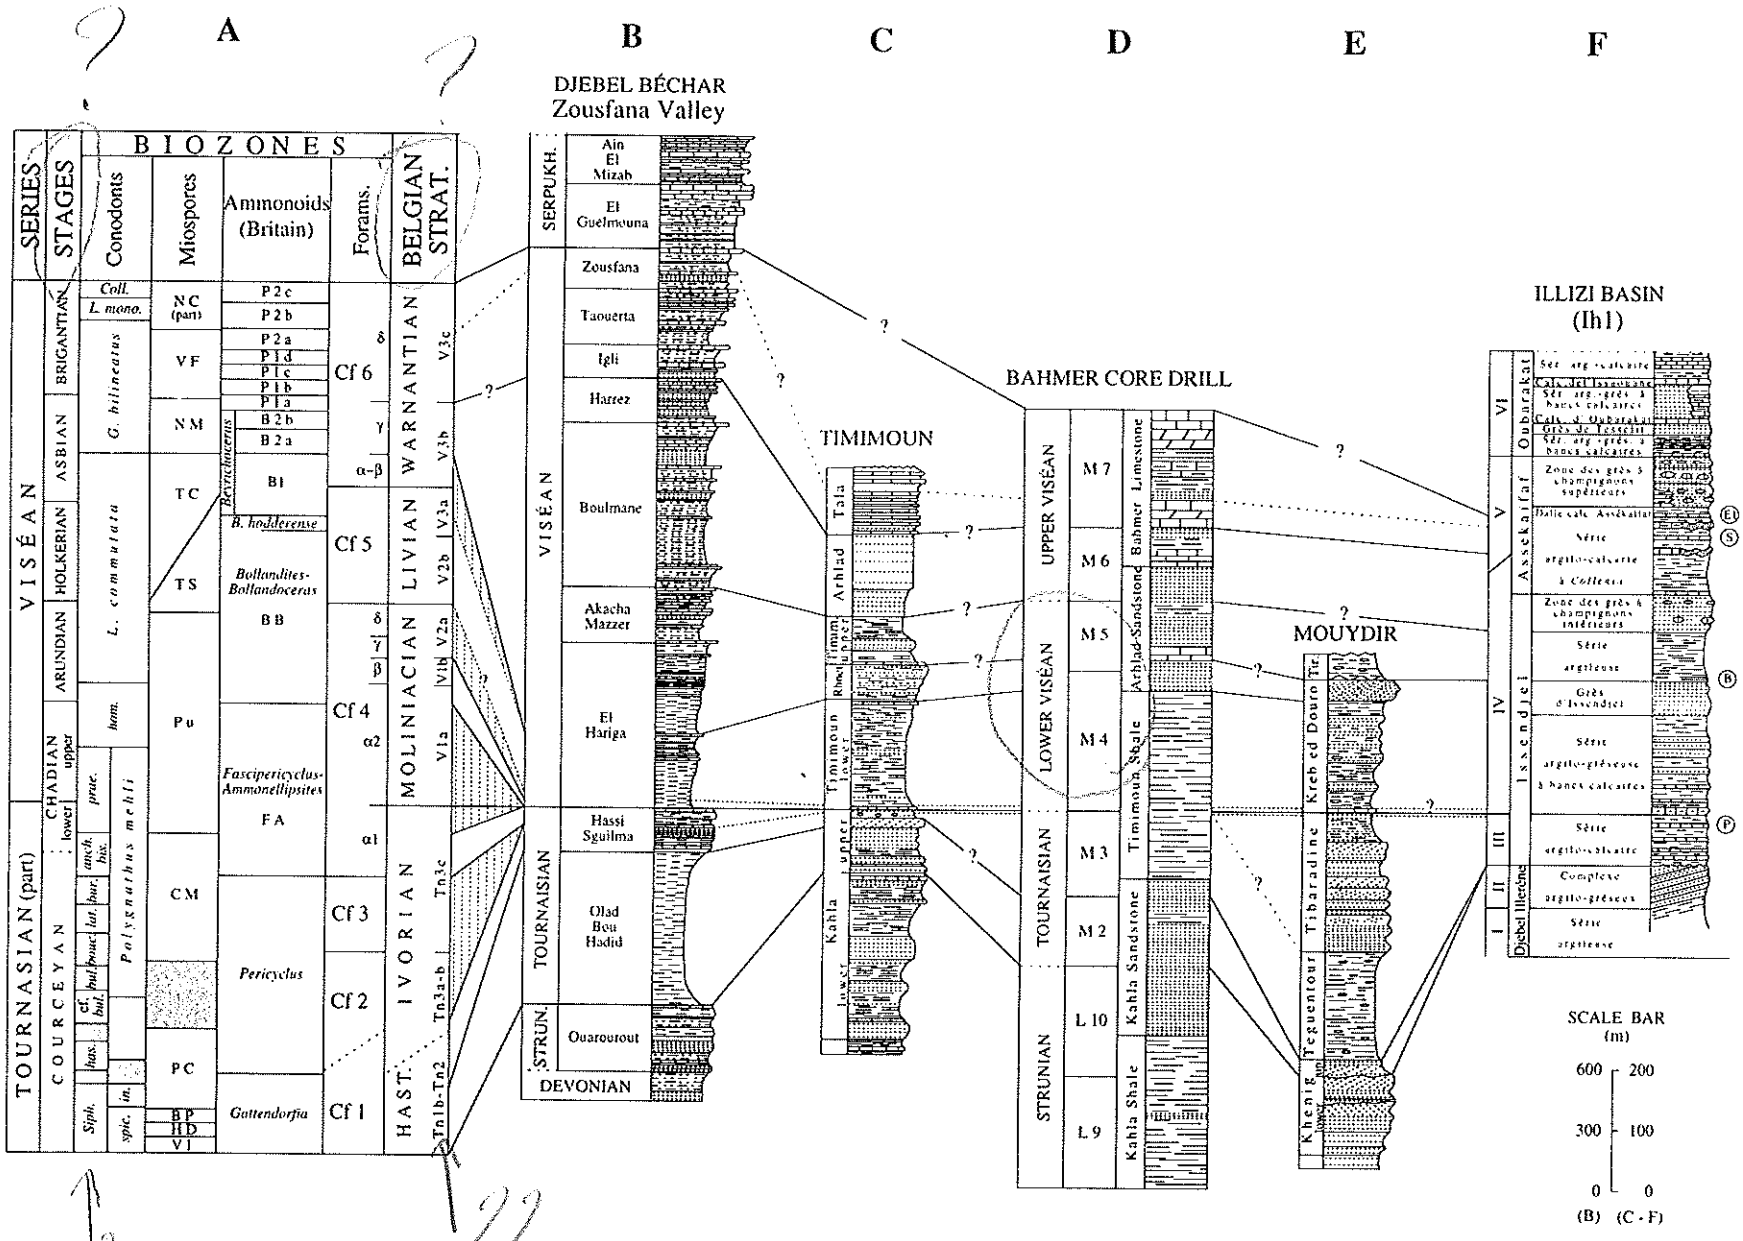

- 1 = approximate area covered by the geological sketch of LANZONI & MAGLOIRE (1969, Fig. 1);
- 2 = site of reference well UT-2 (LANZONI & MAGLOIRE, 1969, Fig. 2, 3);
- 3 = site of the Timimoun core-drill (Gourara area);
- 4 = site of reference Bahmer core-drill in Touat area (LANZONI & MAGLOIRE, 1969, Fig. 2, 3).

the Betaina Formation (CONRAD, 1985c, Fig. 6; CONRAD, 1985e, p. 326).

(c) Evidently, LANZONI & MAGLOIRE (1969) overlooked the significance of the thin Merocerites limestone band, an equivalent of the Iridet Ledge that condenses most of the Late Tournaisian and Early Viséan sedimentation in the Touat sec-

tion. It probably accounts for the "mixed", incongruous faunal lists given by those authors to justify the age of Palynozozones M3 and M4.

In several Algerian Saharan basins, highly condensed marine beds intervene between the Tournaisian and Viséan sequences. Probably due to long-lasting starved basin condi-

tions, latest Tournaisian marine faunas lie almost directly on Middle Tournaisian ones, and are joined in close succession by earliest Viséan fossil assemblages. The condensed sediments comprise the Iridet ledge ("Dalle des Iridet") in the Reggan and Ahnet-Mouydir Basins, as well as the equivalent *Dalle à Merocanites* of the Timimoun region (CONRAD, 1985b, p. 316; LEMOUSQUET *et al.*, 1985, p. 370). The Iridet, an obvious marker-band of the Saharan Carboniferous, is a decimetric to metric layer (sometimes two) of oolitic, phosphatic, pellet limestone which is remarkably widespread". There is a faunal renewal at the generic level with the appearance of *Merocanites*, the extinction of *Pericyclus* and *Imitoceras*, and the last representatives of *Ammonelilipites* (...) (CONRAD, 1985c, p. 321). The Iridet/*Merocanites* limestone band blankets the top of the Tibaradine and upper Kaha Formations in the forementioned basins (Fig. 2). Equivalent strata are best developed in the Béchar Basin, where they consist of thicker limestones and silticlastics making up the upper member of the Hassi Sguilma Formation (LEMOSQUET *et al.*, 1985, p. 370).

d) It seems that the Viséan part of LANZONI & MAGLOIRE'S (1989, Fig. 2) "*Argiles de Timimoun*" in Touat corresponds to only the lower Timimoun Shale of the Gourara section. This implies that the Rhnet Sandstone and the upper Timimoun Shale in the latter area (with limestone and sandstone intercalations) are partly coeval with the Arhjad Sandstone sensu LANZONI & MAGLOIRE (1989). The Tala Formation corresponds approximately to the misnamed "*Calcaires de Bahmer*" of the Touat section, as explained by CONRAD (1985b, p. 316).

3.1. PALYNOZONES M2 AND M3 (TOURNAISIAN)

Megafossils (e.g., brachiopods, ammonoids) with disparate stratigraphic ranges are referred indistinctly to these two bio-

zones. If correctly identified, some are clearly related to the Early and Middle Tournaisian faunas, e.g.: *Gaillardotia* sp., *Imitoceras rotatorium*, *Pugilis vaughani*, and *Alyeiphorus tomacensis*. Others, of Late Tournaisian or Early Viséan affinity, are most probably restricted to the *Merocanites* Bed near the M3/M4 boundary, such as *Merocanites* sp., *Muensteroceras rotella*, *Stenoschisma isothyncha*, and *Syringothyris cuspidata* (unless if representing misidentified specimens of the older Tournaisian *S. ahnetensis*). Due to the highly condensed nature of latest Tournaisian - Early Viséan sedimentation in that region, it is very doubtful if their palynological content has been documented at all by LANZONI & MAGLOIRE (1989, Tab. 1, Pl. 4, 5). In any case, the vast majority of miospores illustrated for Palynozozones M2 and M3 derives undoubtedly from the underlying section of Early to early Late Tournaisian age (equivalent to upper Tr1b to Tr2 or lowermost Tr3 in Belgium).

3.2. PALYNOZONES M4 AND M5 (EARLY TO EARLY LATE VISÉAN)

Of the foraminifera listed from an erosional remnant of Palynozone M4 (well UT-2; LANZONI & MAGLOIRE, 1989, p. 450), i.e., possibly from its lower part, the most diagnostic elements are *Archaeodiscus* and *Omphalotia omphalota*. The former is a genus recorded in the British Isles only from foraminiferal Zone Cf5 (Holkerian) upwards (RILEY, 1993, Fig. 9), whilst *O. omphalota* usually indicates ages not older than Middle Viséan (D. YACHARD, pers. comm., in LOBOZAK *et al.*, 1998). In Belgium, *O. omphalota* is generally absent in the older (V2b, Early Luvian) part of that biozone (D. YACHARD, writ. comm., 1999). In the eastern Alborz Range of Iran, according to LYS *et al.* (1978, p. 70), the F.A.D. of *O. omphalota* is immediately above that of *Archaeodiscus* spp., near the base of the local Cf5 equivalent. Likewise, LYS (1985, p. 361, Tab. 2, 4) demonstrates that, in many Saharan basins of North Africa (including the Béchar and

FIGURE 2

Proposed correlation and dating of Lower Carboniferous lithological successions from selected Algerian Sahara localities (B - F) with reference to standard western European bio- and chronostratigraphic units (A). Based on reinterpreted faunal data and lithological correlations of Algerian sections by CONRAD (1985c, 1985f). Areas in vertical dashed pattern between columns A and B represent time intervals with poor biostratigraphic resolution, attributed to sedimentary condensation. Note that only sections C to F are drawn to the same vertical scale.

Corrélations et datations proposées pour les successions lithologiques des sites sélectionnés du Sahara algérien (B - F) avec référence aux unités bio- et chronostratigraphiques standards d'Europe occidentale. Basées sur une réinterprétation des données faunistiques discutées dans le texte et des corrélations lithologiques par Conrad (1985c, 1985f) des sections algériennes. Les aires en hachurés verticaux entre les colonnes A et B représentent des intervalles temps avec une résolution biostratigraphique faible, attribuée à une condensation sédimentaire. A noter que seules les sections C à F sont tracées à la même échelle verticale.

A = Lower Carboniferous chronostratigraphic and biostratigraphic units in Britain and Belgium;
B = lithological succession of the Béchar Basin (Zoustaana Valley outcrop area), regarded by many authors as a reference section to all other Saharan Carboniferous basins;

C = Timimoun outcrop section (Gourara area, Timimoun Basin), assumed herein as an approximate equivalent of the Timimoun core-drill section

D = Bahmer core-drill section and palynozozones in Touat area (Reggan Basin);

E = Oued Temerrasset outcrop section (Mouydir Basin);

F = type lithological succession and palynozozones of the Illizi Basin.

B = after LEMOSQUET & PAREYNI (1985);

C, E = after CONRAD (1985c);

D = after LANZONI & MAGLOIRE (1989); F = after ATTAH *et al.* (1980), with the lower boundary of the Assékaita Formation modified after ABDESSLAM-ROUGHI & COQUEL (1997).

Illizi Basins), the earliest archaeidiscids and *O. omphaloia* are only recorded in regional equivalents of the C15 foraminiferal Zone. These data suggest that both foraminiferal taxa may be good indicators of Holkerian and younger ages in North Africa and the Middle East.

The conchiferous faunas listed by LANZONI & MAGLOIRE (1969, p. 450) include elements of quite different ages. If correctly identified, they probably reflect distinct sampled intervals from the Timimoun and Bahmer core-drills. Part of the fossils derive from the latest Tournaisian - Early Viséan condensed interval, which includes the M3/M4 palynozonal boundary. This is exemplified by FA zone ammonoids from the Tournaisian/Viséan transition (*Muensteroceras browni*, *M. inflatum*, *M. occidentale*, *Dzhatprakoceras hibernicum*, *Eurites copulenti*), as well as *Composita ambigua*, an Early Chadian-Late Asbian brachiopod (RAMSBOTTOM & SAUNDERS, 1985, Fig. 4; RILEY, 1993, Fig. 6, 7; N.J. RILEY, writ. comm., 1997). *Bollandoceras hoddense* and *Beyrichoceratoides rededahlensis* are both known from the lowest part of the Tirechoumine Formation in the Ahnet Basin (CONRAD, 1985c, p. 321), which is not older than latest Holkerian according to western European standards (RILEY, 1993, Fig. 1, 2). *Beyrhoceras obtusum* is from a higher interval, correlative with the upper Timimoun Shale member, which succeeds the Rhnet Sandstone in the Timimoun section (CONRAD, 1985c, p. 321). In the British Isles, that species (along with *Bollandites castletonense*) is seemingly restricted to the uppermost Asbian only (B2b Zone), according to RILEY (1990, p. 153, 154, and 1993, Fig. 2). Their entry is preceded (B2a ammonoid Zone, Upper Asbian) by that of *Posidonia becheri*, a distinctive Late Viséan bivalve also mentioned by LANZONI & MAGLOIRE (1969), which persists up to the mid-Brigantian P1d ammonoid Zone (RILEY, 1993, p. 433; N.J. RILEY, writ. comm., 1997).

In conclusion, according to available faunal data, the bulk of Palynozone M4 is not older than Holkerian, whilst Palynozone M5 ranges well into the Late Asbian. The base of Zone M4 may be inside a very thin interval with latest Tournaisian / Early Viséan sediments, which also comprises the top of underlying Palynozone M3.

3. PALYNOZONES M6 AND M7 (LATE VISÉAN)

Faunal lists for this biozonal interval (LANZONI & MAGLOIRE, 1969, p. 450, 451) have been compiled from at least five distinct subsurface sections, i.e., the Bahmer core-drill and wells UT-1, UT-2, BU-1 and KE-1. Unfortunately, listed foraminifera are of doubtful biostratigraphic value, because they include practically no index species used nowadays in Late Viséan correlations of North Africa or western Europe. On the other hand, some of the associated megafossils can be more easily evaluated in terms of Algerian and British Viséan faunal successions.

The brachiopod *Filuctaria undata* is recorded from the Rhnet Sandstone in the Timimoun area, and from the Tirechoumine Shale of the Ahnet-Moydir regions (an equivalent of the upper Timimoun Shale member). In Britain, it is only known from Late Asbian to the earliest Brigantian (RILEY, 1993, Fig. 7). It is therefore likely that Algerian occurrences of this species prove restricted to sandy/shaly sections underneath the Tala or Diebel Berga carbonates, i.e., not ranging above Palynozone M6.

On the other hand, gigantoproductids and corals mentioned by LANZONI & MAGLOIRE (1969) are probably all from a higher stratigraphic position, i.e., carbonates of the Tala Formation (*sensu stricto*). In terms of western European Viséan faunal successions, the coral *Koninckophyllum interriptum* is apparently the most age-restrictive of all listed species, as in Britain it first appears in assemblage I at a mid-Brigantian position (RILEY, 1993, Fig. 5) and ranges into Namurian strata. In the Béchar Basin, its F.A.D. is within the Boulmane Formation (SEWENOFF-TIAN-CHANSKY, 1985, p. 375). In the Tala section, it concurs with other coral species with older F.A.D.'s in western Europe, viz., *Dibunophyllum bipartitum* (Late Asbian onwards) and *Siphonophyllia benburbensis* (Early Asbian onwards). Gigantoproductids in general can be as old as Early Asbian, but *Latiproductus edelburgensis* is only recorded from Late Asbian or younger intervals in at least the British Isles (RILEY, 1993, Fig. 7). Altogether, these faunal elements are only in permissive agreement with the more constrained datings (Late Brigantian) provided by foraminifera and conodonts from the Viséan part of the Tala and Diebel Berga Formations (CONRAD, 1985d; LYS, 1985; WEYANT, 1985). This is probably the actual age of Palynozone M7, whereas Palynozone M6 can be as old as the Asbian/Brigantian transition.

Subsurface correlations in the westernmost Grand Erg Occidental (LANZONI & MAGLOIRE, 1969, Fig. 3) point out to an unconformity at the base of Palynozone M6, southeast of Béchar Basin's main exposure areas. This is probably an effect of the generalized regression mentioned by CONRAD (1985c, p. 321), "caused by uplift of the basement, [which] can be traced all along the northern border of the Hoggar". It gave rise to extensive fluvial and littoral deposition over much of the Saharan Platform, as documented by prominent, widespread sandy units of Late Viséan age, including the Garet Denb Formation of the Ahnet-Reggan Basins, the Arhlad Formation (*sensu stricto*) in the Timimoun Basin and adjacent Touat area, and possibly the topmost sandstone unit of the Issendjel Formation ("Zone des grès à *champhignans inférieurs*") in the Illizi Basin. In the remote Taoudeni Basin, to the southwest (Fig. 1), a similar truncation of condensed Middle-Late Tournaisian and Early Viséan fossiliferous sediments by Late Viséan strata (containing brachiopods and foraminifera of V3b-V3c affinity) is also demonstrated by LEGRAND-BLANI (1985a, p. 327, 328) and LYS (1985, p. 361), within the lithostratigraphic range of the Bir en Naharat and Safia Formations.

4. — LOWER CARBONIFEROUS FAUNAL CONTROLS IN WESTERN LIBYA

In comparison to the aforementioned Algerian Saharan basins, Tournaisian and Viséan faunal successions in western Libya are yet too poorly controlled to allow reliable biozonations to be established. The stratigraphic significance of Early Carboniferous marine faunas from scattered sections of the Hammadah and Mourzouk Basins is further obscured by the vague way in which data was presented by the main published account (MASSA & VACHARD, 1979), without any clear indication of stratigraphic ranges or F.A.D. successions. Conodont assemblages reported by WEYANT & MASSA (1985), although conveniently tied to reference sections, are too poor to allow any biostratigraphic refinement of pre-Serpukhovan sections. Ammonoid datings by COQUEL & MASSA (1993, p. 148, 149) are

partly based on doubtful taxonomic identifications and correlations with Algerian localities (STREEL & LOBOZIAK, 1994, p. 269; ABDESSELAM-ROUIGHI & COQUEL, 1997, p. 49). Most of the following discussion will focus on western Libyan faunas only.

4.1. TOURNAISIAN FAUNAS

According to MASSA & VACHARD (1979), the lowest part of the M'rar Formation in the Hammadah Basin is dated as latest Tournaisian, and makes up their "Zone 1 à *Fusella* et *Muensteroceras*". The main argument for the alleged age consists of some ammonoids referred to as *Muensteroceras rotella*, *M. cf. crassum* and *Pericyclus* sp. (COQUEL & MASSA, 1993, p. 148), plus *Gnathodus* gr. *texanus*, regarded as "*un indice du Tournaisien supérieur*" (WEYANT & MASSA, 1985, p. 86).

Palynological data do not seem to support any age younger than the M'rar Formation. Late Middle or early Late Tournaisian (PC miospore Zone) for the bulk of the Tournaisian section of the lower M'rar Formation, which corresponds to MASSA et al.'s (1980) Palynozone XII (see discussion ahead). Faunal data are partly in permissive agreement with this assumption, and partly contradictory. It should be pointed out that WEYANT & MASSA's (1985, p. 86, Fig. 9) identification of *Gnathodus* gr. *texanus* is based on one single specimen from core 8 of well C1-49, whereas closely underlying cores 9 to 11 (formerly misassigned to the Famennian Tahara Formation by MASSA et al., 1980, Fig. 4, 5) contain specimens of *Pseudopolygnathus dentilineatus* and *Polygnathus* gr. *inornatus*. These elements possess quite different stratigraphic ranges. *G. texanus* (which ranges into the Holkerian) is usually unknown below the *Scalognathus ancho-ralis* / *Polygnathus bischoffi* conodont Zone of Late Courceyan/Early Chadian age, i.e., latest Tournaisian (SWEET, 1988, Chart 6; RILEY, 1993, Fig. 3). On their turn, *P. dentilineatus* and British representatives of *P. inornatus* are supposedly restricted to the *Siphonodella sulcata* - *S. crenulata* zonal range of Early Courceyan age (SWEET, 1988, Chart 6; RILEY, 1993, Fig. 3). It is therefore clear that local conodont data are still too insufficient and contradictory to provide any precise datings.

's concerns the ammonoid genera *Pericyclus* and *Muensteroceras*. RAMSBOTTOM & SAUNDERS (1985, Fig. 4, Tab. 1) and KULLMANN et al. (1991, Fig. 1) show that they can occur in intervals as old as the Middle-Late Tournaisian transition. The biostratigraphic significance of western Libyan specimens assigned to *M. rotella* and *M. crassum* (MASSA & VACHARD, 1979, p. 9) is still questionable, and not much can be said about them until a taxonomic review is carried out, and their source strata are clearly indicated.

Finally, the alleged "Late Tournaisian" brachiopods do not pose any particular age constraints, as many of them are endemic Saharan species (LEGRAND-BLAN, 1985c, p. 372). The brachiopod genus *Fusella*, one of the eponymous taxa of Zone 1, is too poorly characterized. Indeed, most species formerly assigned to it should rather go under *Utrispirifer* (WILLIAMS et al., 1965, p. 705), a genus represented since the Early Tournaisian in Britain and Algeria (LEGRAND-BLAN, 1985c, p. 372, Tab. 8; RILEY, 1993, Fig. 6).

In conclusion, Tournaisian strata of the basal M'rar Formation are still poorly dated by their faunal content. It is not unlikely that part of the apparent contradictions derives from yet undetected sedimentary condensation of latest Tournaisian and Early Viséan beds near Massa & VACHARD's (1979) Zone 1

/ Zone 2 boundary, such as herein proposed for coeval sections of some Algerian Sahara basins (Fig. 2).

4.2. VISÉAN FAUNAS

Following MASSA & VACHARD's (1979) zonal scheme, the Tournaisian Zone 1 is succeeded by an interzone ("*Zone intermédiaire* 2") within the lower M'rar Formation, grossly equivalent to Palynozone XIII sensu MASSA et al. (1980), whose age cannot be determined on a faunal basis. It was assigned by MASSA & VACHARD (1979, p. 9, Fig. 3) to the whole V1a - V3a interval based only on the assumption of continuous sedimentation from latest Tournaisian into the early Late Viséan.

In the middle to upper M'rar Formation, the next biostratigraphic unit "Zone 3 à *Beyrichoceras hoderdense* et *Fluctuaria undata*" (providing faunal calibration for Palynozone XIV) was proposed on the basis of scattered occurrences of ammonoids and brachiopods assigned to the eponymous species. The former are from the Illizi and Mourzouk Basins, as well as the Tin Hieddan section at the Algerian/Libyan border, whereas the latter are from sections in the Hammadah Basin and at Serdelés (western margin of the Mourzouk Basin) (MASSA & VACHARD, 1979, p. 9; COQUEL & MASSA, 1993, p. 149). The ranges of those two species are not known to overlap in western Europe: *Bollandoceras hoderdense* is restricted to the highest part of the *Bollandites-Bollandoceras* (BB) ammonoid Zone, of Late Holkerian age, whilst *Fluctuaria undata* only occurs in brachiopod assemblages G-H, equivalent to foraminiferal zone C16g and ammonoid zones B2a through P1b, of Late Asbian - earliest Brigantian age (RILEY, 1993, Fig. 1, 7). However, many previous Early Carboniferous ammonoid identifications from western Libya and the Algerian Sahara are currently under serious doubt (STREEL & LOBOZIAK, 1994, p. 269; ABDESSELAM-ROUIGHI & COQUEL, 1997, p. 49) and strongly need updated taxonomic revisions. Indeed, age implications from ammonoid lists such as that of COQUEL & MASSA (1993, p. 149) from Illizi Basin are contradictory at face value, as far as western European conspecific ranges are concerned. At least in Britain, *Dzhaprakoceras subglobosum* is from the Tournaisian/Viséan boundary interval, whereas *Bollandoceras hoderdense* and *Beyrichoceras obtusum* are respectively Late Holkerian and Late Asbian in age (RILEY, 1990, p. 154; RILEY, 1991, p. 137, 138; RILEY, 1993, Fig. 1, 7).

The highest Viséan biostratigraphic unit, "Zone 4 à *Goniatites striatus* et *Collenia*", is very poorly characterized in western Libya because the most relevant faunal controls are in the Illizi Basin. According to the single microfossil account of that biozone in Libya, based on conodonts (WEYANT & MASSA, 1985, Fig. 8), the *Collenia* unit has yielded a low-diversity assemblage with *Ligonodina* sp., *Ozarkodina* spp. and *Raschistognathus* aff. *muricatus*. The latter is rather a Serpukhovan or younger species in Euramerica and the Algerian Béchar Basin (WEYANT, 1985, Tab. 5; SWEET, 1988, Chart 6). In respect of the shelly fauna (MASSA & VACHARD, 1979, p. 10), "*Neospirifer fascicostatus* and *Saharoptera* are known from Asbian equivalents in Algerian Saharan basins (Ahnet, Timinou), but can also persist upwards into younger strata. In the Illizi Basin, for instance, "*N. fascicostatus* is reported from the Assékalfat Ledge within the mid Assékalfat Formation, associated with Serpukhovan ammonoids (LEGRAND-BLAN, 1985b, p. 329).

There seems to be no indisputable faunal evidence for the strict synchronism of the *Collenia* Horizons between the Illizi and Hammadah Basins. In the latter, the *Collenia* unit (of alleged latest Viséan age, equivalent to the upper V3c lithological interval) corresponds to the basal section of Palynozone XV sensu Massa *et al.* (1980), whose main part extends into the Serpukhovian (E1-H) Assedjefar Formation, *i.e.*, "Zone 5 à *Calcolium punctatum et Cravenoceras*" of Massa & Vachard (1979, p. 10-13). In the central Illizi Basin, namely in well 1h1, the lowest *Collenia* Horizon, which corresponds to the basal Palynozone V sensu Attar *et al.* (1980), is locally 71 metres below an ammonoid occurrence attributed to the species *Goniatites striatus* (now under the genus *Paraglyphioceras*), according to COQUEL & MASSA (1993, p. 149).

In well BN1 of Illizi Basin, furthermore, only the upper *Collenia* Horizon is within Palynozone V, immediately below the Assékafat Limestone Band at the Viséan-Serpukhovian transition (Abdesselam-Rouighi & Coouel, 1997, Fig. 4). The lower *Collenia* Horizon is placed by those authors in the underlying Palynozone IV, which is only distinguished from unit V by lacking *Lycospora* spp.

Thus, in case the latter is accurately identified, the oldest *Collenia* beds cannot be younger than the Asbian / Brigantian transition (RILEY, 1993, Fig. 2; VACHARD & BERKHLI, 1992, Fig. 3). Massa & VACHARD (1979, p. 10) admit that the *Collenia* Horizons from Djado (southernmost extension of the Mourzouk Basin) are younger than those to the north. It is not unlikely that a similar condition could exist across the Themboka Arch between the Hammadah and Illizi Basins. On the other hand, as pointed out by N. RILEY (writ. comm., 1998), "there are a number of stratoid gonataceans which if carelessly identified may be confused with *P. striatus*. These forms, which have stratoid ornament, range from B2b to P2 in Britain. Elsewhere (*e.g.*, North Africa, China, USSR and USA), the stratigraphic range of forms that could be confused with *P. striatus* is even broader (B2a-E1)". This case exemplifies the current need for taxonomic revision of many faunal identifications in the older literature concerning the Lower Carboniferous of North Africa.

5. — CORRELATION BETWEEN PALYNOZONAL SCHEMES OF NORTHERN BRAZIL AND NORTH AFRICA

The correlation of latest Devonian to early Late Carboniferous miospore biozones from northern Brazil and North Africa (Grand Erg Occidental, Illizi and Hammadah Basins), as currently envisaged by us, is schematically shown in Figure 3. Zonal correlations are discussed below, mainly by reference to the regional schemes erected in North Africa by LANZONI & MAGLOIRE (1969), ATTAR *et al.* (1980) and MASSA *et al.* (1980), and the Brazilian biozonation updated by MELO *et al.* (1999).

As most palynomorph identifications by LANZONI & MAGLOIRE (1969) are given in open nomenclature, tentative taxonomic reinterpretation of specimens illustrated in their plates provides the only means of correlating Algerian Sahara successions with other zonal schemes from North Africa and Brazil.

5.1. LATEST DEVONIAN PALYNOZONES

There is practically no major controversy involving the correlation of end-Devonian palynozones of northern Brazil (VIII,

and locally upper VII) with their North African counterparts, *i.e.*, L7 through L10 Subzones in the Algerian Sahara. Biozones II in the Illizi Basin and XI in the Hammadah Basin. All these units contain *Retispora lepidophyta* and several of its usual latest Famennian associates. However, concerning some of these latter apparent discrepancies have been detected in regional palynomorph ranges or successions of palynomorph F.A.D.'s, which demand further clarification.

Judging from miospore data presented by LANZONI & MAGLOIRE (1969, Tab. 1) for the Algerian Sahara, a *R. lepidophyta* - *I. explanatus* (LE) - *R. lepidophyta* - *V. nitidus* (LN) zonal range seems warranted for at least Subzones L9 and L10, if one envisages their *Knoxisporites* sp. n° 3286 (*id.*, Pl. V, fig. 3, 4) and *?Hy-menozonitietes* sp. n° 2918 (*id.*, Pl. V, fig. 11, 12) as actual representatives of *Knoxisporites literatus* and *Indotrifidites explanatus*, respectively. On the other hand, the oldest Subzone L7 already contains *Cordylisporites marciae* and possible *Turnulispora rarituberculata* [respectively *Reticulatisporites* sp. n° 3207 and *Knoxisporites* sp. n° 2895 (*id.*, Tab. 1, Pl. VI, fig. 7, 8 and Pl. VII, fig. 2, 3)]. In the Amazon Basin, these two species are considered to first occur in sections assigned to the LN Zone. In the same basin the F.A.D. of the acritarch *Umbellaspheeridium saharicum*, within Late Famennian age (Fa2c in Belgium) strata, precedes that of *Retispora lepidophyta*. By contrast, Algerian Saharan occurrences of *U. saharicum* are first recorded [as *Acritarche à "entomois"* n° 441-33 by LANZONI & MAGLOIRE (1969, Tab. 1, Pl. VIII, fig. 17, 18)] only at the base of Subzone L8. Therefore, in view of the apparently random pattern displayed by distinctive palynomorph F.A.D.'s in LANZONI & MAGLOIRE'S (1969, Tab. 1) range chart, it is not unlikely that Subzones L7 and L8 also correlate with the younger part of the LE - LN zonal interval, much as palynozones VII (upper part) and VIII of northern Brazil.

The poor characterization of Palynozone II given by ATTAR *et al.* (1980) in the Illizi Basin is insufficient to permit any reasonable correlation. However, this can be attempted with the limited miospore data provided by COQUEL & LARÈCHE (1989) and ABDÉSSELM-ROUIGHI & COQUEL (1997). The former divided biozone II into three sub-units (IIa to IIc from base to top) based on quantitative data and respectively named the *Speleotrietes granulatus*, *Retispora lepidophyta* and Acritarch "abundance" zones. Unfortunately, stratigraphic ranges are omitted for most of the miospore species listed by COQUEL & LARÈCHE (1989, p. 53, 54).

According to the miospore range chart for well ALS2 and data compiled from other boreholes in the Illizi Basin (COQUEL & LARÈCHE, 1989, Tab. 3-5, Pl. 1, 2), *Indotrifidites explanatus* first appears only within sub-unit IIb, as possibly also *Turnulispora rarituberculata* (= "*Lophozonitietes rarituberculatus*") in at least well FRG1. The F.A.D. of *Verrucosisporites nitidus* is also recorded in the highest part of Palynozone II (ABDESSELM-ROUIGHI & COQUEL, 1997, Fig. 3). This suggests that sub-units IIb and IIc could correspond to part or all of the LE - LN zonal interval, whereas sub-unit IIa may correlate with the oldest "Strunian" *R. lepidophyta* - *K. literatus* (LL) Interval Zone of western Europe (so far unrecorded in Brazil). On the other hand, in cored sections from wells ALS2 and GTD1, the earliest specimens of *Cordylisporites marciae* (= *Dichotrietes fibrariatus sensu* COQUEL & LARÈCHE, 1989 and ABDÉSSELM-ROUIGHI & COQUEL, 1997) are recorded along with *Leiotrietes strunianis*, *Cyrtospora cristifera*, *Fugospora radiata* and *Grandispora cornuta* within Palynozone I. This seems to be the regional equivalent of the *D. versabilis* - *G. cornuta* (VCo) Opel Zone, of Late Famennian age (Fa2c to lowermost Fa2d

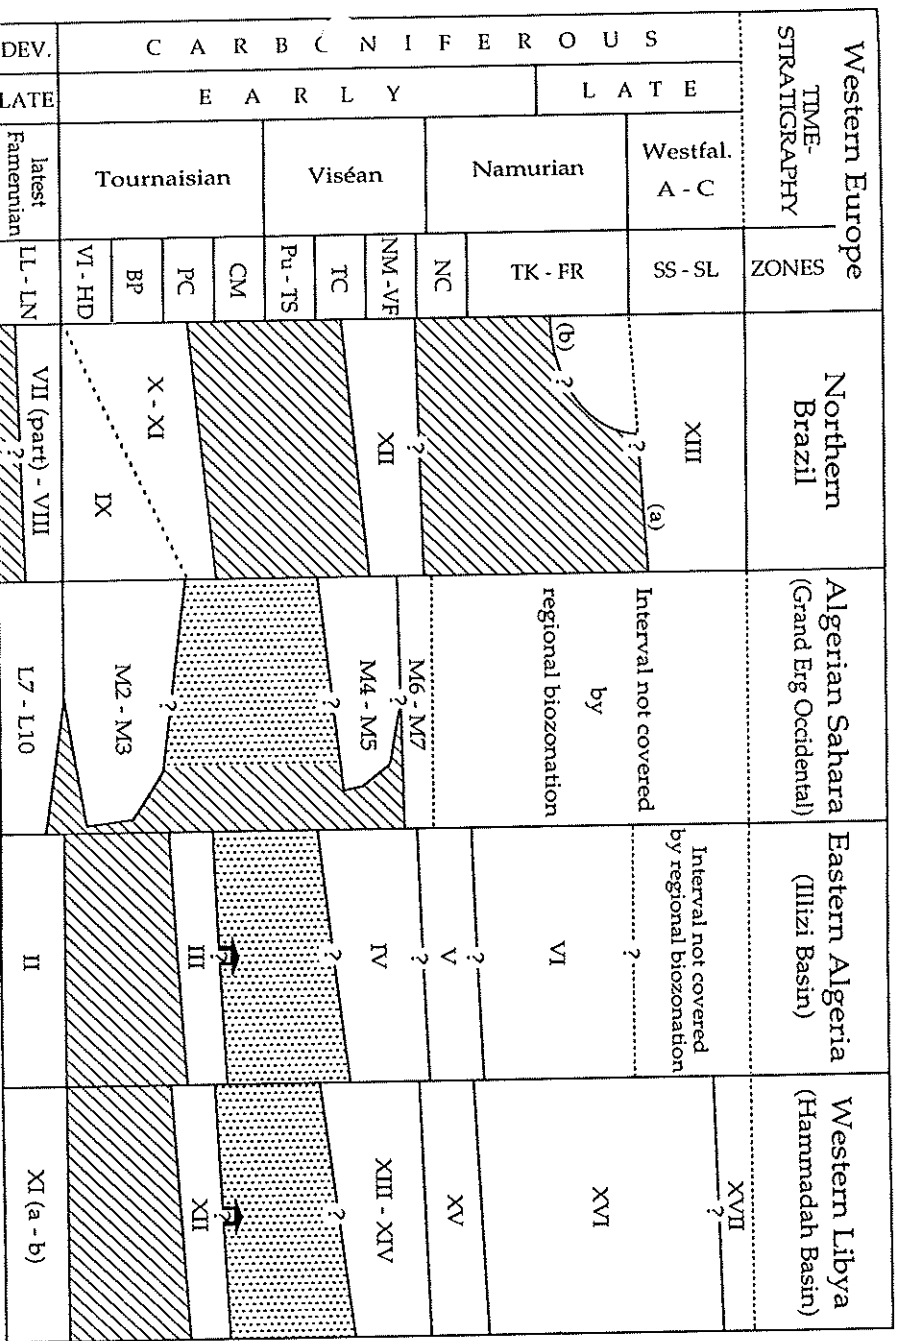

Figure 3

Correlation of latest Devonian and Early to early Late Carboniferous palynozones from northern Brazil and selected North African Basins (based on miospore and faunal datings discussed in text), with reference to western European miospore zones and chronostratigraphic units. Intervals in hatched pattern are interpreted as erosional or nondepositional gaps, and vertical dashed lines represent intervals with possible sedimentary condensation.

Corrélations des palynozones du Dévonien le plus récent et du Carbonifère ancien à début du récent du nord du Brésil et des bassins sélectionnés d'Afrique du Nord (basées sur les datations de miospores et de faunes discutées dans le texte), avec référence aux zones de miospores et aux chronostratigraphiques d'Europe occidentale. Les intervalles en hachurés obliques sont interprétés comme érodés ou non déposés, tandis que les pointillés verticaux représentent des intervalles avec une possible condensation sédimentaire.

Bibliographic sources

Miospore biochronostratigraphy for western Europe after Neves et al. (1972), CLAYTON et al. (1977, 1978) and HIGGS et al. (1988a-b). Regional palynozones for northern Brazil (biostratigraphic intervals VII to XIII) modified from DAEMON & CORRÊRAS (1971), DAEMON (1974, 1976) and AVORAGE & DAEMON (1974). As concerns interval XIII, (b) and (a) point out to possible diachronism of its base, as noticed between the Solimões Basin (b) and the Amazon/Parnatiba Basins (a), respectively (after Melo et al., 1999). Grand Erg Occidental units (Subzones L7 to L10 and M2 to M7) modified from LANZONI & MAGLOIRE (1969). Palynozones of Illizi Basin (II to VI) and Hammadah Basin (Xla-b to XVII) modified from ATTAH et al. (1980) and Massa et al. (1980), respectively, including also subsequent changes by others (Coocuel et al., 1988; Coocuel & Massa, 1993; Aboesselaw-Rouichi & Coocuel, 1997).

in Belgium) (Loboziak et al., 1997c). So, Algerian data, including also those from the Grand Erg Occidental (Lanzoni & Magloire, 1969, Tab. 1), suggest that the F.A.D. of *C. marciae* may be somewhat older in North Africa than in the Amazon Basin. A possible reason could be that, in at least the Illizi Basin, Late Famenian sedimentation was apparently more continuous than in northern Brazilian basins.

In western Libya (Hammadah Basin), Palynozone XI was designed to equal the regional range of *Fetispora lepidophyta* (Massa & Moreau-Benoit, 1976, Fig. 5). It was further charac-

terized by the alleged presence of species like *Knoxisporites hederatus*, *K. literatus*, *Verrucosisporites nitidus* and *V. congestus*, whose poor documentation renders their identification, very doubtful to say the least. The unit was divided by Massa et al. (1980) into Subzones Xla and Xlb. The former is the acme zone of *Fetispora lepidophyta*, and contains such species as *Verrucosisporites gibberosus*, *Tumulispora rartuberculata* and *Cordyosporites marciae* (respectively: *Pustulatiporites gibberosus*, *Lophozonotrites rartuberculatus* and *Dicotyleites firmibriatus*, according to those authors' nomenclatural usage),

Subzone X1b comprises the decline of *R. lepidophyta*, and is further characterized, amongst other species, by the first appearance of *Aratisporites saharænsis* (= *Grandispora balteata sensu* Massa et al., 1980, Pl. VI, fig. 7).

It is therefore clear that Palynozone XI in Hammadah Basin corresponds to at least a portion of the LE - LN zonal range. On the other hand, due to the absence of detailed miospore control, its base is still too poorly characterized to allow any precise correlation with other zonal schemes. Furthermore, certain range extensions shown in the chart of Massa et al. (1980, Fig. 4) are unacceptable to us. This is the case of *Speleotriletes arenaceus*, a distinctively Viséan and younger species, whose alleged presence since the base of Palynozone XI must reflect either taxonomic misidentifications or poor sampling control.

5.2. TOURNAISIAN PALYNOZONES

Imprecisions concerning the age, correlation and faunal controls of Tournaisian and Viséan biozones from North Africa, discussed herein and in previous papers (RAW et al., 1994; STEEL & LOBOZIAK, 1994; LOBOZIAK et al., 1993), still persist up to the present day. Incongruous miospore ranges and faunal datings, sometimes biased by doubtful lithological correlations, have hampered recent attempts at integrating the different palynozonal schemes now existing for the Lower Carboniferous of that region. Unfortunately, the situation will remain largely unchanged until important stratigraphic and taxonomic revisions are undertaken. However, critical reinterpretations of available data may not only disclose the nature of some pending problems, but also suggest possible ways to solve them.

According to the miospore biozonation of the Grand Erg Occidental (LANZONI & MAGLOIRE, 1969), the Tournaisian in that area is to be restricted to Subzones M2 and M3. The former is characterized by the disappearance, at its base, of diagnostic Devonian species such as *Retispora lepidophyta* and *Valaisporites hystricosus*, noted as *Hymenozonitrietes lepidophytus* Kedo n° 2939 and *Valaisporites* sp. n° 2910, respectively. In addition, Subzone M2 is further characterized by continued occurrence of latest Devonian holdovers, including *Cordylisporites marciae* and large spiny forms of the *Grandispora uncatata*-*senitcosa* plexus (= *Peticulatisporites* sp. n° 3207 and *Sporoleptis a grandis spinis*, n° 3268), as well as "severat-densosporites and muronate/reticulate forms. However, the persistence of *Ancyrospora* spp. and Devonian acritarchs (*id.*, Tab. I) is herein interpreted as the result of reworking.

Practically all miospore taxa supposedly first appearing in Subzone M2 are shown to range into the overlying Subzone M3. Of these, apparently only a few are of potential stratigraphic significance for regional correlations, like *Raistrickia strumosa* and possible representatives of *Raistrickia macrura* and *Valaisporites splendens* (respectively: cf. *Peticulatisporites pelatus* n° 2932 and 2932B, *Raistrickia cf. baculosa* n° 2951 plus *Raistrickia* n° 2928, and *Valaisporites cf. splendens* n° 2930). In Subzone M3, they are joined by miospores assignable to such species as *Neoraisrickia loganii*, *Waltzispora lanzonii*, *Schopfites augustus* and *Densosporites infacetus* (respectively: *Triquitites* sp. n° 2836, *Waltzispora* sp. n° 2890, *Raistrickia* sp. n° 2928 and *Densosporites* sp. n° 3284). All these taxa are usually found in the IX - XI zonal range [= V-verrucosus - *R. inchoatus* (V1) - *S. pretiosus* - *R. clavata* (PC)] of

northern Brazilian basins (MELO et al., 1999; S. LOBOZIAK, unpublished data). ARRAT et al. (1980, Tab. III, p. 603) refer to the conspicuous absences of *Speleotriletes pretiosus* and *Valaisporites valatus* in M2-M3 miospore assemblages, in contrast to their occurrence in Tournaisian equivalents of the Illizi and Hammadah Basins. Another missing species is *Aratisporites saharænsis*, which is first recorded by LANZONI & MAGLOIRE (1969, Tab. I) only in the Viséan section of the Algerian Sahara (under the designation "Spore monolete zonale" n° 2874). In the Illizi and Hammadah Basins, the same species is noted (as *Grandispora balteata*) since the Tournaisian and latest Famennian, respectively (ARRAT et al., 1980, Tab. I; MASSA et al., 1980, Fig. 4). The latter conforms to the F.A.D. of *A. saharænsis* in Brazil.

As already pointed out herein, faunal lists given by LANZONI & MAGLOIRE (1969, p. 449) to justify the Tournaisian age of Subzones M2 and M3 in the Timimoun and Bâhmer core-drills (Timimoun and Reggan Basins) are ambiguous. Implied ranges are partly discrepant in terms of currently accepted Early Carboniferous marine megafossil biozonations (BRUNTON, 1964; RAWSBOTTOM & SAUNDERS, 1965; RILEY, 1993), and suggest that a considerable time span is involved. The ammonoid *Gatendorfia*, for instance, is restricted to the homonymous genus-zone in Early Hastarian (Early Tournaisian) strata, whereas the concurrence of *Imitoceras* and *Muensteroceras* is only verified in the succeeding *Pericyclus* genus-zone, of Late Hastarian - Early Ivorian (late Early to early Late Tournaisian) age. The brachiopods *Pugilis vaughani* and *Unispirifer* are widely distributed in the British Courceyan. These faunal elements all correspond to the VI - PC zonal range indicated by the miospores.

On the other hand, brachiopods like *Spirifer koninki*, *Syringothyris cuspidata* and *Stenoschisma isorhyncha* are seemingly restricted to Chadian - Early Arundian (Early Viséan) sections in the British Isles, corresponding to parts of the *Schopfites claviger* - *Auroraspora macra* (CM) and *Lycospora pusilla* (Pu) miospore Zones (RILEY, 1993, Fig. 1, 7). If coeval strata actually occur in the Grand Erg Occidental, then they have no distinct palynological signature. Indeed, miospore assemblages from Subzones M2 and M3 apparently do not support any age assignments younger than Middle or early Late Tournaisian. One possible explanation is that latest Tournaisian - earliest Viséan strata have passed unnoticed (unsampled?) in previous palynological investigations of that area, either in the form of very condensed sections or as erosional remnants of limited extent (Fig. 3).

It is concluded that, in the Grand Erg Occidental, a regional gap or sedimentary condensation occurs on the top of Tournaisian strata, i.e. around the M3/M4-zonal boundary, separating them from late Middle or early Late Viséan strata (LOBOZIAK et al., 1998). This is confirmed by natural evidence from adjacent basins ("*Dalle des lides*" and correlative rock units of the Algerian Sahara), and also by the distinctive palynological break noted at the M3/M4 transition (LANZONI & MAGLOIRE, 1969, Tab. I). The latter is partly due to the regional disappearance of several miospore species. These include *Waltzispora lanzonii* and *Densosporites infacetus* (Tournaisian index species in northern Brazilian basins), *Valaisporites cf. bairferensis*, plus forms herein assigned to *Raistrickia strumosa*, *Neoraisrickia loganii*, *Schopfites augustus*, *Knoxisporites lites*, *Indotridites explanatus*. Stratigraphic correlations by LANZONI & MAGLOIRE (1969, Fig. 3) across the Grand Erg Occidental indicate that Subzone M4 truncates older units (M3 down to L7), varying in age from Middle or Late Tournaisian

through "Strunian", much in the same way as Palynozone XII in northern Brazilian basins (Loboziak *et al.*, 1998). On the other hand, no major gap can be inferred from Algerian Sahara microspore successions at the Devonian/Carboniferous (L10/M2) boundary, at least in sections where the palynozonal sequence is fully preserved, such as in the Bahmer and Timimoun cores-drills.

Tournaisian strata in the Illizi and Hammadah Basins contain essentially analogous microfloras, and are seemingly restricted to Palynozones III and XII, respectively (ATTAR *et al.*, 1980; MASSA *et al.*, 1980; ABDESSELAM-ROUGHI & COQUEL, 1997). The faunal calibration on which both palynozonations rely (MASSA & VACHARD, 1979) places the Tournaisian interval of those basins within Zone 1, named the *Fusella - Muensteroceras* Zone (ATTAR *et al.*, 1980, Fig. 3; MASSA *et al.*, 1980, Fig. 3, 4). Due to the scarcity or poor characterization of its diagnostic elements, this faunizone is too poorly defined to allow any precise dating. As currently understood, Zone 1 is only consistent with a comprehensive Middle-Late Tournaisian age.

According to our current interpretations (Fig. 3), microspore assemblages of Palynozones III and XII lie most probably within the late Middle to early Late Tournaisian age and hence, can be correlated with the PC Zone of western Europe. In the Illizi Basin, this is confirmed by the appearance of the two epynymous species, *Speleotriletes pretiosus* and *Fistulicella clavata*, in cores recovered from the base of the Issendjel Formation (= lowest Palynozone III), only a few meters above the top of the Famenian Illerene Formation (ATTAR *et al.*, 1980, Tab. 1; ABDESSELAM-ROUGHI & COQUEL, 1997, Fig. 3, 4). In addition, *Umbonatisporites baculatus* in ABDESSELAM-ROUGHI & COQUEL (1997, Fig. 4, Pl. 2, fig. 9) probably corresponds to *Neotrilectaria loganii*, another species common in *S. balearicus - R. polyptycha* (BP) - PC age strata of the Amazon Basin (MELO *et al.*, 1999). In the Hammadah Basin, the PC Zone is indicated by the presence of *S. pretiosus* and *Colatisporites decorus - C. denticulatus* in the basal Mirar Formation, *i.e.*, at the base of Palynozone XII (MASSA *et al.*, 1980, Fig. 4, 5). Amongst the other constituents of the Tournaisian microflora in those basins, there is also *Valatisporites vallatus*, *Arastrisporites sahraensis*, *Cordylisporites marciae* (= *Dichytroletes fimbriatus* in the usage of those authors), *Radizonates genuinus*, *Ve. rosiporites nitidus*, etc. In the absence of any younger zoospores, these microspores are all in permissive agreement with a PC Zone assignment. Most of them also occur in PC equivalents of northern Brazilian basins.

Microspore data implies that a considerable gap intervenes between latest Devonian and late Middle to Late Tournaisian strata in parts or all of the Illizi and Hammadah Basins. Therefore, their poor correlation with Subzones M2 and M3 of the Grand Erg Occidental (ATTAR *et al.*, 1980, p. 603) highlights the fact that the Tournaisian is partly older in the latter area (Fig. 3). The Devonian acritarchs recorded in Palynozone III (ATTAR *et al.*, 1980, Tab. 1) probably derive from reworking of Famenian strata. Reworked Middle to Late Devonian microspores and chitinozoans are also detected in this biozone (ABDESSELAM-ROUGHI & COQUEL, 1997, p. 52). On the other hand, alleged occurrences of well-known Viséan microspores within Tournaisian biozones (e.g., *Diatomozonitriletes fragilis*, *Speleotriletes arenaceus*, *Valatisporites agadesi*, *V. ciliaris*) are now unacceptable to us, and must reflect deficient sampling controls. In the Illizi Basin, most of those can be regarded as caved-in specimens in cuttings (e.g., in well BN1; see ABDESSELAM-ROUGHI & COQUEL, 1997, Fig. 4). However, lithological miscorrelations may have been another cause of conflu-

sion in the Hammadah Basin, where proposed Early Carboniferous microspore successions do not rely on discrete reference sections. Instead, their documentation is based on a series of composite sections, involving parts from different boreholes (MASSA *et al.*, 1980, Fig. 4, 5). Because vertical ranges of microspores and faunal elements have not been demonstrated for separate wells, we suspect that, in cases like this, rock intervals of similar lithology but different ages may have been lumped together into one same biozone.

5.3. VISÉAN PALYNOZONES

Most problems and controversies involving the age and correlation of the Viséan strata in North Africa have been discussed in sufficient detail elsewhere (STREEL & LOBOZIAK, 1994; LOBOZIAK *et al.*, 1998), and so, no unnecessary repetition is given here. In particular, the dispute about the "belated" first appearance of *Lycospora* spp. in regions of the *Arastrisporites sahraensis* Microflora (COQUEL & MASSA, 1993; RAW *et al.*, 1994) has lost much of its former significance in view of the latest developments. First, our recent palynological results from northern Brazilian basins confirm that *Lycospora* spp. may be too erratic and facies-sensitive to be reliably used in long-distance correlations, and even in tracing synchronous Viséan sections within a same sedimentary basin. Secondly, following the viewpoint adopted in our latest Brazilian reviews (MELO & LOBOZIAK, 1997; LOBOZIAK *et al.*, 1998; MELO *et al.*, 1999), we now suspect that Early Viséan strata may be missing or highly condensed over much of western Gondwana. This is possibly in response to common tectono-eustatic settings.

Reinterpretation of published accounts on Viséan microspore and faunal successions from North Africa (LOBOZIAK *et al.*, 1998, and herein) now suggest that Subzones M4 - M7 in the Algerian Sahara, Palynozones IV and lower V in the Illizi Basin, and Palynozones XIII to lower XV in the Hammadah Basin are mostly of Middle to latest Viséan age (Fig. 3). Altogether, these units seem to correspond to the *P. tessellatus - S. campylopleura* (TC) - lower *Bellisporites nitidus - Reticulatisporites carnosus* (NC) microspore zonal range of western Europe, currently dated as Late Holkerian through latest Brigantian.

Integrated foraminiferal/microspore data from the Mdaktra Massif in Morocco (LOBOZIAK *et al.*, 1990), as pointed out by LOBOZIAK *et al.* (1998), indicate that the base of TC Zone can be older than usually shown in western European charts. In Morocco, it coincides with the boundary of foraminiferal zones CF4g and CF5, which in Belgium lies near the Molinaean/Lvisan stage boundary (V2a/V2b transition). In Britain, the same horizon corresponds approximately to the Arundian/Holkerian stage boundary, which is currently placed within the *K. triadialis - K. stephanephorus* (TS) microspore Zone.

The remainder of Palynozones V and XV are possibly coeval with the upper NC Zone, of earliest Namurian (E1) age, as suggested by faunal data, despite the apparent scarcity of saccate pollen grains, whose earliest known record is in the topmost part of Palynozone XV (COQUEL *et al.*, 1988, p. 7). Except for their youngest and oldest age extensions, which remain unproven in Brazil, those North African units are essentially equivalent to Interval XII of northern Brazilian basins, that contains very similar microspore assemblages.

Judging from available microspore range charts for the Illizi and Hammadah Basins (ATTAR *et al.*, 1980, Tab. 1; MASSA *et al.*, 1980, Fig. 3; ABDESSELAM-ROUGHI & COQUEL, 1997, Fig. 4), the

IV/V and XIII/XIV/XV zonal boundaries seem rather diffuse. Some of the miospore events used to characterize them may only reflect paleoecological controls, like the disappearance of *Speleotriletes pretiosus*, alleged rises and falls in the proportion of *Aratrisporites saharaensis* (a reasonably abundant component of northern Brazilian microfossils from latest Devonian to latest Viséan), and the "belated" entry of *Lycospora* spp. Others may be of biostratigraphic significance, such as the "development" (possibly the actual F.A.D.) of *Speleotriletes ateneaceus* / *S. triangulus* within Palynozones IV and XIII and the entry of *Rotaspora* spp. in the lower part of Palynozone XIV. This is because they represent potential tie-points for identifying the *R. nigra* - *T. marginatus* (NM) and succeeding miospore zones of western Europe, with Late Asbian and younger ages (CLAYTON *et al.*, 1977, 1978). Faunal datings on which both Illizi and Hammadah zonal schemes rely (e.g., Massa & VACHARD, 1979) fail to provide any appropriate justification for the "Early Viséan" interval in those basins (STREEI & LOBOZIAK, 1994; LOBOZIAK *et al.*, 1998). In fact Palynones IV (lower part) and XIII are said to correspond to a section "non caractérisée paléontologiquement" (ATTAR *et al.*, 1980, Fig. 3; Massa *et al.*, 1980, Fig. 3, 4).

On their turn, Subzones M4 and M5 from the Grand Erg Occidental (LANZONI & MAGLOIRE, 1969, p. 450) are calibrated, in the Timmoun and Bahmer core-drills, by faunal elements with disparate ranges, some of which contradict the proposed Early Viséan age. Indeed, the bivalve *Posidonia* cf. *becheri* (shared with Subzone M5) points out to a Late Viséan (Late Asbian - Middle Brigantian) age, equivalent to that of the B2 - P1d ammonoid zones (N.J. RILEY, personal communication, June 1997). The shelly fauna listed for the upper part of Subzone M5 is more clearly of Late Viséan age. Ammonoids like *Bolandoceeras hoderdense*, *Beyrichoceratoides redesdaniensis* and *Beyrichoceras obtusum* are consistent with a latest Holkerian - Asbian age span (RILEY, 1993, Fig. 1, 2, 7), which is precisely that of the combined TC - NM miospore zones in Britain.

Based on correlations with adjacent Saharan basins (Fig. 2), we interpret faunal datings for Subzone M4 as corresponding to an indeterminate portion of the Holkerian - Early Asbian range while Subzone M5 is certainly as young as Late Asbian. However, we admit that the basal part of this whole unit may locally include thin, strongly condensed beds of latest Tournaisian - earliest Viséan age in areas like Colomb-Béchar, Gourara and Touat, where the M3/M4 transition was preserved from younger Viséan erosional events. A similar Holkerian - Asbian age range is also implied for Palynozones XIII-XIV and the bulk of Palynozone IV in the Hammadah and Illizi Basins, if one accepts their correlation with Subzones M4 and M5 of the Grand Erg Occidental, as proposed by ATTAR *et al.* (1980, Tab. III) and COQUEL *et al.* (1988, Tab. 1).

From the palynological viewpoint, and in the light of new miospore data obtained from northern Brazilian basins, the following two arguments are also in favor of a Middle to Late Viséan age for biozones M4/M5, IV and XIII-XIV in North Africa:

— sections from forementioned palynozones (and also from biostratigraphic interval XII in Brazil) yield the distinctive miospore *Diatomozontriletes fragilis* (ATTAR *et al.*, 1980, Pl. 3 Fig. 7; Massa *et al.*, 1980, Fig. 4, Pl. V, fig. 22; ABDESSELAW-ROUGHI & COQUEL, 1997, Fig. 4, Pl. II, fig. 4; *Diatomozontriletes* sp. n° 2997 in LANZONI & MAGLOIRE, 1969, Tab. I, Pl. III, fig. 20, Pl. IV, fig. 1). The earliest occurrence of prominently saetose-cornate miospores (i.e., the true *Diatomozontriletes* spp.) is a widely recognized biostratigraphic event in the Lower

Carboniferous of Euramerica, which is first recorded only from lower Asbian (upper TC Zone) regional equivalents (CLAYTON, 1996, p. 562). Assuming that this bio-event also affected western Gondwana at about the same time as Euramerica, then North African and Brazilian sections containing similar miospore groups are possibly not older than Late Holkerian or Asbian. In Algeria, *Diatomozontriletes* spp. proliferate in intervals as low as Subzone M4 in the Grand Erg Occidental, and also occur since the basal part of Palynozone IV in the Illizi Basin (LANZONI & MAGLOIRE, 1969, Tab. I, p. 449; ABDESSELAW-ROUGHI & COQUEL, 1997, Fig. 4).

— North African and northern Brazilian basins share some characteristic Gondwanan (*Aratrisporites saharaensis* Microflora) miospore species, including *Radizonates* sp. cf. *Hymenozontriletes dolianiti*, *Dicyotriletes* sp. cf. *Reticulatisporites magnidictyus*, *Speleotriletes benghaziensis*, *S. owensii* and *Vallatisporites agadesi*. At least in Brazil, they often occur associated with usual TC-VF elements of western Europe, such as *Lycospora* spp., *Granulatisporites* spp., *Perotriletes tessellatus*, *Waltzispora polita*, *W. planiangulata*, *Cirratridites rarus*, *Rotaspora ergonulii*, etc. This confirms the Holkerian - Asbian age assigned to those Gondwanan taxa in North Africa, based on independent palynological and faunal datings.

5.4. LATEST VISÉAN - EARLY SERPUKHOVIAN PALYNOZONES

The latest Viséan age of M6/M7, lower V and lower XV miospore zones of Algeria and western Libya is indisputable. As indicated by previous discussions, this seems to be in good agreement with available faunal data from those regions and surrounding North African basins. On the other hand, as already pointed out herein, the palynological criteria used to separate them from underlying biozones seem unconvincing and not age-diagnostic.

Subzones M6 and M7 in the Grand Erg Occidental contain numerous densospores and verrucose forms, but are best characterized by the proliferation of Gondwanan species which continue from older biozones. The regional disappearances of *Aratrisporites saharaensis* and *Diatomozontriletes* spp. (LANZONI & MAGLOIRE, 1969, Tab. I) can be best referred to paleoecological constraints, because these elements persist (even though in decreased numbers) within contemporary Palynozones V and XV (Massa *et al.*, 1980, Fig. 4, 5; ABDESSELAW-ROUGHI & COQUEL, 1997, Fig. 4). The lack of reported *Lycospora* spp. from Subzones M6 and M7, discussed by COQUEL *et al.* (1988, p. 12, 14), can be ascribed to similar facies controls, or still, to the fact that patchy occurrences of those tiny miospores may simply have been overlooked by LANZONI & MAGLOIRE (1969). There is currently no palynological or faunal evidence of Serpukhovian age for even the youngest unit (Subzone M7) whose main parts seemingly assignable to the upper-V3c-based on faunal correlations (Fig. 3).

In the Illizi and Hammadah Basins, the Viséan part of Palynozones V and XV is also poorly differentiated from underlying units. The most remarkable palynological feature is the early appearance, higher up within those units, of insufficient representatives of the praecolpate genus *Schoffoiporites* (COQUEL *et al.*, 1988, Fig. 2; ABDESSELAW-ROUGHI & COQUEL, 1997, Fig. 4), much in the same way as in biostratigraphic interval XII of the Amazon Basin (Loboziak *et al.*, 1998). Particularly

in Palynozone XV, the entry or proliferation of certain miospores with clear Late Viséan affinity allow improved correlations with coeval miospore successions of western Europe and northern Brazil, including *Granulatisporites* spp., *Walzispora* spp., *Tricidarispories* spp., *Foveosporites appositus*, etc. (Massa et al., 1980, Fig. 4). On the other hand, entries of *Schulizospora campyloptera* reported from near the Viséan/Serpukhovich boundary within Palynozones V and XV are less age-significant. Elsewhere, the earliest *Schulizospora* spp. are reported from the Middle of Late Viséan (Canton, et al., 1977) as demonstrated in the Moroccan Variscides by Loboziak et al. (1990). Most of the other miospore species present in those two biozones (including many Gondwanan taxa shared with northern Brazilian basins) persist upwards into younger sections. For this reason, the Viséan/Serpukhovich boundary does not have any distinct palynological signature in the Illizi Basin, and even in the Hammadah Basin, where the earliest *Florinites* spp. (near the top of Palynozone XV) are found only some tens of meters above the entry of Serpukhovich marine faunas (Coquel et al., 1988, p. 7). Likewise in northern Brazilian basins, the an-Serpukhovich transition (if present at all) cannot be distinguished on the basis of palynological evidence.

6. — CONCLUSIONS

This study confirms the unity of the *Atratisporites saharænsis* Microflora, which allows long-range correlations of Early Carboniferous miospore assemblages from northern Brazil and Saharan Platform basins. It also suggests that latest Toundaisian and Early Viséan microfloras remain largely unbroken in those areas. This may be partly due to erosional truncations, and partly ascribed to sedimentation. The latter possibility (often, but not necessarily, associated with black shales or thin, pelagic phosphate-carbonate beds) has been seldom considered in previous stratigraphic studies of Gondwanan regions. This is possibly because it can be readily detected only on sound paleontological grounds. Condensation events partly coeval with those proposed herein for Saharan basins have been identified in the Lower C₂, oniferous of western Europe, so suggesting that they may have shared common tectono-eustatic causes. They are exemplified by the Rubschiefer Formation of Thuringia, Germany, where only ca. 20 m of black shales contain the basal lower *grenulata* through *anchoralis-latus* conodont zonal succession of early Middle to latest Tournaisian age (Kullmann et al., 1991, p. 128). The Erdbach Limestone in Germany also includes non-sequences and highly condensed sequences within the range of the FA and BB ammonoid zones (Flüxer, 1991, p. 137), which in Britain comprises nearly the entire Chadrian - Holkerian succession of Early and Middle Viséan age (Fig. 2).

COQUEL & MASSA (1993, p. 150) state that only marine faunas - in particular goniatites, conodonts and foraminifera - can provide the "Vérité Stratigraphique Essentielle" for accurately dating and correlating the Carboniferous palynozones of the Saharan Platform. However, the present paper demonstrates that several unsolved contradictions still persist in the biostratigraphy of North African Carboniferous faunas. These, as currently documented, suggest disparate ages for a same interval, even when one single fossil group (e.g., ammonoids) is considered. Moreover, different reinterpretations of published faunal data from Saharan basins are possible, some of which seem to

confirm our independent miospore datings based on the western European palynozonation.

The problem of disparate faunal - miospore ranges in the North African Carboniferous literature, as compared to standard zonal schemes of Euramerican regions, is rather complex and may have multiple causes. At least five can be suggested: (a) some critical taxa of the North African faunas and microfloras may have been misidentified in the literature; (b) their local ranges are still poorly controlled and dated or (c) they actually differ to some extent from those in Euramerica, possibly in response to ecological or paleogeographic factors; (d) critical horizons yielding some key fossil groups (e.g., ammonoids, conodonts) may have not been considered for others (e.g., miospores) due to unsuitable lithology, coarse or selective sampling, and other biases; and finally, (e) some proposed biozones or rock units may enclose gaps, condensed sections, or uncorrelated intervals with discrepant ages. Obviously, none of these hypotheses can be favored *a priori*, until detailed taxonomic and stratigraphic revisions are carried out in Carboniferous basins of North Africa.

Acknowledgements

The authors are indebted to geologists LUMA M. R. BARRILARI and MIRSURI ARAI (Petrobras/Cenpes, Rio de Janeiro) for the constructive criticism and review of the manuscript; to Mme R. NETTER (UPRESA 8014 du CNRS, Villeneuve d'Ascq, France) for typing the final versions of the text; to FERNANDA F. ROBERTO (geology graduate student at URFJ, Rio de Janeiro) for preparing computerised drawings, and to PETROBRAS - Petróleo Brasileiro S.A. for the permission to publish this paper. N.J. RILEY (British Geological Survey, Keyworth, UK) and D. VACHARD (UPRESA 8014 du CNRS, Villeneuve d'Ascq, France) kindly provided ammonoid and foraminiferal data mentioned in the text.

Stanislas Loboziak, Doctor of Science at the University of Lille, is a researcher at the French National Centre of Scientific Research. His work deals mainly with the palynology of Paleozoic dispersed miospores and its applications, especially in the field of biostratigraphy. He has contributed to the development of reference scales for the Devonian and Carboniferous of Western Europe and to their implementation in comparative studies, particularly with Central Europe, North Africa, Western Asia and North and South America. He is a consulting palynologist to Elf E.P. and Petrobras, and has participated for a few years, in an updating of the chronostratigraphy of the Devonian and Lower Carboniferous of North Brazil Paleozoic basins.

Stanislas Loboziak, Docteur ès Sciences de l'Université de Lille, est chercheur au C.N.R.S. Ses travaux concernent surtout la palynologie des miospores dispersées du Paléozoïque supérieur et ses applications, dans le domaine de la biostratigraphie plus particulièrement. Il a contribué à l'élaboration d'échelles de référence pour le Dévonien et le Carbonifère d'Europe Occidentale et à leur mise en application dans des études de comparaison, notamment avec l'Europe centrale, l'Afrique du Nord, l'Asie occidentale et l'Amérique du Nord et du Sud. Il est consultant auprès de Elf E.P. et de Petrobras, et participe, depuis quelques années, à une actualisation de la chronostratigraphie du Dévonien et du Carbonifère inférieur des bassins paléozoïques du nord du Brésil.

José Henrique G. Melo holds a B.Sc. in geology from the Rio de Janeiro Federal University (1978), and an M.Sc. from the same university (1985). Since 1984 he has worked at Petrobras Research Centre (CENPES) as a stratigrapher, paleontologist and palynologist. His main research interests are in Silurian-Devonian palynology, stratigraphy and paleogeography of Brazilian Paleozoic basins. Jointly with Dr. Stanislas Loboziak, he is currently leading a research project at CENPES. This involves a re-evaluation and an update of the Devonian-Mississippian miospore biostratigraphy in the Amazon and Solimões basins of northern Brazil.

José Henrique G. Melo a reçu son diplôme de géologie (1978) et sa Maîtrise *es-sciences* (1985) à l'Université de Rio de Janeiro. Depuis 1984 il est stratigraphe, paléontologue et palynologiste au Centre de Recherches Petrobras (CENPES). Ses thèmes de recherches concernent principalement la palynologie, la stratigraphie et la paléogéographie du Silurien-Dévonien des bassins paléozoïques du Brésil. Actuellement à la tête d'un projet de recherches du CENPES, il travaille avec le Dr. Stanislas Loboziak à la révision de la palynostratigraphie du Dévonien-Mississipien des bassins d'Amazonie et de Solimões au nord du Brésil.

Maurice Streeel graduated (1957) as a Botanist from Liège University, Belgium. His Ph.D (1961) was a contribution to the phytogeography of Central African Savannas. Later he joined the Department of Palaeontology in the same University and taught Palaeobotany and Stratigraphy to students of Botany, Geology and Applied Geology. His main research interest was in the miospore stratigraphy of the Devonian of the Ardennes-Rhine regions. He retired from the University in 1995 but still works in Palynology particularly on the Quaternary and the quantitative approach of Late Devonian assemblages in relation to sedimentology and climatology.

Maurice Streeel a reçu son diplôme de botaniste en 1957 à l'Université de Liège, Belgique. Son Doctorat (1961) concernait la phytogéographie des savannes d'Afrique Centrale. Ulérieurement il a rejoint le Département de Paléontologie de la même Université et a enseigné la paléobotanique, la palynologie et la stratigraphie aux étudiants en botanique, géologie et géologie appliquée. Ses principales recherches concernent la stratigraphie par miospores du Dévonien des régions ardennes-rhénanes. Il a pris sa retraite en 1995, mais continue à s'intéresser à la palynologie, en particulier dans les domaines du Quaternaire et de l'approche quantitative des associations de miospores en relation avec la sédimentologie et la climatology.
