Abstract: There is a growing interest for vitamin D in the medical and scientific community as well as in the public medias as illustrated by a huge number of publications. Most experts claim that vitamin D deficiency/insufficiency is widespread with potential important public health consequences. It may seem surprising for many persons that a deficiency in a vitamin may be so frequent in countries where food is so diversified and easily available. In fact, vitamin D is not a vitamin stricto sensu as it is mainly synthesized in the skin under the action of UVB rays, while its food sources are scarce. Furthermore, UVB rays are absent during a marked part of the year at latitudes greater than 35-40°, while pollution and cloud cover reduce the number of UVB reaching the earth, and many factors such as age, skin pigmentation, covering clothes, sun creams reduce the capacity of the skin to synthesize vitamin D3. Vitamin D must be hydroxylated to form 1,25dihydroxyvitamin D (1,25OHD2), the active metabolite. As 1,25OHD2 is released into the bloodstream and binds to a receptor present in several distant tissues, it may be considered as a hormone, vitamin D being thus a pre-prohormone. In the present article, we review briefly the metabolism and various effects of vitamin D as well as the vitamin D assays and vitamin D treatments. We define vitamin D deficiency/insufficiency considering separately the population and the patient level and propose our opinion about which patients may benefit from vitamin D testing.

Keywords: Vitamin D, 25-hydroxyvitamin D, Calcitriol, Parathyroid hormone, Immunoassay, Mass spectrometry, Reference values.

METABOLISM AND EFFECTS OF VITAMIN D

Vitamin D comprises a group of fat-soluble seco-steroids that play an essential role in calcium homeostasis and the development and maintenance of the skeleton. The two major forms of vitamin D are vitamin D3, also known as cholecalciferol, and vitamin D2, also named ergocalciferol. Vitamin D2 is found in plants, mainly yeast and fungi, whereas vitamin D3 is synthesised in the human skin from its precursor, 7-dehydrocholesterol, under the influence of ultraviolet B light (UVB). In addition, vitamin D3 is also contained in a few foods of animal origin. As vitamin D3 can be produced by exposure of the skin to sunlight, it is not a vitamin in the strict definition. The dietary sources of vitamin D are scarce, the only really significant ones being marine fatty fish (D3) although egg yolk (D3) and some mushrooms (D2) could be additional sources.

One exception is the dried Shitake mushroom which contains significant quantities of vitamin D2. Some countries practice fortification of certain foods with vitamin D2 or D3, most often milk, cereals, margarine and/or butter and infant formula. It is important to recognize that vitamin D is primarily made in the skin after exposure to the sun (D3) and less than 20% is derived from dietary sources. While the sufficient UVB is present throughout the year in the tropical zone, its is absent for a significant part of the year when we move away from the Equator (i.e. approximately 6 months in our cities, Paris and Liège). Whereas somebody with a fair skin exposing himself or herself to the sun in a bathing suit during 20-30 minutes around noon in a clear summer day can make up to 15,000 IU vitamin D3 [1], living in a sunny area is not synonymous of having an optimal vitamin D status. Indeed, one needs to expose his or her skin to the sun to produce vitamin D3. It is of note that the cutaneous synthesis of vitamin D3 is less efficient in elderly compared to young people, and in Blacks compared to Caucasians, while it is decreased by the use of sunscreen, and absent in those wearing covering clothes. Furthermore, cloud cover or pollution both decrease the amount of UVB reaching the earth, and thus the production of vitamin D3 by the skin.

Vitamin D, either D2 or D3, circulates in the bloodstream, bound to a specific protein, the vitamin D binding protein (DBP). To become fully active, vitamin D needs to be transformed twice. A first hydroxylation occurs in the liver to form 25-hydroxyvitamin D (25OHD). This liver hydroxylation is not tightly regulated and the more vitamin D is synthesized or ingested, the more 25OHD is released into the bloodstream and binds to a receptor present in several distant tissues, it may be considered as a hormone, vitamin D being thus a pre-prohormone. In the present article, we review briefly the metabolism and various effects of vitamin D as well as the vitamin D assays and vitamin D treatments. We define vitamin D deficiency/insufficiency considering separately the population and the patient level and propose our opinion about which patients may benefit from vitamin D testing.

The main classical effects of vitamin D through the endocrine action of calcitriol are to stimulate the absorption of calcium and phosphate by the gut, to regulate bone metabolism, and to exert a negative feed-back on PTH secretion. A severe deficiency in vitamin D may induce diseases characterized by bone mineralization defects, such as rickets in children and osteomalacia in adults [3]. Less severe deficiency may favour/worsen osteoporosis, especially on cortical bone. Supplementation with vitamin D (800 IU/day at least) with calcium has been shown to significantly reduce the relative risk of non vertebral fractures in...
subjects aged 60 years or older [4]. Correction of vitamin D deficiency/insufficiency is also a prerequisite before prescribing anti-osteoporotic drugs [5] and especially bisphosphonates [6].

Numerous tissues not involved in bone and/or calcium/phosphorus metabolism are also able to express both the VDR and the enzymatic machinery that activates/inactivates vitamin D. 25OHD enters these tissues and is locally transformed into calcitriol that binds to the VDR expressed in the cell and exerts various (non “calcemic”) genomic effects. This locally produced calcitriol is thought to stay within the producing tissue and thus does not participate in calcium/phosphorus metabolism. Its production does not seem to be regulated by calcitropic hormones (PTH, FGF23…) and depends probably on the 25OHD concentration in the extra-cellular fluid of these tissues. This is the basis for the (commonly called) “non-classical” effects of vitamin D that can be considered as “intracrine” by contrast with the endocrine above-mentioned classical effects. It is of note that a huge number of genes contain VDRE and are thus probably responsive to vitamin D. Circulating calcitriol can also exert non genomic effects through the binding in some tissues to membrane proteins with subsequent modification of the intra-cellular calcium flux and stimulation of tyrosine-kinases.

The metabolism of vitamin D is summarized in Fig. (1).

Among the most frequently discussed non classical effects of vitamin D are those on:

- The muscle, with several studies showing that vitamin D supplementation (800 IU/day at least) with calcium significantly reduces the relative risk of falls in elderly patients [7], which may explain in part the reduction in the risk of non-vertebral fractures.
- The immune system. Briefly vitamin D stimulates innate immunity with potential protective effects against some infectious diseases [8], and inhibits some part of the adaptive immunity (especially shifting Th1 and Th17 lymphocytes towards a Th2 and Treg phenotype) with potential protective effects on some auto-immune diseases [9].
- The cardio-vascular system possibly via direct (cardiac and vascular cells express both the VDR and the 1-alpha hydroxylase) and indirect effects (calcitriol controls insulin secretion and sensitivity, inflammation, PTH, and renin, and thus blood pressure [10]).
- Adverse pregnancy outcomes such as preeclampsia and gestational diabetes [12; 13]. It is important to underline that vitamin D metabolism is greatly modified during pregnancy. In brief, while the 25OHD concentration of the pregnant women seems similar to what is found in the general population, the DBP and calcitriol levels both increase. Especially, the 1,25OHD level of pregnant women is 50-150% higher than in non pregnant women without any increase of serum calcium[14]. This calcitriol increase seems to be due to a secretion by the placenta in addition to the usual renal synthesis, and probably allows an increase in the intestinal absorption, and placental transport of calcium and phosphorus. A recent RCT comparing the effect of 400, 2000, and 4000 IU vitamin D3/day in 350 pregnant women has shown that 1,25OHD concentrations of the participants were directly influenced by their circulating 25OHD levels throughout pregnancy, with maximal production of 1,25OHD in the 4000 IU group [15]. Serum 25OHD concentration of the foetus is dependent on the maternal level while 1,25OHD2 is probably produced by the kidney of the foetus.

All the effects of vitamin D are probably partly influenced by the genetic environment. Indeed several single nucleotide polymorphisms of the genes coding for the DBP, the 1-alpha hydroxylase or the VDR exist with potential influence on the 25OHD and 1,25OHD2 concentrations and their effects.

DEFINITION OF OPTIMAL VITAMIN D STATUS

This chapter aims to define vitamin D deficiency/insufficiency on the one hand, but also vitamin D excess on the other hand. First of all, it must be reminded that the measurement of 1,25OHD2, the most active vitamin D metabolite, is not indicated to evaluate vitamin D status. It must be limited to the diagnosis and management of rare disorders of phosphate and vitamin D metabolism, to the management of some patients with renal failure, and to the differential diagnosis of conditions presenting with hypercalcemia/hypercalciuria associated with low/low normal PTH levels. Second, it is a consensus, even among groups that released divergent recommendations on vitamin D [16; 17], that the measurement of 25OHD is the only measurement indicated to evaluate somebody’s vitamin D status. What is not consensual however is the 25OHD cut-off value below which vitamin D status may be considered as insufficient. Indeed, contrary to most other biological parameters, 25OHD reference values should not be “population-based” (i.e. the range of values corresponding to what is found in 95% of an apparently healthy population) but should rather be “health-based”. This means that defining vitamin D insufficiency corresponds to define the 25OHD level below which adverse outcomes may occur on the one hand, and/or above which beneficial effects of vitamin D may be observed. This supposes that RCTs demonstrating positive effects of vitamin D compared to placebo on clinical (“hard”) outcomes are available, and that the 25OHD concentrations in the “vitamin D groups” of these RCTs have been evaluated. It must be underlined that, with the exception of the effect on the risk of falls, the many evidences concerning the various potential extra-skeletal effects of vitamin D, although plentiful, are mostly based on observational and mechanistic studies. Although numerous prospective studies have shown that subjects in the highest quantile of 25OHD concentrations (usually>70-80 nmol/L; multiply by 2.496 to convert ng/ml to nmol/l) have a lower relative risk for many diseases than those in the lowest quantile (usually <30-40 nmol/L) [see for example 18-21], the observational nature of these studies does not allow to conclude a causal relationship between low vitamin D status and these diseases, and thus prevents defining clear clinical cut-off(s) to optimize these potential effects.

Like the expert panels from the Endocrine Society [16] or the Institute of Medicine (IOM) [17] who both recently released recommendations on the use of vitamin D, we thus acknowledge that the only effects of vitamin D for which a “reasonably evidence-based” target value may be proposed are the effects on the musculoskeletal health and mineral metabolism (prevention of rickets/osteomalacia, elevated PTH levels, osteoporotic fractures, and falls in the elderly). While the recent report by the IOM [17] indicated that a 25OHD level of 50 nmol/L is largely sufficient and “covers the requirements of at least 97.5% of the population”; we consider that the Endocrine Society group and as many other vitamin D scientists [16; 22-30], that the optimal 25OHD level for musculoskeletal health should be 75 nmol/L and more in our (individual) patients. The discrepancy between these two conclusions may seem surprising as they are based on the analysis of virtually the same published data. It should be considered that the IOM cut-off is intended for public health recommendations while the Endocrine Society group targets its recommendations on patient care and considers that vitamin D deficiency (what should be avoided in any patient) corresponds to 25OHD levels <50 nmol/L, and insufficiency (what may be deleterious for a significant proportion of patients) to levels of 50 to 75 nmol/L. [16]. To make things simple however, it is obvious that in clinical practice, we care for one patient at one time (not populations) and want that our
patients achieve a “sufficient” level, not an “insufficient” one. Our target concentration is thus above 75 nmol/L. Indeed, in the RCTs that shown positive effects of vitamin D on non-vertebral fractures [4] and falls [7], subjects in the “vitamin D groups” had generally 25OHD levels of more than 75 nmol/L, whereas those in the “placebo groups” had levels mostly in the 30-60 nmol/L range. Consistent with these RCTs, bone biopsy data showed that histomorphometric signs of bone mineralization defect are not detected in subjects with a serum 25OHD level of more than 75 nmol/L while they are present, as defined by the most conservative threshold of the OV/BV ratio of 2%, in approximately 20% of those with a 25OHD level between 50 and 75 nmol/L [31]. Furthermore, Japanese patients with a basal 25OHD concentration of up to 70 nmol/L decreased their PTH concentration when they were given vitamin D (without calcium) [32], while the relationship between serum 25OHD and PTH levels in various populations indicated in some studies (but not all), that the PTH concentration may increase when 25OHD is below 75-80 nmol/L [33]. Also, in one study (but not others), it was demonstrated that calcium absorption was improved in menopausal women when the 25OHD serum concentration increased to approximately 80 nmol/L [34]. Finally, recent data indicate that a 25OHD serum level of 82 nmol/L at least is required to optimize the anti-fracture efficacy of bisphosphonates [6].

Fig. (1). Summary of the metabolism of vitamin D. Vitamin D2 and vitamin D3 are transported in the blood by the DBP and hydroxylated in the liver to form 25OHD, the concentration of which represents an individual’s vitamin D status. Regulation of this hepatic hydroxylation is weak, and, the more vitamin D is ingested (D2 or D3) or synthesized in the skin (D3 only), the more 25OHD is produced. 25OHD is hydroxylated again to produce 1,25OH2D (also called calcitriol), the active vitamin D metabolite. This second hydroxylation can take place either in the proximal renal tubule, or in many other tissues. Renal hydroxylation – which is tightly regulated by calciotropic hormones, PTH and FGF23 – allows production of the 1,25OH2D “hormone” (i.e. which enters the blood and acts on distant target tissues binding to its receptor, the VDR). Peripheral hydroxylation seems independent of the calciotropic hormones but is dependent on the amount of circulating 25OHD. It forms 1,25OH2D which binds the VDR in the local tissue (where this 1,25OH2D has been formed), acts locally (in an intracrine manner), and does not participate to the calcium/phosphorus/bone metabolism. It is now demonstrated that in some tissues, circulating 1,25OH2D is able to bind membrane proteins (probably variants of the VDR) with subsequent activation of different intra-cellular enzymes and/or modification of the intracellular calcium flux. Of note, an inactivating pathway through a 24-hydroxylase exists both in the kidney and peripheral tissues.
Considering this threshold of 75 nmol/L, but even with the more conservative IOM cut-off of 50 nmol/L, insufficient vitamin D status is highly frequent. Indeed, approximately 80% and 50% of the general European population have a 25OHD level below 75 nmol/L, and 50 nmol/L, respectively, and some groups such as institutionalized persons, dark-skinned individuals or immigrants, are even very frequently severely deficient (25OHD<25 nmol/L) as reviewed recently [35]. Then, an obvious question arises: “How could it be possible to find so frequently a deficiency in a vitamin in countries where food is largely available and varied?” The obvious answer is, as mentioned above, that vitamin D is not a true vitamin as its main source is not nutritional but through the synthesis by the skin.

Having proposed a threshold for vitamin D insufficiency, we must now propose an upper optimal level. In our laboratories, we use a value of 150 nmol/L which is chosen arbitrarily as a level that is much lower compared to the potential toxicity zone (25OHD>375 nmol/L [36]). Furthermore, to date no data exist on long-term tolerance (several years) of 25OHD serum levels of 200 nmol/L and more, and similarly there are no RCT showing that a 25OHD level of 150-350 nmol/L has any clinical advantage compared to levels of 75-150 nmol/L. We can also take into consideration that some observational studies (very few in fact) have suggested a U-shaped relationship between 25OHD serum concentrations and the relative risk for prostate cancer [37], and other rare cancers [38] (higher risk for low 25OHD concentration but also for high concentrations) which urge caution while awaiting more definitive data. Thus our proposed 25OHD reference range that we call “desirable” or “recommended” values rather than “normal” values is currently 75-150 nmol/L. While taking due note of the abundant scientific literature, we do not rule out the possibility that these “desirable” values may evolve as new data are published. It can be noted that the upper levels of this target range is very close to the 25OHD concentrations recently found in traditionally living population in East Africa, the Massai, and the Hadzabe, who have lifelong, year-round exposure to tropical sunlight [39].

VITAMIN D ASSAYS

25OHD assays should be considered as routine assays since they allow evaluation of vitamin D status. They are still not easy to develop [40] and those available do not all meet the quality criteria that should be required for a routine clinical measurement. The main difficulties arise from the fact that 25OHD is a highly hydrophobic molecule, and there are two forms to be assayed, 25OHD2, and 25OHD3. The presence of significant amounts of a 25OHD C3-epimer in some patients, especially in newborns, renders the problem even more complex as it is still unclear whether this variant should be measured or not [41]. 25OHD assay techniques can be split into two large families, immunoassays, the most commonly used currently, and separation methods such as high performance liquid chromatography (HPLC) or tandem mass spectrometry (MS-MS). Both have their own advantages and limitations. Immunoassays are relatively easy to perform but they may be limited by cross-reactivity of the antibodies which may induce non equimolecular recognition of the various vitamin D compounds such as 25OHD2 and 25OHD3. They produce global results (i.e. the sum of all the measured metabolites). Separative methods need very experienced technicians, and necessitate highly expensive machines. However, once the machine is present in a laboratory and has been paid, the cost of a measurement in terms of reagents is much less than with the immunoassays. These methods provide separate concentrations for the different measured compounds that have to be subsequently summed.

In practice, there is no obvious argument for preferential use of a particular type of sample (serum or plasma). Serum seems to be used most often although it is suggested to avoid gel tubes [42].

25OHD is extremely stable in the serum, probably as a result of its binding with the DBP, making any special precaution for sample storage unnecessary. It is important that the laboratory participates in an external quality control (as for any other biological parameter). However, the hydrophobic nature of 25OHD is likely to induce very significant matrix effects which means that external quality control programs that offer “spiked” samples instead of real serum samples do not allow inter-method comparison [43]. An external quality control that uses “true” serum samples and is now accepted by many laboratories worldwide is the UK-based DEQAS (www.deqas.com). It is important to choose an assay technique that measures both 25OHD2 and 25OHD3 equally. This is particularly important in countries where vitamin D 2 is available as a supplement or in fortified food. A technique assaying only 25OHD3 inevitably underestimates the (total) 25OHD concentration so that a patient taking vitamin D2 supplements could easily be considered as vitamin D deficient while he is not [44]. If a method such as MS/MS, measuring separately 25OHD2 and 25OHD3, is used, it is imperative that the sum of the two forms appears as the main results on the result sheet [45]. This is the only important information for the clinician.

It must be understood that the threshold(s) defining vitamin D deficiency (50 or 75 nmol/L) is (are) based mostly on studies that used the same 25OHD assay, i.e. the “historic” DiaSorin radioimmunoassay (RIA) [46], but these thresholds are currently used whatever assay method is used. However, with the increase of laboratories that measure 25OHD, and with the availability of fully automated immunoassays, the DiaSorin RIA is now used by only a limited number of laboratories. It is thus important to question whether the different available assays produce similar results, in other words, whether they are standardized. Indeed, in case of poor standardization, strict application of a cut-off value would lead to different diagnoses and therapeutic actions. To standardize different assay methods for a given analyte, one needs a reference preparation and a reference method with a reference measurement procedure. Although not yet official (February 2012), it is probably a matter of months. Indeed, candidate reference measurement procedures for serum 25OHD3 and 25OHD2 by using isotope dilution liquid chromatography-tandem mass spectrometry (LC-MS/MS) and an accepted reference material (NIST) have been achieved and published recently [47]. It must be understood that this reference measurement procedure was developed to enable unequivocal validation and calibration of immunoassays and other methods and is not a routine practice. Its goal is to harmonize the results from the different methods used worldwide. When looking at the results of the International 25OHD quality control DEQAS, or at the results of recent studies that compared the most commonly used 25OHD assays [48; 49] two different conclusions may be reached. The optimistic conclusion is that the situation is not so bad as, according to the DEQAS results, the mean difference between the two most discrepant assays is 25-35 % for concentrations in the 20-80 nmol/L range. This is very comparable to and even better than what is found when different assays for other commonly measured steroids such as testosterone [50] or progesterone [51] are compared. A great difference however between 25OHD assays and testosterone assays is the fact that testosterone reference values are specific to each kit, reducing thus greatly the impact of the inter-method variability, whereas a 25OHD concentration is interpreted (low, normal, or high) by comparison with the same cut-off values whatever the 25OHD assay is. Thus, the obvious and more pessimistic conclusion is that even a moderate difference of, say 10-15%, between the results of two 25OHD kits may have clinical/therapeutic consequences, as a significant proportion of patients may be classified differently (“insufficient” or “normal”) by the two kits by comparison to the clinical cut-off. This has been reported and discussed in several publications during the recent years [52-54]. It is likely that in the near future, these discrepancies
will be reduced due to the harmonization of the various commercial assays by comparison with the reference method procedure.

**IN WHICH PATIENTS SHOULD VITAMIN D TESTING BE PERFORMED?**

The considerable amount of recently published data on the proven or potential effects of vitamin D has raised much interest in the medical community. One of the consequences has been a great increase in the prescription of vitamin D measurements in clinical practice. In France, for example, the prescription of 25OHD testing has been multiplied by almost 3 between 2008 and 2010. As this measurement is reimbursed by the public health insurance (currently 17.55 Euros in France), it seems obvious to evaluate whether these prescriptions are justified or not. It must be emphasized that definitive recommendations on testing or not testing vitamin D in clinical practice must only be released by official Clinical Societies such as the Endocrine Society, and, thus, the following suggestions should only be considered as reflecting our current opinion (which may change with the publication of new data) based on our own analysis of the literature, and our routine clinical practice. We must mention a quite recent article co-signed by both of us [30], which reported the opinion of a panel of 25 experts from various disciplines. In this paper, most authors recommended to measure the 25OHD serum level in clinical practice in a myriad of medical conditions including pregnant women, patients with cancers, auto-immune diseases, cardiovascular diseases, hypertension and diabetes. Two years after the publication of this article, we (JCS, EC) would not give the same advice concerning the need to test vitamin D in these patients. Indeed, time has passed, and it has become clear that vitamin D doses of 2000 IU/day (and even more) are perfectly safe even if administered to subjects who have a spontaneous 25OHD level in the highest quartile of the general population (usually in the 70-90 nmol/L range), assuming they have no granulomatous disease (sarcoidosis, tuberculosis…) or hypersensitivity to vitamin D due to a genetic defect [2]. We thus do not recommend anymore to evaluate vitamin D status systematically in patients with (or at risk of) cardiovascular diseases, auto-immune diseases, cancers, infections, as well as in pregnant or lactating women. However, this opinion may change again according to newly published data (for example if one of the ongoing RCTs demonstrates that vitamin D supplementation improves one or several clinical extra-skeletal outcomes when a given 25OHD level is achieved). In the interval, we rather propose to supplement these patients with vitamin D without prior testing (although we don’t consider that measuring 25OHD in some cancer, multiple sclerosis, HIV, or hypertensive patients is a “crime”). We are aware however that in our countries (France and Belgium) at least, many doctors are still reluctant to prescribe vitamin D supplementation without knowing the vitamin D status of their patients, and, similarly, some patients would not agree to take a vitamin D treatment if a vitamin D deficiency/insufficiency has not been evidenced by a low 25OHD level.

In our opinion, vitamin D testing is still highly legitimate in several groups of patients for whom a “reasonably” evidence-based target concentration is available. As indicated above, our target concentration for musculoskeletal health and mineral metabolism is above 75 nmol/L. Let us also underline that, due to the measurement uncertainty of 25OHD measurements (which is comparable to what is reported for the measurement of other steroid hormones), a value of 75 nmol/L in an individual patient means that the true value is (grossly) above 60 nmol/L, and somewhere between 60 and 90 nmol/L [55].

So, among the patients in whom we propose to measure 25OHD to optimize bone/mineral health, we include:

- Patients with rickets/osteomalacia.
- Patients with osteoporosis (with and without fracture).
- Patients at risk of osteoporosis/bone loss because they receive specific treatments such as glucocorticoids chronically at a dose of 7 mg prednisone or more for any cause (see a recent review in [56]), analogs of GnRH for prostate cancer, or anti-aromatase therapy for breast cancer.
- Patients at risk of osteoporosis/bone loss because they have a malabsorption syndrome (celiac disease, inflammatory bowel disease, cystic fibrosis, Crohn’s disease…).
- Patient who had bariatric Surgery, specially gastric bypass. Obese patients are usually vitamin D deficient but are not osteoporotic. However, after gastric bypass they have an accelerated bone loss. These patients cumulate two reasons for being vitamin D deficient: 1) even if they have lost 50 kg or more, they are usually still obese and trap vitamin D in their fat mass, and 2) they have a malabsorption due to the surgical procedure.
- Patients with chronic kidney disease (CKD) stage 3-5D and kidney transplant recipients. Measuring 25OHD in CKD patients and treating vitamin D deficiency/insufficiency as in the general population is a recommendation of the KDIGO guidelines [57]. This recommendation is in fact only a suggestion which is graded 2C. Secondary hyperparathyroidism is a hallmark of CKD, with several deleterious consequences. It must be underlined that until recently, nephrologists used to treat their patients only with active vitamin D (analog of calcitriol), not “natural” vitamin D, to control PTH secretion. Recent studies have shown that supplementation with cholecalciferol or ergocalciferol was able to decrease modestly but significantly PTH levels not only in non-dialyzed, but also in dialyzed and in transplant patients [58-61]. Furthermore, several prospective observational and non randomized interventional studies have linked vitamin D deficiency to increased mortality in CKD [62], accelerated GFR loss [63], and albuminuria [64]. This has made things to change, and supplementation with vitamin D is an increasing practice in CKD patients.
- Patients with primary hyperparathyroidism (PHPT). These patients are often vitamin D deficient and osteoporotic, but they are also hypercalcemic. Treating hypercalcemic patients with a molecule that increases calcium absorption, and which may, when given at extremely large doses, cause hypercalcemia, hypercalciiuria, and extra-skeletal calcifications was regarded with suspicion by most physicians. It was shown in 2005 that the administration of large doses of cholecalciferol to PHPT patients with a serum calcium level <3 mmol/L, did not increase serum calcium or phosphate, but decreased PTH significantly [65]. This was followed by similar published results (reviewed in [66]) so that the expert panel for the diagnosis/management of asymptomatic PHPT recommended to treat with vitamin D any PHPT patient with a 25OHD<50 nmol/L [67]. It is also recommended to supplement all PHPT patients with vitamin D (and calcium) once they have been surgically treated. This will allow an increase in bone mineral density and prevent symptomatic hypocalcemia due to “hungry bone syndrome”. In our experience, 25OHD levels >75 nmol/L (and sometimes more) are to be targeted after parathyroidectomy.
- Patients with granulomatous disorders such as sarcoidosis or tuberculosis. In these patients it is prudent to target a 25OHD concentration around 50 nmol/L to avoid both hypercalcemia/hypercalciiuria due to uncontrolled synthesis of calcitriol on the one side, but also severe vitamin D deficiency which is frequent in these patients because of the fear of inducing hypercalcemia on the other side.
- 25OHD should also be measured in patients in whom symptoms compatible with a severe vitamin deficiency (such as...
those with diffuse pain or elderly subjects who frequently fall), or with a vitamin D intoxication (such as those with extra-
skeletal calcifications, nephrocalcinosis or recurrent renal
stones) are present and persist without a clear explanation.
Patients having a disease, such as hepatic failure, or receiving
treatments that may modify vitamin D metabolism such as
some anti-convulsants or ketokonazole can be included in this
category. In these patients there is no special 25OHD range to
recommend although it is logical to consider 50-150 nmol/L.

- More generally, 25OHD testing is recommended in any patient
in whom an exploration of calcium/phosphate metabolism
which includes a measurement of serum PTH is prescribed
whatever the reason is (osteoporotic patients to exclude a
secondary cause of low bone mass and/or fractures, patients
with kidney stones, chondrocalcinosis, and in case of
existence without explanation of symptoms of both hyper-
or hypocalcemia). In such cases, knowing the 25OHD level is
specially important when a high PTH concentration is detected
in a patient who has otherwise a normal serum calcium
and phosphate level. Indeed, this may help to differentiate
between a secondary hyperparathyroidism, for which vitamin D
insufficiency/deficiency is one of the most common causes
along with renal failure, and a so-called “normocalcemic”
PHPT which is now recognized as a quite frequent entity,
probably necessitating the same treatment as hypercalcemic
PHPT when osteoporosis, kidney stones or renal failure is
present [68].

TREATMENT/SUPPLEMENTATION WITH VITAMIN D

Here, we can separate recommendations for the general
population, and recommendations for individual patients distinguishing
those in whom we measure 25OHD, and the other patients.

Since insufficient vitamin D status is so common, since
treatment is inexpensive and has a large safety margin (even the
IOM considers doses up to 4,000 IU/day as safe in adults [17]), and
since we already have much data suggesting that in addition to its
classic proven effects on bone and mineral metabolism, vitamin D
may potentially be helpful for the prevention/management of
colorectal cancer, cardiovascular disease, and some auto-immune diseases, perhaps should it be prescribed to
everyone (without prior testing)? It is not up to us to give advices
for the general population, but rather to the health authorities to implement - if they become convinced that the benefit-risk/cost
ratio may be favourable - a prudent supplementation policy at
national or regional level with the objective to increase the 25OHD
levels so that most persons (95%?) have 50 nmol/L or more. This
would mean shifting the mean 25OHD level of the population of
most European countries from approximately 50 nmol/L to
approximately 75 nmol/L. Assuming this goal, intake of 600 IU/day
as proposed by the IOM group for adults up to 70 years is probably
insufficient as we know that, according to a rule of thumb, 1000
IU/day vitamin D will increase the 25OHD serum concentration by
a mean 15 to 25 nmol/L, but with a huge inter-individual variability
[69]. So, intake of 1000 IU/day is probably a better choice as
suggested by a recent systematic review and meta-regression
analysis of the vitamin D intake-serum 25OHD relationship [70].
We must however acknowledge that this is far from clear and there
is a need for further studies. Indeed, in a more recently published
RCT [71], a dose of 800 IU vitamin D3/day given for one year to
healthy postmenopausal white women allowed to reach a mean
25OHD level of approximately 75 nmol/L and a level above 50
nmol/L in almost all participants, while this was only achieved with
1600 IU/day, and 2000 IU/day in two other very recent trials
respectively [72; 73].

In patients in whom 25OHD testing is done, treatment will
depend on the results of the measured 25OHD concentration
with the aim to reach and maintain a serum level within the 75-150
nmol/L range. One can thus consider two phases, the first one
aiming to raise the 25OHD level above 75 nmol/L ("correction"
phase), and the second one aiming to maintain the 25OHD level
>75 nmol/L ("maintaining" phase). We know that the 25OHD
concentration reached after taking one specific dose of vitamin D
varies greatly from one patient to another. Two very important
determinants of the increase in serum 25OHD when a subject is
given a specific dose of vitamin D are the initial 25OHD concentration
and the patient’s weight. A Dutch group has established an equation based on these two parameters that
calculates the cumulative dose to be given in weekly doses of
25,000 IU to achieve an average concentration of 75 nmol/L ten
days after the last 25,000 IU dose [74]:

Dose (IU) = 40 [75- serum 25OHVD (nmol/L)] x [body weight
(kg)]

Thus, if we consider a 70 kg patient with a 25OHD level of 25
nmol/L, the dose calculated will be 140,000 IU, which, in practice,
is 25,000 IU every week over six weeks (150,000 IU in total). We
should point out that the value of 75 nmol/L in this study was an
average target, and that in practice around only half of the patients
treated achieve a concentration >75 nmol/L. This study at least has
the merit of opening a path for the determination of the “correction”
dose. It is of note that several propositions of “correction” protocols
using higher doses have been proposed by different experts (see for
eexample [22; 75]) and can be adapted according to the vitamin D
forms available in a given country. Once the “correction” phase
is completed, a maintaining phase using the doses suggested by the
Endocrine Society group as being the mean daily requirement that
can be prescribed (for example 1500-2000 IU/day for adults -see
Table 3 in [16]). Based upon the known variability in 25OHD
response, it is advisable in these patients to repeat 25OHD
measurement after 4-6 months of vitamin D supplementation at
the “maintaining” dose and adapt the posology.

For other patients in whom 25OHD is not measured, we may
consider two different propositions. The first one is to do for these
patients as it is recommended for the general population [17]. The
second one is to consider that, despite a lack of RCT with “hard”
end-points, the many observational and experimental data linking
vitamin D deficiency to an increased risk of several chronic disease,
as well as the increasing number of RCTs showing better outcomes
on intermediary parameters may encourage doctors to prescribe
higher dosages. For those, like us, who prefer this second
proposition, the above-mentioned doses suggested by the Endocrine
Society group are encouraged without prior testing and, thus,
without a “correction” phase, until the results of adequately
powered RCTs are available. It is probable that, with these doses,
and due to the important inter-individual variability in the 25OHD
response to a given vitamin D dose, not everybody will have a
25OHD level above 75 nmol/L, but a level of more than 50 nmol/L
can be expected in most patients.

It must be underlined that due to the great disparity of vitamin D
supplements that are available from one country to another, it is
impossible to propose universal supplementation protocols. Indeed,
in some countries only supplements providing daily doses of either
vitamin D2 or vitamin D3 are available, while in other countries it
is possible also to prescribe large doses of either compounds for
intermittent administration. It is possible however to highlight
several points for the clinical practice. A first question is whether
daily dosages (which may seem more physiologic) or intermittent
dosages (in order to favour observance/adherence) should be
preferred when both are available. There is no obvious answer to
this question but we think that, after having explained why vitamin D
supplementation is important for the patient, the doctor may let
the patient choose. If intermittent dosages are chosen (most
frequently in our practice), doses, and interval between doses
should not be too large. Indeed, daily doses and the same
cumulative doses administered weekly or monthly (i.e. 1,500 IU daily, 10,500 IU weekly, or 45,000 IU monthly) induce the same increase in the 25OHD concentration [76], while this is less obvious for larger intervals. Furthermore, in a recent 3-year RCT of 500,000 IU vitamin D3 versus placebo administered once a year to elderly women, more fractures and falls were recorded in the vitamin D group than in the placebo group [77]. Interestingly, this excess in the number of falls and fractures was only observed during the 3 months following each yearly administration of this large dose of vitamin D. A second question is whether vitamin D2 and vitamin D3 are equivalent. To answer to this question one has to differentiate the daily and the intermittent treatment. Indeed, it is now quite clear that when given intermittently, vitamin D2 is less potent than vitamin D3 to sustain the 25OHD level in a desirable range [78-79]. However, when given daily, D2 and D3 seem to maintain the 25OHD similarly [80] although this is discussed [81].

CONCLUSION

Knowledge on each aspects of the vitamin D field have increased these last years.

This has led to question previously well-established thoughts. For instance, we know now for sure that the vitamin D status of a patient should not be based on the determination of 1,25(OH)2OHD (the most active metabolite), but rather on 25OHD. We also know that 25OHD reference range should not be based on a “reference population” but on clinical data. There is now a large consensus to acknowledge that insufficient vitamin D status is highly frequent in the general population, and that vitamin D supplementation to reach serum levels of 75 nmol/l is mandatory for a good bone-mineralization, to reduce fracture and falls in the elderly. However, the target levels for other outcomes (hypertension, cardiovascular diseases, infections, auto-immune diseases, diabetes,…) are currently unknown and will probably be found according to new or ongoing randomized controlled studies with very well defined hard endpoints. Of note is that these targets will certainly vary according to the expected outcome. At that time, an important work on vitamin D assays standardization should have been done in order to avoid misinterpretation of the results. Finally, in medicine, the truth of today is not necessarily the truth of tomorrow, an misinterpretation of the results. Finally, in medicine, the truth of
