Opening Lecture

Plant biology in the 21st century

D. H. von Wettstein;
Washington State University, Pullman, WA, United States.

Since the second half of the 20th century plant biological research is characterized by a period of strong convergence. Genetics, physiology, biochemistry, biophysics and other sub-disciplines of biology are joined in the common goal for clarification of the molecular processes behind the function of organelles, cells, organs and organisms. The whole chain from the information in the genome to properties and function is analyzed with sophisticated methods. Surprisingly, *Arabidopsis*, rice and *Homo sapiens* have only 30,000 genes. Analyses of the genomes reveal that different combinations of a large but limited number of protein domain units form the basis for the variation and development of the plants and animals as we see them. With the increasing and exciting information accruing from studies with model organisms, plant biologists now have the important and very urgent task to translate the benefits of this knowledge into better crop plants to combat hunger, destruction of the environment, and waste of non-renewable resources on our planet. Examples how this can be done will be presented.

General Lectures

GL1.1 Angiosperm evolution and classification from the perspective of DNA data: a review of 15 years of progress

M. W. Chase;
Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

Gene (DNA) data have been used extensively in studies of angiosperm evolution for only the past 15 years, but the impact of this approach has been immense. Previous classifications of angiosperms relying upon largely intuitive weighting of the available data from biogeography, morphology and phytochemistry could not be used to frame research in other areas of scientific study because they reached different conclusions. Analyses of DNA data and non-molecular data avoided the subjectivity of previous classifications. In 1998, the Angiosperm Phylogeny Group published a classification of the angiosperms that relied primarily on the molecular studies, and this set the stage for advances along several lines. The first involved molecular clock studies, which set the time frame for angiosperm diversification, and this has been extended into many other areas. Ideas about evolution of several groups of angiosperms have been drastically revised, none more so than Orchidaceae.

GL1.3 Allelopathy: challenges and achievements

Inderjit;
University of Delhi, New Dehli, India.

Allelopathy as the suppression of seed germination and growth of one species by another through the release of chemical compounds. Few studies are acknowledged to have demonstrated probable allelopathy in nature, most appeared limited to in vitro circumstances. Allelopathic effects are often modified by additional biotic and abiotic stress factors, uncertain climatic events or, edaphic factors all of which can influence the concentration and fate of allelopathic compounds in the environment. One of the major concerns about allelopathy research is inadequate methodology. However, there are some good examples providing a solid basis for inferring the significance of allelochemicals in explaining plant dominance in certain natural situations. Allelopathy as a science has certainly progressed the way beyond the days of Harper’s criticisms. Allelopathy can be better conceptualized in terms of soil chemical ecology. Allelochemicals have been shown to play an important role in natural control of agricultural pests. While the major challenge is to establish the role of allelochemicals in natural conditions, the major achievement of allelopathy is its role in natural weed management.

GL1.5 Learning from enclosures: large-scale controlled environment facilities for experimental ecosystem and global change research

B. Osmond;
Forschungszentrum Jülich, Jülich, Germany.

A few decades of plant ecophysiological research with small, enclosed, controlled environment measurement devices have helped establish that, for all intents and purposes, Earth is an enclosed system made habitable over evolutionary time scales by the plant biosphere on land and sea. This paper makes the case for substantial expansion in the size and diversity of enclosed facilities for experiments in botanical research that will improve our ability to anticipate, and whereever possible, take advantage of, responses of the plant biosphere changing global climates. In the ,,Anthropocene“ it is already clear that we have left the domain from which we can expect to anticipate future responses of the Earth’s ecosystems from past observations over the period of human evolution (Falkowski et al Science 2000, 290, 291-296), from contemporary small scale experiments, or from simply monitoring the uncontrolled experiment in global climate change. Some believe we are stalled on opposite sides fo the Darwinian-Newtonian divide in Earth Systems science (Harte 2002, Physics Today October 29-34) as we try to deal with biocomplexity in ecology on the one hand and uncertain models in fluid dynamics on the other, and that we need experiments to bridge the divide. We must move rapidly to devise enclosed, controlled environment measurement systems at scales large enough to allow us to exercise our imaginations in experiments that bridge the Darwinian-Newtonian divide. Some evidence will be presented in support of this case from experience in the Biosphere 2 Laboratory 2001-2003. Without a large and sustained effort of this sort, we seem destined to deal with closure of a different kind from the presently inexorable, and largely irreversible, experiment in global climate change.

GL2.1 Pollen and spores: microscopic keys to understanding the earth's biodiversity

S. Blackmore;
Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

The most distinctive feature of planet Earth is that, unlike any other in this solar system, it is rich in biodiversity. Our species, which evolved as part of the biosphere that sustains us, has the intelligence and curiosity to explore the world around us and to understand its complexity. Given the environmental challenges that lie ahead we have much to learn by exploring all aspects of biodiversity. One astonishingly informative field of investigation is palynology, the study of the pollen grains and spores of plants. These microscopic, self-contained biological units are surrounded by chemically resistant cell walls with distinctive structures and symmetry. They provide insights into such fundamental questions as how and when plants first colonised the land or how the earth’s vegetation has developed through geological time and on finer time scales. They provide phylogenetic evidence important in plant systematics and model systems for understanding plant development at the cellular level. This will be a personal account of the interest and importance of these microscopic keys to understanding the Earth’s biodiversity.

GL2.2 Short silencing RNA: the dark matter of genetics?

D. Baulcombe; The *EMBO* Lecture
John Innes Centre, Norwich, United Kingdom.

RNA silencing is a newly discovered mechanism of genetic regulation in eukaryotes. Six years ago the evidence for RNA silencing was based on mysterious experimental observations in plants, a fungus and in *C. elegans*. Today we know that this process has natural biological roles and we have an outline understanding of the mechanisms. In addition RNA silencing is part of powerful enabling technologies for functional genomics. The story of this recent progress is revealing about the way that science accommodates and adapts to unexpected results. It also illustrates the power of combined molecular, genetic and biochemical approaches to problems in biology. In my lecture I shall summarise key discoveries in the elucidation of the silencing mechanisms. I shall also describe findings about diverse silencing mechanisms affecting genetic regulation at the DNA and RNA levels and affecting processes including virus protection, genome maintenance and control of gene expression in response to environmental and developmental stimuli.

GL2.3 Spread and impact of alien plants: fear, data, and uncertainity

M. Rejmanek;
Section of Evolution and Ecology, University of California, Davis, CA, United States.

Biological invasions (spread of non-native organisms introduced by people) currently represent a very popular topic. There is even a certain hysteria about alien organisms, of which only some are conclusively harmful. Several hasty and premature generalizations have been made. However, biological invasions are very often just symptoms of other man-caused changes in our environment. Local anthropogenic enrichment of floras by alien species is a real phenomenon, but many naturalized plant species are probably benign. On the other hand, it is well known that some invasive plant taxa have a strong tendency to form monodominant stands and that some invaders can alter whole ecosystems. Nevertheless, reliable data on the harmful impacts of "exotic pest plants" are often missing. We have made a substantial progress in predictions of plant invasiveness and invasibility of ecosystems, but very little in predicting the environmental impacts of invasive plants. As scientists we should do our best to make it clear what we do know and what we do not know. Doing otherwise would only threaten our credibility.

GL2.4 Nod factor signaling during subsequent steps of root nodule formation

T. Bisseling;
University of Wageningen, Wageningen, The Netherlands.

The root nodule symbiosis of *Rhizobium* bacteria and legumes is set in motion by rhizobial Nod factors. This are lipochito-oligosaccharides. that are secreted by the bacteria. These molecules induce the curling of root hairs, the start of the infection process as well as the mitotic activation of cortical cells. The latter results in the formation of nodule primordia that upon infection by the rhizobia develop into a nodule. A small set of legume genes is specifically involved in perception and transduction of Nod factors and several of these genes have recently been cloned. During this talk the role of the Nod factor signaling genes during root hair curling, and infection thread and nodule primordium formation in *Medicago* is discussed. *Medicago* forms indeterminate nodules. These nodules have a persistent meristem that adds cells to the different tissues of the nodule. The central tissue contain the cells that are infected by rhizobia. Infection threads grow towards the dividing meristem cells and after entering these cells bacteria are released from the threads. The Nod factor signaling genes are expressed in the cell layers of the nodule where infection threads grow and the bacteria are released. By reducing the expression level of Nod factor signaling genes it is shown that they are essential for the releaseof rhizobia from the infection threads

GL2.5 Mechanisms of plant response to global atmospheric change.

S. P. Long[1], E. A. Ainsworth[1], C. J. Bernacchi[1], A. D. B. Leakey[1], P. B. Morgan[2], S. L. Naidu[1], A. Rogers[3], H. J. Bohnert[1], D. R. Ort[1], R. L. Nelson[1]; sponsored by *Plant, Cell and Environment*

[1]University of Illinois, Urbana, IL, United States, [2]USDA-ARS, Raleigh, NC, United States, [3]Brookhaven National Laboratory, Upton, NY, United States.

The CO_2 and ozone (O_3) concentrations of the troposphere are rising with direct impacts on plants. O_3 currently costs crop production > 5bn Euro a year with parallel damage to natural ecosystems. In the short-term, elevated CO_2 stimulates and elevated O_3 depresses photosynthesis in highly predictable ways. Longer-term effects are less predictable, but new patterns are now emerging via meta-analysis of realistic field treatment in Free-Air Concentration Enrichment (FACE) facilities. The chain of effects from gene expression to acclimated phenotype that result from long-term growth in elevated CO_2 or O_3 will be reviewed. Significant season long increases in photosynthesis and production with CO_2 are found, with some surprising changes in plant development that were not apparent or suspected in studies with field enclosures. Season-long exposures to the moderate increases in O_3 observed in the field cause more transcripts to be down-regulated than up-regulated, cause a chronic decrease in photosynthetic capacity, largely attributable to decreased Rubisco activity, and cause slightly accelerated senescence.

GL3.1 Plant bio-inspired biomimetics: successes and challenges

G. Jeronimidis;
Centre for Biomimetics, Reading, United Kingdom.

Plants have always inspired mankind, from majestic trees to humble flowers, mostly on an esthetical level. More recently plants, plant tissues and organs at various levels of scale have provided paradigms and inspiration for many technological applications: from smart materials, to engineering structures, architecture, actuation, adaptive systems, etc. The best known example is “Velcro” but other applications emerging in various sectors. Plants are unique as effective examples of good design, i.e. biomimetic solutions. One of the main reasons for this is that materials and structures evolved by plants for their survival and strategies for adaptation are perhaps easier to translate and implement in a technological context. Without muscles, a nervous system and locomotion, plants have had to push optimisation of available resources to the limit in order to be successful. Existing achievements and future opportunities for plant- inspired biomimetics will be presented and discussed.

GL3.2 Sperm delivery in flowering plants: the control of pollen tube growth

P. K. Hepler[1], M. Bosch[1], A. Lovy-Wheeler[1], K. L. Wilsen[1], L. Cardenas[1,2], S. T. McKenna[1,3], J. G. Kunkel[1];
[1]University of Massachusetts, Morrill Science Center III, Amherst, MA, United States, [2]UNAM, Institute of Biotechnology, Cuernavaca, Mexico, [3]Long Island University, Brooklyn, NY, United States.

Pollen tube growth, which is essential for double fertilization in flowering plants, is fast and highly polarized. Here we focus on processes that might regulate growth, including cytoskeletal dynamics, ionic gradients, and cell wall changes. Current progress has benefited from the fact that the rate of growth oscillates as do the expressions of most underlying processes. Using cross-correlation analysis to compare these oscillatory processes, we have distinguished between events that precede versus those that follow the change in growth rate. Events that anticipate growth may have a closer affinity to the central regulator than those that follow growth. We have identified three processes that anticipate growth as follows: 1) the increase in pH in the alkaline band, 2) the forward motion of endoplasmic reticulum in the apex, and 3) the increase in apical cell wall thickness. We propose that increases in pH stimulate remodeling of the actin cytoskeleton, which facilitates transport and secretion of cell wall components.

GL3.3 Comparative seed plant phylogenetics: evolutionary syndromes and phylogenetic phases

F. Ehrendorfer;
Institute of Botany, University of Vienna, Vienna, Austria.

Many DNA-supported phylogenetic trees of seed plant clades are now becoming available. They form a fascinating new basis for comparative analyses and permit the search for generalized syndromes and phases in evolution. Differences in life and growth forms, vegetative and reproductive features, types of cytogenetic changes, and eco-geographical positioning are parameters to characterize evolutionary syndromes. Slow or rapid change of taxa in time, balance between divergence and hybrid reticulation, rates of speciation versus extinction, and branching patterns of trees are linked with phylogenetic phases of clades (initial-differentiation-declining). Correlations between all these parameters and past to present environmental conditions clearly suggest extrinsic and intrinsic constraints in evolutionary processes. Examples demonstrate how comparative phylogenetics and the concepts of evolutionary syndromes and phylogenetic phases can contribute to a better understanding, typification and application of evolutionary phenomena and to their future modelling.

GL3.4 Phytohormones - research between whole plants and molecules

E. Beck;
Universität Bayreuth, Bayreuth, Germany.

Considerable progress has been made in the field of phytohormones, especially on the molecular level. For several classes of these effectors, receptors were identified and some of the signalling cascades have been at least partly elucidated. Examples will be presented in the lecture. Following the more general aspects of phytohormone cell biology, interactions between exogenous (also artificial) and endogenous phytohormones will be discussed, especially in the context of plant ageing and senescence. Interaction of phytohormones with other signals will be briefly addressed. The lecture then switches to the significance of phytohormones at the whole plant level. Emphasis will be on cytokinins as effectors regulating plant growth in adaptation to supply of resources such as CO_2 and nutrients. Cytokinins may also be involved in the solid-substrate effect, i.e. a higher biomass production of plants growing in soil as compared to hydroponic culture.

GL3.5 Metabolomics, phenolic metabolism in *Arabidopsis*

N. G. Lewis;
Institute of Biological Chemistry, Pullman, WA, United States.

The biochemical pathway elaboration to the myriad polyphenols in the plant kingdom began with transition of plants to a land base some 400 million years or so ago. Of these, lignins represent Nature's second most abundant organic substances in vascular plants such as *Arabidopsis*. Nearly five decades ago, an unproven notion of random assembly was proposed to account for lignin biopolymer formation, even though essentially the entire basis of this working hypothesis was disproven. Yet some investigators still cling to this now disproven hypothesis (recently renamed "combinatorial" biochemistry) even today, with extravagant unproven claims that the biopolymer is composed of billions of isomeric forms! The recent ability to study biochemical processes at the single cell level, e.g. using laser micro-dissection, together with the application of metabolomics, proteomics and metabolic engineering, has permitted the study of both lignin assembly and the phenolics in developing *Arabidopsis*. The results obtained show the first evidence for *ordered lignin primary structure*, as well as assisting in the identification of the phenolics present in this species.

GL4.1 The green roof of the globe in a changing atmosphere

C. Körner;
Institute of Botany, Basel, Switzerland.

Elevated CO_2 can affect plant photosynthesis and thus the biosphere directly. Given that close to 90 % of the planet's biomass is tied up in trees, it is key to know how this large life carbon pool will respond to rising CO_2. For practical reasons the scientific exploration of this aspect of global change in large remained limited to experimental approaches using young, vigorously growing test systems. In this lecture, I will focus on growth, biomass responses and water relations of older trees. I will demonstrate the overarching significance of developmental processes and biodiversity. Elevated CO_2 is likely to enhance forest dynamics, rather than increase carbon storage. Forests carbon storage does and will depend on the size of land area they cover and on their successional stage. The slower carbon turns over and the closer forests are to a steady state carbon balance, the greater the amount of carbon they store. Thus, a global, carbon storage oriented policy will care for the protection of old growth forests, with pulp and fiber largely produced in fast rotation plantations. Their productivity can profit from elevated CO_2, provided soil nutrients permit.

GL4.2 The evolution of plant allometry: insights from mosses to trees

K. J. Niklas;
Cornell University, Ithaca, NY, United States.

All biological phenomena depend on the absolute sizes and the proportional relationships among the constituent parts of organisms. Intensive research has identified 'rules' for these scaling relations spanning 20+ orders of magnitude in body mass across aquatic and terrestrial plants and animals. A review of these rules indicates that deeply rooted, fundamental principles must dictate the expression of organic form and structure. The elucidation of these principles is therefore critically important to all biological research agenda. Although their explication remains elusive, recent developments in nitrogen and phosphorous allocation patterns at the cellular level (to proteins and rRNA, respectively) have provided recent insight, e.g., across diverse plant species, foliage N content scales as the 3/4 power of foliage P content, and P scales as the 4/3 power of total body mass. These and other N/P stoichiometric relations are used to argue that the ribosomal 'machinery' driving growth at the cellular level increases disproportionately with increasing body size. This claim may explain some if not all of the 'canonical scaling rules' previously reported.

GL4.3 Plants, people, and phytochemicals: therapies or threats

P. A. Cox;
Institute for Ethnomedicine, National Tropical Botanical Garden, Provo, UT, United States.

Indigenous peoples use plants rich in phytochemicals. Some phytochemicals can be used for new drugs, such as prostratin from *Homalanthus nutans,* used in Samoa to treat hepatitis. The AIDS ReSearch Alliance will return 20% of its profits from prostratin to Samoa. The University of California, Berkeley will share equally with Samoa any revenues from cloning the prostratin gene sequence. Phytochemicals, however, sometimes present undetected threats. Chronic neurological disease, such as konzo (from *Manihot esculenta*), lathyrism (from *Lathyrus sativus*), and ALS/PDC (linked to *Cycas micronesica*) are caused by toxins in crop plants. ALS/PDC symptoms are similar to Amyotrophic Lateral Sclerosis (ALS), Parkinson's Disease (PD) and Alzheimer's Disease (AD). Cyanobacterial symbionts in *Cycas* roots produce BMAA, a potent neurotoxin, which is then biomagnified within the ecosystem. Whether phytochemicals represent therapies or threats to indigenous peoples, ethnobotanical studies of wellness and disease among the indigenous peoples can lead to significant pharmaceutical advances.

GL4.4 The role of correlated traits in plant-insect interactions

L. S. Adler;
University of Massachusetts, Plant, Soil, & Insect Sciences, Amherst, MA, United States.

Plant-insect interactions are thought to have played a key role in the diversification of angiosperms, due in part to selection by herbivores and pollinators on defensive and attractive phenotypes. Interactions with antagonists and mutualists have historically been studied independently. However, pleiotropy or genetic correlations between traits may constrain the ability of plants to evolve optimal solutions to selection pressures from these different interactions. For example, several studies have linked the expression of floral color traits with production of defense compounds and resistance to herbivory in leaves. In my research we have found tight correlations between alkaloid levels in leaves and nectar within and between species of *Nicotiana*, suggesting that defense traits may evolve in response to selection by pollinators as well as herbivores or pathogens. Other research shows that integration across tissues such as roots and shoots may constrain or enhance responses to different herbivores. Thus, the evolution of defense phenotypes may be best understood in light of the multi-species interactions that plants experience in nature.

GL4.5 The sweet side of economic botany: Biotechnology and molecular biology of cocoa: *Theobroma cacao*

R. Lieberei;
Biocenter Klein Flottbek, Hamburg, Germany.

Cocoa is one of the economically most important plant resources. It started its way around the world from the Amazon basin. As many tropical plant resources it was distributed to the former colonies around the tropical belt of the globe, and rising world wide consumption was answered by enlargement of plantation areas. First problems in production were caused by fungal diseases in the beginning of the 20th century, followed by virus and pests. Installation of gene banks, breeding and selection for resistance allowed for more efficient production, but it was only in the late sixties that a rational research on flavour and aroma quality started. Nowadays we are facing wide international molecular activities on gene pools, plant biotechnological studies on the right and efficient post harvest treatments, esp. fermentation processes, to improve and to maintain a stable quality of raw cocoa. New production areas develop in South East Asia, concomitant with their growing markets. The paper focuses on the biotechnological insights into quality determining post harvest processes and provides an overview over the molecular biological activities on the cocoa plant.

GL5.1 Transgenic food plants for the Third World

J. A. Thomson;
University of Cape Town, Cape Town, South Africa.

In Africa 70% of the population depends on agriculture as the sole source of income. However, Africa's crop production is the lowest in the world. Genetically modified crops are some of the tools that could improve efficiency, quality and productivity. African experts have prioritised biotechnology-derived crops as follows: insect resistant (Bt) African maize varieties, resistance to African plant viruses, resistance to parasitic weeds, decreased mycotoxin levels in maize and drought tolerant crops. Colleagues and I have developed Maize streak virus resistant plants using a severely mutated form of the replication associated protein. These are being bred into commercial varieties of maize. A consortium of African and American scientists are developing cassava resistant to the African cassava mosaic virus. A major parasitic weed is Striga, or witchweed. Field trials have been carried out on herbicide resistant maize with very promising results. South Africa recently began planting Bt white maize for human consumption and we are finding a decrease in the levels of post-harvest fungal infection with a concomitant decrease in mycotoxin content. Bt cotton, although not a food crop, is providing a much-needed increase in revenue to small scale farmers. The source of our genes for the development of drought tolerant maize is a South African indigenous "resurrection plant" which can loose 95% water content and, upon watering, "resurrect" in three days. Our first transgenic plants are showing resistance to water loss, heat and salt.

GL5.2 The fossil record of angiosperm evolution

D. L. Dilcher;
Florida Museum of Natural History, University of Florida, Gainesville, FL, United States.

Angiosperm flower origins are best determined from early angiosperm fossil flowers and fruits. Molecular systematics provides a framework for extant angiosperm relationships; the fossil record is used to document the age of major basal clades. Molecular clocks combined with fossil data provide minimum ages for major lineages. The basal angiosperms based on molecular data needs to be reconciled with the morphologically based fossil record. The overwhelming tendency is to find roots of modern major clades and families based upon limited and poorly defined characters of fossils. This results in overlooking much angiosperm evolution. Angiosperm paleobotany should be focused on "character based" data rather than finding the "first" or "oldest" record of extant taxa or modern families. Early angiosperm major extinct taxa are often not recognized or incorporated into angiosperm phylogeny. Ancient extinct angiosperm diversity, past abundance and distribution dominate angiosperm history during their first 70 to 90 million years. A better understanding of these extinct taxa and lineages must become incorporated into the record of angiosperm evolution.

GL5.3 Invasive plant species: a global problem or a question of perspective?

R. J. Hobbs;
Murdoch University, Murdoch, Australia.

It is generally argued that invasive plant species often have important environmental and economic impacts through their impacts in natural and managed ecosystems, and hence it is assumed that invasive species should be eliminated or controlled wherever possible. However, it has also recently been argued that human movement of species is simply part of the natural process of species migration, that invasive species actually increase diversity, and that the evidence for adverse effects of invasive species has been oversold. Certainly, there are so many non-native species in many parts of the world that control or elimination of them all is unlikely. So should we worry about invasive species, or simply take them as a fait accompli and part of the natural order? In this talk I discuss the evidence for important ecosystem and biodiversity impacts of invasive plant species, critically examine the proposition that these impacts have been oversold. In the light of this discussion, I then review common policy and management approaches to the problem.

GL5.4 Approaching a global view on plant signal transduction

H. Hirt;
University of Vienna, Vienna, Austria.

As sessile organisms, plants must continuously monitor for changes in their environment. Information transfer and processing, commonly called signal transduction, leads to modification of gene expression and physiological adaptation. Passing information from one factor to the next most commonly occurs by phosphorylation through protein kinases. Almost 5 % of all genes code for different types of protein kinases, accounting for a total of more than 1000 protein kinases in the genetic model plant *Arabidopsis thaliana*. We are interested to study signal transduction in response to environmental stress and have recently identified signalling pathways for various biotic and abiotic stresses. Since most signalling pathways are interlinked with each other, signalling along one pathway often affects other pathways as well. To obtain a more global view on cellular signalling processes, we have established novel methods to detect the state of tens of signal pathways under any one condition and time. The uses and applications of these new tools will be discussed in the context of global environmental change in this century.

GL5.5 Are modern evolutionary theories and methods coherent?

M. Pigliucci;
Dept. of Ecology & Evolution, SUNY, Stony Brook, NY, United States.

Natural selection is often conceived of as a "force" that acts on populations through the differences in fitness between individuals; recent work by various authors points towards difficulties with the force metaphor and the attendant concept of fitness. Far from being a trivial semantic quibble, the way in which one conceives of natural selection and fitness strongly influences what one will take to be evidence for natural selection having occurred, and how one thinks of the difference between drift and selection. These issues also have implications for our ability to measure selection in natural populations, for the level of selection debate, for our ability to distinguish selection from drift, for our conception of constraints on evolutionary change, and for the way that the metaphor of adaptive landscapes is used.

GL6.2 Communicating plant cell biology by CD-ROM: information for students and a resource for teachers

B. E. S. Gunning;
Plant Cell Biology Group, Australian National University, Canberra, Australia.

A versatile user interface has been developed for presenting comprehensive pictorial information on plant cell biology in CD format, for use by students and teachers at all levels. Details are available at www.plantcellbiologyonCD.com. Light and electron micrographs of many types are included, plus anaglyph stereos, confocal animations, static and animated diagrams. Live cell phenomena which few biology students can experience directly are highlighted by inclusion of many time-lapse movies. Topics can be studied systematically (progress monitoring is provided) or by browsing *via* comprehensive navigation facilities. The CD set currently contains nearly 1000 "pages" (screens), many with multiple images. Concise, referenced text essays introduce many topics. All images have labels and captions. To facilitate use by teachers in tutorials and other presentations a built-in recorder allows sequences of screens to be pre-selected for subsequent display with single mouse-clicks, as in a slide-show. Sequences are preserved as text files, ready to be opened for re-use. The program can be used on individual PCs or on servers for classroom local area networks.

GL6.3 African ethnobotany: prospects and constraints

R. Bukenya-Ziraba;
Department of Botany, Makerere University, Kampala, Uganda.

Ethnobotany as a practice, in Europe, goes back to the 1st Century, A.D. It started as a descriptive discipline, but today it employs highly quantitative methods, although qualitative methods are still used. In the tropics the use of plants by man also dates to time immemorial, but as an organised discipline, serious ethnobotanical studies are recent. Although the indigenous people in the tropics are endowered with rich ethnobotanical knowledge and resources, they have mainly acted as informants for scientists from the developed countries, who have for a long time dominated ethonobotanical studies. People and Plants Initiative, which started in 1992 as a joint collaborative effort of WWF, UNESCO and Kew, was influential in the growth of ethnobotany particularly in Eastern and Southern Africa. Today Ethnobotany addresses among other things: edible wild plants; medicinal plants; fuel wood and charcoal; crafts and plants in domestic use; hidden economy and management of plant resources. Recent studies in ethnobotany especially in Uganda will be outlined and constraints related to the study will be briefly discussed.

GL6.4 Plant phylogeography in the Alps

P. Taberlet;
Laboratoire d'Ecologie Alpine, CNRS UMR 5553, Grenoble Cedex 09, France.

The first part of the talk will be dedicated to a general presentation of the concept of phylogeography, and to the molecular tools used in plant phylogeography. The second part will concern a review of the current results about plant phylogeography in the Alps, with a special emphasise about the relationship between putative glacial refugia and current genetic polymorphism. The main species concerned are *Ranunculus glacialis*, *Androsace sp*., *Erithrichium nanum*, and *Phyteuma globulariifolium*. Finally, the first results of the ongoing European project IntraBioDiv will be presented. The goal of this project is (i) to assess the intraspecific genetic polymorphism of 25-30 plant species over the Alps, (ii) to precisely map the geographic distribution of about 1500 plant taxa, and (iii) to compare the two datasets in order to find possible relationships among inter- and intraspecific plant diversity.

GL6.5 Genomics and phylogeny

W. Martin;
University of Düsseldorf, Düsseldorf, Germany.

The evolution of the plant kingdom starts with the endosymbiotic origin of plastids from a cyanobacterial ancestor, an event that occurred more than 1.2 billion years ago. In the wake of that fateful symbiotic association, several thousand genes were transferred to plant nuclear chromosomes, but between ~60 and ~200 protein coding genes have remained in the plastid of various algal and land plant lineages. Because of their high gene density and conserved gene repertoires, plastid genomes are a convenient and useful tool for investigating plant phylogeny. In particular, they hold the promise of getting the backbone of plant phylogeny fully resolved for the most important evolutionary splits. Much larger numbers of site patterns are observable in plastid genome sequences as opposed to sequences from one or a few genes. But we still need to be concerned whether the models of sequence evolution currently in widespread use approximate the historical process of sequence difference accumulation in protein-coding regions sufficiently well as to give us reliable anwers about plant history.

Closing Lecture

Think big in conservation - the Eurasian perspective

M. Succow;
Botanisches Institut und Botanischer Garten der Ernst-Moritz-Arndt Universität Greifswald, Greifswald, Germany.

I would like to dedicate this lecture to the protection of our Earth's vegetation, the forests and mires, the rivers and lakes, the steppes and deserts, the mountains and oceans. The conservation of the ecological benefits these ecosystems provide is essential to the future of humanity. The current degree of destruction of the natural vegetation cover forces us to protect those natural ecosystems that are hardly affected by human activities. On the other hand, also the preservation of the ecological benefits of anthropogenic ecosystems should receive highest priority. In order to achieve these goals, the monetarisation of ecological benefits will be unavoidable; in particular following benefits of the Earth's vegetation should be considered: CO_2 storage; groundwater recharge; evapotranspiration (cooling); binding and disposal of pollutants; surface stability; preservation of genetic resources. This conservation and management is supported by consolidated international (IUCN) protection categories: world natural heritage sites, national parks, biosphere reserves. Specific examples for the implementation of these programmes in Eurasia will be given, illustrating the conservation and wise use of tundra and taiga, deciduous forests, steppes and deserts, tugai gallery forests, and alpine vegetation.

Symposium Presentations

1.1.1. Changes in sphingolipid metabolism caused by disruption of *Arabidopsis thaliana LAG*1 homologues are associated with programmed cell death

J. Hille, T. Gechev, J. E. Markham, L. Bernier, M. Ferwerda;
Research School GBB, Haren, The Netherlands.

Sphingolipids are important regulators of cell fate and function in animals, fungi and plants. The longevity assurance gene 1 (*LAG*1) family has been identified as essential for ceramide synthase activity and sphingolipid metabolism. T-DNA insertional mutants were isolated for all three members of the *Arabidopsis thaliana LAG*1 gene family. Disruption of *LAG*1 homologue 2 conferred sensitivity to the ceramide synthase inhibitor AAL-toxin. Challenge with AAL-toxin resulted in accumulation of free long chain bases, inhibition of inositolphosphoceramide biosynthesis and ultimately Programmed Cell Death (PCD). To obtain more insights into the nature of AAL-toxin-induced cell death and to identify genes of potential importance for PCD, we carried out transcription profiling of AAL-toxin-induced cell death in this knock out. In addition, we isolated mutants from this knock out that are more tolerant to AAL-toxin. Interestingly, some of these mutants were also more tolerant to H_2O_2-induced PCD.

1.1.2. The genetic basis of singlet oxygen-induced cell death in *Arabidopsis thaliana*

K. Apel;
Institute of Plant Sciences, Zürich, Switzerland.

Plants under oxidative stress suffer from damages that have been interpreted as unavoidable consequences of injuries inflicted upon plants by toxic levels of reactive oxygen species (ROS). However, this paradigm needs to be modified. Upon generation of singlet oxygen in plastids of the *flu* mutant of *Arabidopsis,* plants stop growing and die. Several suppressor mutations were identified that abrogate these stress reactions. One of the mutated genes, dubbed *Executer*1, has been characterized in greater details. The *executer1*/*flu* double mutant behaves like wild type despite its continuous production of singlet oxygen. Reintroduction of a wild-type copy of the *Executer*1 gene into the *executer*1/*flu* mutant line restores the cell death phenotype of the *flu* parental line. Thus, these stress reactions formerly attributed to physico-chemical damage during oxidative stress are the result of an actively pursued genetic program that requires the Executer1 protein.

1.1.3. Plant cell death regulators and stress tolerance

H. Uchimiya, Y. Ihara-Ohori, M. Kawai-Yamada;
Inst. Mol. Cellu. Biosci., The University of Tokyo, Bunkyo-ku, Tokyo, Japan.

Cellular calcium level plays an important role in death pathways triggered by apoptotic stimuli. Apoptotic death is inhibited by the decreased calcium concentration at ER lumen by over-expression of plasma membrane-localized Ca^{2+}-ATPase while increase of calcium uptake into ER by over-expression of SERCA pump caused cells higher sensitive toward apoptotic stimuli. Anti-apoptotic Bax inhibitor-1 (BI-1), ER membrane protein exists in a wide range of higher organisms. Here, we found that Arabidopsis BI-1 interacted with calmodulin (CaM) protein via unknown protein. Yeast mutant lacking Ca^{2+}-ATPase failed to survive by Bax even when AtBI-1 was expressed. Thus, intactness of this Ca^{2+}-ATPase may be essential for the cell-death suppression by AtBI-1 in yeast. Addition of CPA; SERCA pump inhibitor, altered calcium response to H_2O_2 treated tobacco cells over-expressing AtBI-1, suggesting the functional relationship between AtBI-1 and SERCA pump in plant cells. On the basis of this finding the role of cell death regulators in relation to biotic and abiotic stress resistance will be discussed.

1.1.4. The ricinosome: an organelle for programmed cell death (PCD) in plants

C. Gietl;
Technische Universität München, Freising, Germany.

Ricinosomes are found in senescing nucellus and inner integument during castor bean seed development and in dissolving endosperm after mobilization of oil and protein stores during germination. Cells with these organelles undergo nuclear DNA fragmentation a landmark of PCD. A 45kDa pro-cysteineendopeptidase with a C-terminal KDEL ER retention signal (CysEP) in the ricinosomes is processed and released. Protein cleavage sites for the CysEP have been determined with fluorogenic peptide substrates and digests of bovine ?-casein. Based on the highest second-order kinetic constants kcat /Km for amino acids at the P1 and P2 position the covalent binding inhibitor H-D-Val-Leu-Lys-chloromethylketon was chosen as substrate analogue for replacement in the catalytic site. The CysEP with the inhibitor in the active site was crystallized and its structure solved by molecular replacement at 2Å resolution. The more open catalytic pocket of the Ricinus CysEP correlates with the extended varieties of substrate amino acid residues accommodated by this enzyme at the P1 and P1' position, as would be expected for an enzyme attacking a greater variety of proteins during PCD.

1.1.5. Interaction of light with living matter: a paradigm for cellular study

J. S. D'Souza, S. Moharikar, M. Gudipati, J. A. Dharmadhikari, A. Dharmadhikari, A. Kulkarni, D. Mathur, B. J. Rao;
Tata Institute of Fundamental Research, Mumbai, India.

When *Chlamydomonas* cells were exposed to 1-100 J/m^2 of UV-C, a cell death-like process occurred. Dying cells showed hallmarks of apoptosis; like cell shrinkage, phosphatidylserine flipping, and DNA fragmentation. The chromatin degrades in the nucleus, 'spills out' in the cytoplasm and is 'thrown out' to the periphery of the cell. We propose that *Chlamydomonas* harbors biochemical machinery for an apoptotic-like pathway to operate in response to UV-C. *Chlamydomonas* cells were trapped in an optical trap and such cells may be used as controllable micron-sized motors, to generate torques of up to 12,000 pN nm. Nickel-poisoned, *paralyzed flagella* and *deflagellated* mutant cells do not exhibit rotation, while *phototactic*, *eyespot* and *cytokinetic* mutants showed rotational speeds same as that of wild type. The origin of this rotation is entirely flagellar motor system driven. The force associated with a rotating cell (~10 pN) indicates that either the activity of 5% dynein molecules per beat cycle is sufficient to generate flagellar motion, or that a 'gear system' exists in the flagella.

1.1.6. Flooding-induced programmed cell death in pea (*Pisum sativum*) primary root apical meristems occurs mainly in the elongation zone

D. K. Gladish[1], T. Niki[2];
[1]Miami University, Hamilton, OH, United States, [2]Takushoku University, Hachioji, Japan.

In previous studies, sudden flooding of pea roots 5 d old at 25 C frequently resulted in cessation of primary growth of pea taproots and often the curling of the root tips. TEM revealed morphological abnormalities in cell nuclei, and DNA extracted from flooded root tips laddered on sizing gels. TUNEL in situ analysis showed the presence of hydrolysed DNA in the nuclei of affected cells. For the present study, under sterile conditions pea seeds were placed between paper and glass in 1 l tall beakers lined with filter paper that were then filled with vermiculite moistened with 375 ml of water. After 5 d the root systems were flooded. Root tips were collected after 3, 6, and 12 h. Some were prepared for light microscopy, including TUNEL, and some for confocal microscopy. Cells in the pericycle and endodermis opposite protoxylem poles in the elongation zone were the first to be affected by flooding. These cells showed the same symptoms of programmed cell death as previously reported.

1.2.1. Global patterns of gene expression in *Synechocystis sp*. PCC 6803 in response to inorganic carbon limitation and the definition of a key regulon

R. L. Burnap;
Oklahoma State University, Stillwater, OK, United States.

Synechocystis possesses multiple inorganic carbon (Ci) uptake systems regulated according to Ci availability. Regulation of these systems and their integration with other cell functions remain to be clarified. Changes in global gene expression in response to Ci downshift and inactivation of transcriptional regulator, *ccmR* (sll1594), were observed. Ci-limitation elicited upregulation of both inducible CO_2 and HCO_3^- uptake systems. An alternate Type-1 NDH complex with products homologus to antiporter proteins was also upregulated. This leads us to propose that these genes encode in sodium efflux system, driven by redox energy and used to drive the Na^+ dependent bicarbonate transporter, *SbtA*. Inactivation of *ccmR* resulted in constitutive upregulation of *sbtA*/*sbtB*, *ndhF3/ndhD3/cupA*/sll1735 and slr2006-13 including *ndhD5* and *ndhD6,* indicating a\ role of the regulatory gene in both CO_2 and HCO_3^- and suggesting a regulon for an integrated system of proteins operating to concentrate Ci using redox energy transduced by Type I dehydrogenases directly as with the CUP subsystem or indirectly via a sodium gradient generated by the *NdhD5/NdhD6* subsystem.

1.2.2. A CO_2-signal transduction pathway, which regulates the carbon-concentrating mechanism by sensing CO_2 availability and cross talk with light signaling in *Chlamydomonas reinhardtii*

H. Fukuzawa;
Kyoto University, Kyoto, Japan.

Chlamydomonas modulates photosynthetic characteristics to acclimate to CO_2-limiting stress by sensing CO_2 availability and light by inducing a set of genes for carbon-concentrating mechanism. We have analyzed regulation of a gene Cah1 for a carbonic anhydrase to elucidate the CO_2-signal transduction pathways. By using Ars-reporter fused with Cah1 promoter, cis-acting elements and DNA-binding proteins involved in CO_2-regulation were elucidated (Kucho 2003). Regulatory mutants showing abnormal responses to the changes in CO_2 levels, were isolated (Yoshioka 2004). Genome wide analysis of gene expression of regulatory mutants revealed that CO_2-responsive genes were grouped into several categories (Miura 2004). Relationship between CO_2-dependent regulation and light-dependent systems will be also discussed based on the analyses of mutants. (Kucho Plant Physiol. 133:783-(2003), Fukuzawa, PNAS 98:5347-(2001), Yoshioka Plant Cell 16:1466-(2004), Miura Plant Physiol.135:1595(2004)

1.2.3. A carboxysome-based inorganic carbon concentration mechanism (CCM) in the glaucocystophyte alga, *Cyanophora paradoxa*?

W. Löffelhardt[1], S. C. Burey[1], S. Fathi-Nejad[1], J. M. Steiner[1], V. Poroyko[2], H. J. Bohnert[2];
[1]Max F. Perutz Laboratories, Vienna, Austria, [2]Departments of Plant Biology and Crop Sciences, University of Illinois, Urbana, IL, United States.

The glaucocystophyte alga, *Cyanophora paradoxa* contains plastids (cyanelles) which are surrounded by a peptidoglycan wall, a cyanobacterial heritage. It is uncertain, if *C. paradoxa* possesses an inorganic carbon concentration mechanism (CCM). The CCM is triggered by growth at ambient (0.04%) CO_2 with concomitant gene induction/repression and accumulation of Rubisco in microcompartments: carboxysomes in prokaryotes and pyrenoids in algae. We postulate that the cyanelles of *C. paradoxa* did also retain another cyanobacterial feature: the unique case of a eukaryotic carboxysome. An isolation procedure for carboxysomes was developed allowing the mass spectrometric identification of proteins other than Rubisco. Rubisco activase was imported into isolated cyanelles and was shown to integrate into carboxysomes. Two cDNA libraries of cells grown under ambient and high CO_2 were established for sequencing and annotation of more than 5000 ESTs. 2300 unique ESTs were chosen for microarray printing. Hybridizations with RNA from cells grown at high and low CO_2 were performed. Around 140 genes were found to be differentially expressed under high and ambient CO_2.

1.2.4. Transcriptome analysis of sugar signal transduction in *Arabidopsis thaliana*

J. Jang, J. Price, S. Kang;
The Ohio State University, Columbus, OH, United States.

Transcriptome analyses have revealed global expression changes occurring over space and time when plants are treated with metabolites such as glucose or inorganic nitrogen. In our study of young Arabidopsis seedlings, which consist primarily of shoot tissues, glucose was generally found to be a more potent signal in affecting gene expression than inorganic nitrogen. Surprisingly, other than genes associated with nitrate assimilation, glucose also had a greater effect in affecting the expression of nitrogen metabolic genes than nitrogen itself. This indicates that sugar may have a significant role in maintaining nitrogen homeostasis via transcriptional control. Furthermore, sugar is capable of modulating the nitrogen response and vice versa- cluster analyses of the transcriptome data showed significant interaction between glucose and nitrogen in regulating gene expression. The important role that glucose might have on nitrogen metabolism was further supported by the results of co-expression analyses, i.e., an over-represented proportion of nitrogen metabolic genes were co-expressed with the glucose-responsive regulatory genes.

1.2.5. Sugar and hormone signaling in *Arabidopsis*

S. Yanagisawa;
Graduate School of Agricultural and Life Sciences, Tokyo, Japan.

Sugars display hormone-like activity and regulate a wide variety of developmental processes in plants. The pleiotropic effects of sugars appear to be generated through regulation of gene expression, at least in part. Recent molecular genetic studies with *Arabidopsis* plants disclosed a crosstalk between sugar and hormone signal transduction pathways. For example, ethylene is antagonistic to glucose. The *ctr1* (constitutive triple response 1) and *ein3* (ethylene insensitive 3) mutants showed hyposensitivity and hypersensitivity to glucose, respectively. Our analyses of the crosstalk revealed that glucose promoted degradation of EIN3, a key transcription factor for ethylene signaling, while ethylene repressed the degradation of EIN3. Two F-box proteins involved in degradation of EIN3 were nuclear proteins, and hexokinase mediating the glucose signal was also detected in nuclear faction. These suggested that the antagonistic effects of sugar and ethylene were generated through the opposite regulation of the degradation of EIN3 in nuclei. I will discuss the possibility that sugar signals might influence degradation of various transcription factors in nuclei, generating the pleiotropic effects.

1.2.6. Regulation of carbon-concentrating mechanism in response to changes in the ambient $[CO_2]$ in marine diatom

H. Harada, K. Sakaue, **Y. Matsuda**;
Department of Bioscience, Kwansei-Gakuin University, Hyogo, Japan.

Marine diatom is the successful group of algae in the ocean and share about 25% of the global CO_2 fixation. It was shown previously that high affinity photosynthesis in the marine diatom *Phaeodactylum tricornutum* was induced in response to decrease in $[CO_2]$ in the medium. This suggested that *P. tricornutum* cells might sense $[CO_2]$ at the ocean surface directly or indirectly. A chlroplastic form of β-carbonic anhydrase in *P. tricornutum* (PtCA1) is repressed in high CO_2 but induced in air. The 1.3 kbp 5'-upstream sequence of the gene encodes PtCA1 (*ptca1*) was isolated by inverse PCR. A series of 5'-truncated fragments of the 1.3 kbp upstream sequence was ligated with GUS reporter gene, *uidA*, and introduced into *P. tricornutum* with microprojectile bombardment. GUS reporter assays of these transformants showed that the critical CO_2-responsive region of *ptca1* promoter reside between -70 and -30 bp relative to the transcription-start site of *ptca1*. This region contained a cAMP responsive element (CRE) and a relating coactivator-binding region. The acclimation mechanisms and a possible concern of cAMP signaling in CO_2-sensing system in marine diatoms will be discussed.

1.2.7. Can QTL and microarrays help us to elucidate the genetic basis of plant adaptation to elevated CO_2

G. Taylor[1], P. J. Tricker[1], L. Graham[1], **N. R. Street**[1], A. M. Rae[1], M. J. Tallis[1], S. Jansson[2];
[1]University of Southampton, Southampton, United Kingdom, [2]UPSC, Umea, Sweden.

Rising atmospheric CO_2 will have an impact on tree growth, development, productivity and survival, but despite this, very few studies have been undertaken to elucidate the genetic basis of response to elevated CO_2. Here we present data to show that poplar is a useful model for studying short- and long-term effects of global climate change on gene expression and the development of adaptive traits and that the latest technologies in genomics and molecular quantitative genetics may be applied to address this problem. In rising CO_2 we have identified important changes in adaptive traits and elucidated several QTL that are now being followed up in more detail. We have determined patterns of gene expression in elevated CO_2 using microarrays, in a long-term experiment lasting six years, providing a highly novel data-set. Important changes in gene expression include those determining transcription, development, cellular biogenesis and photosynthesis have been identified, that are consistent between years 3 and 6 of the experiment. Contrasting patterns of gene expression for leaves that are either sinks or sources of CO_2 have also been identified.

1.3.1. Regulation of the actin cytoskeleton

P. Hussey;
University of Durham, Durham, United Kingdom.

One of the most unique features of plant cells is that they don't move so the development of tissues and organs is dependent on the balance of cell division, cell expansion and the positioning of the new crosswalls in cytokinesis. The plant cytoskeleton governs plant cell morphogenesis and it is composed of microtubules and actin filaments. Both cytoskeletal networks are stimulus responsive being effected by internal stimuli, by biotic and abiotic stresses in signal transduction pathways still to be fully assembled. The completion of the Arabidopsis genome sequence has allowed for a comparative identification of many cytoskeletal proteins and components of signal transduction cascades. These pathways have components common to both plant and animal/fungal pathways but they are not identical presumably because signals in plants are quite unique. This presentation will give an overview of the key stimulus responsive molecules of the actin cytoskeleton.

1.3.2. Actin capping protein is regulated by the stress-inducible phospholipid, phosphatidic acid

C. J. Staiger[1], S. Huang[1], L. Gao[1], L. Blanchoin[2];
[1]Purdue University, West Lafayette, IN, United States,
[2]CEA/CNRS/UJF, Grenoble, France.

Changes in cellular architecture often require actin-binding proteins as stimulus-response modulators of the cytoskeleton. In plants, phosphatidic acid (PA) is gaining widespread acceptance as a major signaling lipid that mediates responses to stress. To investigate the regulation of actin cytoskeleton, we analyzed the properties of a heterodimeric capping protein from Arabidopsis. AtCP binds with high affinity to PA, with a Kd value of 17 µM and stoichiometry of ~1:2. It also binds well to PtdIns(4,5)P2, but not to several other phosphoinositide lipids. The interaction with PA micelles inhibited the activity of AtCP. In the presence of PA, AtCP is unable to cap the barbed or rapidly growing and shrinking end of actin filaments and fails to nucleate filament formation. Pre-capped filament barbed ends can also be uncapped by PA, allowing rapid filament assembly from an actin monomer pool that is buffered with profilin. The findings support a model in which the inhibition of capping protein activity in plant cells by elevated PA results in the stimulation of actin polymerization from a large pool of profilin-actin.

1.3.3. Control of actin dynamics by plant formins

L. Blanchoin;
Laboratoire de Physiologie Cellulaire Végétale, Grenoble, France.

Formins are actin-organising proteins involved in cytokinesis and polarity determination. In plant Arabidopsis, there are more than 20 formin homologues with unknown roles. We characterize biochemical properties of the Arabidopsis formins AtFH1 and AtFH5. Despite low similarity to yeast and mammalian formins, AtFH1 and AtFH5 proteins interact with barbed end of actin filament and nucleates actin filament polymerization in vitro. However the effect of AtFH1 and AtFH5 on actin dynamics in vitro is quantitatively different. In vivo, AtFH5-GFP fusion protein localizes to the cell plate, a plant-specific membranous component assembled at the plane of cell division. Consistent with these data, an atfh5 loss-of-function mutation causes a cytokinesis defect in the seed endosperm. Although cytokinesis in animals, yeast and plants occurs through morphologically distinct mechanisms, our study finds that formin recruitment to sites of actin assembly is a common feature of cell division across eukaryotes.

1.3.4. Actin-annexin relationships in stress signaling

D. Konopka-Postupolska[1], K. M. Gorecka[2], S. Pikula[2], B. Voigt[3], F. Baluska[3], J. Hennig[1];
[1]Institute of Biochemistry and Biophysics, Warsaw, Poland, [2]The Nencki Institute of Experimental Biology, Warsaw, Poland, [3]Institute of Cellular and Molecular Botany, University of Bonn, Bonn, Germany.

Plant response to stresses involves rapid cytoskeleton rearrangement that form structural basis for defense response. Thus proteins that can influence F-actin remodeling in response to stress are intensively studied. In animal cells annexins, a family of highly conserved calcium binding proteins was recently suggested to play a role in actin filaments anchoring near the cellular membranes. We decided the check interactions between actin remodeling and annexins in signal transmission during plant response to stress. In preliminary experiments we found that

AnnAt1 mRNA level was induced in *Arabidopsis* plants after different biotic and abiotic stimuli. It suggests that annexins can function upstream of branching point in diverse signaling pathways. We also found that AnnAt1 is able to bind actin *in vitro*, and this binding could be probably influenced by GTP. Actin cytoskeleton rearrangement in plants deficient in AnnAt1 production will be studied *in vivo* with confocal microscopy. Additionally, we will perform crossing between plants with GFP-tagged actin cytoskeleton (GFP-FABD) with plant (φAnnAt1) do not producing annexin 1.

1.3.5. Myosins of the class XI in *Arabidopsis*

H. Paves, E. Ojangu, K. Järve, B. Ilau, E. Truve;
Tallinn University of Technology, Tallinn, Estonia.

Myosins are eukaryotic molecular motors moving along actin filaments. Arabidopsis thaliana genome contains 17 sequences that could code myosin proteins. Only a small set of myosin classes - VIII with 4 and XI with 13 putative genes - is present in the genome. The specific functions of Arabidopsis class XI myosins are unclear although knockout of a single representative, mya2 has been described (Holweg and Nick, 2004). Loss-of-function mutation in mya2 had pleiotropic effects in plant development. Arabidopsis T-DNA insertional mutants (from ABRC) of myosin genes were used to study the functions of class XI myosin genes. Mutants with homozygote T-DNA insertion in 11 different class XI myosin genes have been identified. Three different T-DNA insertion mutants in a single myosin gene show similar but quantitatively different phenotypes of homozygote plants: impaired root hair cells growth. Morphometric analysis of four-day-old mutant seedlings showed that average length of root hairs was 77, 50, and 41% of wild type root hairs, suggesting involvement of this class XI myosin in cell elongation and tip growth.

1.3.6. Interaction of chloroplasts with actin filaments and plasma membrane in spinach mesophyll cells in vivo and in vitro

T. Kumatani[1], N. Sakurai[1], H. Takamatsu[1], N. Miyawaki[1], E. Yokota[2], T. Shimmen[2], I. Terashima[1], **S. Takagi**[1];
[1]Dept. Biol., Grad. Sch. Sci., Osaka Univ., Toyonaka, Japan, [2]Dept. Life Sci., Grad. Sch. Life Sci., Univ. Hyogo, Harima Science Park City, Japan.

In mesophyll cells of spinach (*Spinacia oleracea* L.), chloroplasts change their intracellular positions in response to illumination. Cytochalasin and BDM inhibited the movement of chloroplasts in a reversible manner. Under low-intensity white light, numerous short, thick bundles of actin filaments were observed in the vicinity of immobile chloroplasts by staining with fluorescent phalloidin. In contrast, one or two long, straight bundles of actin filaments appeared in a cell exposed to high-intensity blue light. Interaction of chloroplasts with endogenous actin filaments and the plasma membrane was examined by preparing membrane ghosts from the mesophyll protoplasts, which had been kept under various conditions. Furthermore, we isolated intact chloroplasts, which retained their outer envelopes, and revealed their ability to bind to exogenously added skeletal muscle F-actin by co-sedimentation assays and immunoblotting. After disruption of the outer envelope of isolated chloroplasts by protease treatment, actin was no longer co-precipitated with the chloroplasts.

1.3.7. A high throughput screen for new plant cytoskeletal proteins in mammalian cells

E. Sadot[1], M. Abu-Abied[1], Z. Kam[2], S. Huang[3], C. J. Staiger[3];
[1]Volcani Center, Bet-Dagan, Israel, [2]Weizmann Institute of Science, Rehovot, Israel, [3]Purdue University, West Lafayette, IN, United States.

Based on the high conservation of the basic cytoskeletal building blocks, actin and tubulin, between the animal and plant kingdoms we have developed a novel method of screening an Arabidopsis cDNA library fused to YFP in rat fibroblasts. Using a newly developed microscope system with computer controlled stage for multi-well plate scanning and fast laser auto-focusing for high magnification imaging we are able to screen millions of fibroblast cells expressing thousands of YFP fussed Arabidopsis cDNAs. This special method overcomes a significant obstacle in the plant cell biology field, which is the high throughput automatic screening of thick plant cells, by using flat adherent fibroblasts cells as a host system. Using the above system, we isolated a couple of plant genes which show strong actin binding activity in fibroblasts. The full length cDNAs of selected genes were isolated and their ability to bind actin in fibroblasts was demonstrated. Selected genes are being tested in plant systems and will be discussed.

1.4.1. The 'giant genus' problem: issues, solutions, opportunities?

K. J. Sytsma, J. Walker;
University of Wisconsin, Madison, WI, United States.

Giant genera comprise up to 20% of all vascular species and are often poorly known systematically. Why do we have giant genera?": (1) historical artifact of the genus concept in ranked systems of classification; (2) recognition of paraphyletic genera using symplesiomorphic features (e.g., Psychotria); (3) failure to identify polyphyletic genera exhibiting convergent or parallel apomorphies (e.g., Salvia); and (4) extensive radiation in one monophyletic lineage through a "key innovation" of an apomorphic feature (e.g., Ficus, Carex). Future systematic studies in giant genera should include collaborative efforts directed in a multi-disciplinary fashion (e.g., Croton, Solanum, Salvia). A "top down" survey approach will be crucial prior to more detailed "bottom up" studies. Web-based dissemination of systematic knowledge will be necessary rather than reliance only on the career-long and often unpublished "big picture." Necessary nomenclatural changes must be explored in a manner that best serves the systematic community and the larger "user" community of systematic knowledge.

1.4.2. Big plant genera: emergence, growth, neglect and renewal

D. G. Frodin;
Chelsea Physic Garden, LONDON, United Kingdom.

That higher plant genera were not uniform in size was early apparent, and indeed the sheer diversity of some soon attracted connoisseurs. However, only around 1900 - with more extensive records - was their size distribution seen as exponential. The 28 with 300 or more species were first listed by N.E. Brown in 1883. Further lists by J.C. Willis and R. Good of genera with 500 or more followed by 1960. Yet these ‘giants’ were but one end of a Zipf curve; at the other were monotypes - and in statistical terms there was no distinction. Some botanists, however, believed big genera to embody more than mere numbers: there might also be keys to a better understanding of plant palaeohistory, evolution, and comparative diversification. Only recently has this challenge been taken up, notably through collaborative effort with approaches from alpha taxonomy to genomic studies and cladistic analyses of relationships and probable phylogeny. I shall here explore the sequence and circumstances of, and approaches to, their documentation (and initial subdivision) prior to the mid-twentieth century, factors leading to their neglect, the faith of their proponents, and recent developments.

1.4.3. Many *Acacia* species, little genetic variation: DNA sequencing and the use of the microarray platform for inferring relationships among closely related species

J. Miller[1], D. Murphy[2];
[1]University of Iowa, Iowa City, IA, United States, [2]Royal Botanic Gardens, Melbourne, Australia.

Acacia contains over 1,500 species mostly found in arid-zones worldwide. Chloroplast DNA sequence analysis has determined the existence of at least 5 lineages which are distributed within the tribes Ingeae and Mimoseae. These lineages conform to established subgenera (*Acacia* and *Phyllodineae*) while a third subgenus is split into three lineages. Within most lineages sequence variation is sufficient to study relationships, biogeography and character evolution hypotheses. However, relationships among the 950 Australian species (subg. *Phyllodineae*) are not well resolved by DNA sequencing. A genotyping technique using the microarray platform, DArT (Diversity Arrays Technology, DArT Pty Ltd), is being used to survey genetic relationships within this group. The procedure digests bulked DNA from target species, clones the fragments and spots them on slides using standard microarray protocols. Digested DNA from an individual is hybridized to the slide yielding data of the presence or absence of thousands of restriction fragments spotted on the slide. These data are compared to DNA sequence data in their ability to uncover phylogenetic relationships.

1.4.4. Euphorbiaceae s.s., a constellation of giant genera

P. E. Berry;
University of Wisconsin-Madison, Madison, WI, United States.

Even when considered in the strict sense, Euphorbiaceae contains three giant genera - Euphorbia, Croton, and Acalypha that together total over 3,500 species (well over 1% of all flowering plants). Euphorbia has always been considered a large genus, but its circumscription has been open to various interpretations. An inclusive view of the genus would group all of the cyathial inflorescences, which may be a key to the great diversification of the clade. Molecular sequence data supports Croton as being largely monophyletic, with just one clade of 12 species (Astraea) split into a distinct clade, and many segregate genera included with Croton, such as Eremocarpus, Julocroton, Moacroton, and Cubacroton. With appropriate sampling and use of molecular data, most of the 40 sections recognized by Webster in 1993 can be evaluated for monophyly and intersectional relationships. Many of the circumscriptions of Old World sections do not hold up, whereas many of the New World sections are strongly monophyletic or can at least be redefined. Pollination mechanisms and ecological roles in the three large genera will be compared as a possible key to their diversifications.

1.4.5. Taxonomy as a team sport: PBI *Solanum* or how to monograph a monster

S. Knapp[1], L. Bohs[2], M. Nee[3], D. Spooner[4], J. Bennett[1], J. Clark[5,6], L. Walley[1];
[1]The Natural History Museum, London, United Kingdom, [2]University of Utah, Salt Lake City, UT, United States, [3]The New York Botanical Garden, Bronx, NY, United States, [4]University of Wisconsin/USDA, Madison, WI, United States, [5]The University of Utah, Salt Lake City, UT, United States, [6]National Museum of Natural History/ Smithsonian Institution, Washington, DC, United States.

Solanum (Solanaceae), with between 1500 and 2000 species, ranks among the ten most species-rich genera of flowering plants, and is a truly large, monophyletic genus. Unlike some other large plant genera, molecular phylogenetic work has supported its monophyly. Taxonomic recognition of such groups must be a mix between pragmatism - ease of recognition for non-botanists is an often over-looked criterion - and perfection. Global taxonomic revision of such large, monophyletic groups is impossible for a single botanist, given the sheer volume of literature, specimens and techniques available today. We will explore how we are approaching a global species-level revision of *Solanum*. Both scientific and sociological issues can impede progress. Harnessing the power of the Internet and presenting data electronically only goes some way to overcoming the barriers to tackling such a group. Cooperation of large groups of taxonomists working towards common, rather than competitive goals, is key for monographing species-rich genera whose monophyly and ease of recognition makes their treatment as a whole logically preferable.

1.4.6. Are there so many species of *Astragalus*? a repris

M. F. Wojciechowski[1], K. P. Steele[2], M. J. Sanderson[3];
[1]Arizona State University, Tempe, AZ, United States, [2]Arizona State University East, Mesa, AZ, United States, [3]University of California, Davis, Davis, CA, United States.

Astragalus (Leguminosae) is considered the most species-rich angiosperm genus. We explore the implications of this claim, beginning with a discussion of the interplay between taxonomy and diversification rate, then revisit previous efforts to reconstruct diversification in Astragalus in light of recent molecular phylogenies and divergence time estimates, and better analytical tools than available a few years ago. Two complementary approaches include estimating net diversification rate based on extant diversity and estimated crown group age of the clade, and using the more powerful Kendall-Moran estimator of rate that is based on all the available node times within a clade. We separately estimate rates for a nested set of clades including the larger Astragalean clade, *Astragalus*, and Neo-Astragalus, with an analysis of confidence limits on the diversification rates that includes consideration of the errors introduced into divergence time estimation. Finally, to place diversification in Astragalus in a broader phylogenetic context, we compare estimates of diversification rates in several other legume genera, such as *Indigofera*, *Acacia*, and *Lotus*.

1.4.7. Treelike and reticulate phylogenetic history of Sileneae and its implications on taxonomy

B. Oxelman[1], M. Popp[1,2], M. Lidén[1], G. Lazkov[3], F. Eggens[1], P. Erixon[1], B. Frajman[1,4], E. Långström[1], A. Rautenberg[1], N. Heidari[1];
[1]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden, [2]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway, [3]Komarov Botanical Institute, St Petersburg, Russian Federation, [4]Biology Department, University of Ljubljana, Ljubljana, Slovenia.

A problem for taxonomic research of species-rich groups is the availability of information itself. This is a bioinformatics problem that has not received the attention it deserves. A classic problem is delays in publication of revisions, due to the strive to be "complete". We suggest that this can be solved with a database-based approach. Another problem for hierarchical taxonomy is violations of the tree-like model. To account for this there is a need to studyi multiple, potentially unlinked gene phylogenies. For the 700+ species in Sileneae, we have chosen the rps16 intron and the psbE/petL spacer from the chloroplast genome, the nuclear ribosomal ITS regions and intron regions from the nuclear low-copy number genes RPA2 and RPB2 as "standard" sequence regions. This serves as hypothesis-generating, and - for specific problems - we add other regions depending on the problem. We exemplify this approach on problems pertaining to homoploid hybridization, allopolyploidy and very short internal branches with the hexaploid Silene hookeri, which has rather remotely related parent lineages.

1.5.1. The evolution of the Cape flora as a model system

H. P. Linder;
Institute for Systematic Botany, Zurich, Switzerland.

The Cape flora is centered in the southern tip of Africa, and is characterised by some 30 clades which have their phylogenetically basal elements and greatest species diversity in the Cape Floristic Region. This flora is remarkably species rich, with numerous closely related species concentrated in a geographically restricted area. Current indications are that many of these clades have been in southern Africa since the mid-Tertiary, but that there was no single trigger for the diversification of the modern species flocks. The oldest radiation documented to date is that of the Restionaceae, which was initiated in the Oligocene. The modern species diversity of the flora may date from the Plio-Pleistocene. This fits the current model of initial climatic deterioration in the Oligocene, followed by a mesic Early Miocene, and then accelerating deterioration after 14 Mya, probably associated with increased summer-drought in south-western Africa. The modern richness might be more the result of little extinction, rather than recent and rapid radiation.

1.5.2. Geographical affinities of the Cape flora

C. A. Galley, H. P. Linder;
Institute of Systematic Botany, University of Zurich, Zurich, Switzerland.

The flora characteristic of the Cape Floristic Region (CFR) is dominated by a relatively small number of clades that have been proposed as ‘Cape clades’. These clades have variously been suggested to have African or Austral affinities. Here we evaluate the support for these hypotheses using data from phylogenetic analyses. We further test the hypothesis that these clades share a common time of differentiation from their geographical neighbours. Many Cape clades show Austral rather than African relationships and relatively few Cape clades show a sister-relationship to South America and tropical Africa, despite their relative geographical proximity. These and other numerous patterns are suggestive of a cosmopolitan flora. There is no simple hypothesis that can account for the geographical sources of the currently distinctive Cape flora. This spatial variation is echoed in the temporal data; although there is wide variance around the dates of disjunctions, it seems that the Cape flora has been assembled over a long time period.

1.5.3. Growth-environment-driven divergence in the Cape flora

J. A. Hawkins[1], D. Edwards[1], E. Shaw[1], F. Forest[2], C. Whitehouse[3];
[1]University of Reading, Reading Berkshire, United Kingdom, [2]SANBI, National Botanic Garden, Kirstenbosch, Cape Town, South Africa, [3]Royal Horticultural Society, Wisley, Woking, Surrey, United Kingdom.

A significant proportion of Cape species diversity is attributed to the radiation in vegetative characters exhibited by several extremely species-rich Cape Clades (clades which have their phylogenetically basal elements and greatest species diversity in the Cape Floristic Region). Two case studies of vegetative divergence in Cape Clades are explored here. The first examines a remarkable case of vegetative convergence (between *Aspalathus*, Legumionosae and *Cliffortia*, Rosaceae) which may retain the footprint of environmental change. The hypothesis that the radiations are contemporaneous is explored here. The second considers the a novel dispersal mechanism (fleshy fruit) in genus *Muraltia* (Polygalaceae) which may act as a key innovation driving vegetative adaptation. Morphological diversity, environmental amplitude and geographic distance are compared for a fleshy-fruited clade and its dry-fruited sister clade. The fleshy-fruited clade shows greater diversity by all three measures.

1.5.4. Can we reject pollinator-driven speciation as a predominant model for the Cape Floristic region?

T. van der Niet[1], S. D. Johnson[2], P. Linder[1];
[1]Institute of Systematic Botany, Zurich, Switzerland, [2]School of Botany and Zoology, Pietermaritzburg, South Africa.

Many lines of evidence point towards a recent burst in speciation in a few large lineages in the Cape Floristic Region. This begs the question as to what was the main mechanism that generated this biodiversity. Historically, two competing hypotheses have been put forward to explain this pattern. Either adaptation of diverging conspecific populations to the ecologically heterogeneous environment was the main factor driving speciation, with adaptation to different pollinators only being necessary upon secondary contact to protect species integrity. Alternatively, adaption to different pollinators was a primary factor driving speciation. To test these, we review all the available evidence by combining phylogenies, ecological data, distribution data and pollinator data of lineages centered in the Cape Floristic Region. Support for either hypothesis is provided by comparing the degree of sympatry, ecological divergence and pollination mode between sister species pairs.

1.5.5. Floral and vegetative evolution in Cape pelargonium (Geraniaceae): fast but uncoupled

F. Bakker[1], A. Culham[2], E. Marais[3], **M. Gibby**[4];
[1]Nationaal Herbarium Nederland, Wageningen, The Netherlands, [2]Centre for Plant Diversity and Systematics, The University of Reading, Reading, United Kingdom, [3]Department of Botany, Stellenbosch University, Stellenbosch, South Africa, [4]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

Pelargonium (Geraniaceae) ranks in the top ten Cape Floral Region genera, with 148 species found within the CFR. Pelargonium consists of five majorclades, structured in two main groups that correlate with chromosome size. A wide range of variation in morphology and life form is found in one large clade, comprising almost 60% of the total number of species known. This Cape 'winter rainfall' clade harbours, apart from many evergreen shrubs, a large xerophytic clade comprising geophytes, stem and leaf succulents. Nested within this is an exclusively geophytic clade, comprising c. 80 species of sect. Hoarea, characterised by the possession of tunicate tubers, and possibly representing a non-adaptive radiation. Speciation in this clade appears to be predominantly allopatric and pollinator-driven. Nectar spurs have enabled Pelargonium to use a wide array of pollinators, notably long-tongue hovering flies and hawkmoths, a pattern that appears to be repeated within the geophytic Hoarea clade. Overall, we conclude that evolution of geophytism shows highest correlation with increase in clade-size in Pelargonium and that floral evolution occurs at a rapid rate.

1.5.6. Leaf shape evolution in *Pelargonium*

C. S. Jones[1], F. T. Bakker[2], C. D. Schlichting[1], A. B. Nicotra[3];
[1]University of Connecticut, Storrs, CT, United States, [2]Nationaal Herbarium Nederland, Wageningen, The Netherlands, [3]Australian National University, Canberra, Australia.

The plant genus *Pelargonium* L' Hér. (Geraniaceae) has undergone an extraordinary South African radiation in growth form and leaf shape. Growth form, which is roughly correlated with sectional classification, ranges from an annual habit, through geophytes, stem succulents and woody shrubs. There also exists remarkable the diversity in leaf shape (which is uncorrelated with growth form) that includes variation in the extent of dissection, leaf size and venation patterns. We scored over one hundred species for traditional shape characteristics (apex, base, outline, margin, degree of dissection and patterns of major veins). We then reconstructed ancestral character states using parsimony for branches leading to major clades. All major clade branches derive from an ancestral state of: rounded apices, cordate bases, and ovate outlines, with palmate major veins. A shift to pinnate/intermediate leaf venation occurs along the branch leading to the winter rainfall clade. The degree of dissection of the lamina showed no resolution at any of the major basal branches, suggesting that dissection reflects species-specific adaptations within clades.

1.5.7. Phylogeny, morphological evolution, and speciation of endemic Brassicaceae genera in the Cape flora of Southern Africa

A. Mühlhausen, K. Mummenhoff;
University of Osnabrueck, Systematic Botany, Osnabrueck, Germany.

Heliophila, *Cycloptychis, Thlaspeocarpa, Schlechteria*, *Silicularia*, *Brachycarpaea*, and *Chamira* are endemic genera in the Cape region of South Africa and they are regarded as the most diversified Brassicaceae in every aspect of habit, leaf, flower, and fruit morphology. Relationships and taxonomic limits among these genera are unsettled. Our ITS study demonstrates monophyly of these genera, excluding *Chamira*. The molecular analysis reveals parallel evolution of fruit characters, typically used in the traditional classification schemes. The recognition of three main clades corresponds largely with the distribution of morphological characters (e.g., habit, leaf shape, etc.) not adequately accounted for in previous studies. Estimation of divergence times of the main lineages of *Heliophila* is in agreement with recent analyses in other plant groups, all of which date the diversification against a background of aridification in the Pliocene/Pleistocene. Eco-geographical evolution and the adaptive significance of various floral structures is discussed in terms of their possible role in the rapid diversification within *Heliophila.*

1.6.1. Introduction to polyploid genome evolution and lessons from *Gossypium*

J. F. Wendel;
Iowa State University, Ames, IA, United States.

Polyploidy is a prominent process generating a great deal of biodiversity. Recent years have witnessed many advances in our understanding of the novel genic and genomic interactions that accompany genome doubling in many plant groups, as encapsulated in this symposium. In *Gossypium*, there have been multiple episodes of trans-oceanic dispersal, some leading to hybridization among lineages that presently are inter-sterile. Allopolyploid *Gossypium* arose from an intercontinental merger 1-2 million years ago of two genomes that evolved in isolation for 5-10 MY. This remarkable biological reunion led to a spectrum of genic and genomic interactions, including concerted evolution, intergenomic transfer, a high frequency of gene silencing and possible functional differentiation among homoeologs. Comparisons of synthetic and natural polyploids demonstrate the scope of epigenetic silencing accompanying polyploid formation and the pace of subsequent expression evolution. Microarray experiments are being used to explore gene expression patterns in polyploids and the possibility of novel gene recruitment in certain pathways following genome doubling.

1.6.2. Precise polyploidy-related evolution mechanisms in wheat (*Triticum and Aegilops)* species

J. Salse[1], N. Chantret[2], F. Sabot[3], P. Joudrier[4], M. Gautier[4], N. Boudet[1], M. Caboche[1], P. Leroy[3], M. Bernard[3], **B. Chalhoub**[1];
[1]URGV, Evry, France, [2]CIRAD- AMIS, MontPellier, France, [3]INRA-UBP, Clermont-Ferrand, France, [4]INRA - UMR Polymorphismes d'Intérêt Agronomique, MontPellier, France.

Although polyploidy has been shown to induce important genetic and epigenetic events, such as DNA sequence elimination, nothing is yet known about their molecular mechanisms. We investigated the molecular basis of such evolution mechanisms by comparing, at several selected loci, corresponding sequences of diploid, tertraploid and hexaploid wheat species (*Triticum* and *Aegilops*). The comparative analysis allowed us to determine the sequences of the rearranged regions as well as rearrangement breakpoints. Among these genomic rearrangements, the previously reported *Pina* and *Pinb* genes loss from the important *Hardness* locus of polyploid wheat species was shown to be caused by a large genomic deletion, through illegitimate recombination, which occurred independently in the A and B genomes. Various illegitimate DNA recombination events that lead to genomic deletions, duplications and inversions were determined and appear to constitute the major evolutionary mechanisms that accompanied tetraploid and hexaploid wheats formation. This work represents the first report on precise molecular basis of polyploidy-related evolution mechanisms.

1.6.3. Recent allopolyploidy and genome evolution in *Spartina* (Poaceae)

M. L. Ainouche[1], A. Salmon[2], J. F. Wendel[3], K. Fukunaga[1], M. Ricou[1], P. Fortune[1], K. Schierenbeck[4];
[1]UMR CNRS 6553 University of Rennes 1, Rennes, France, [2]UMR 118 INRA-ENSAR, Le Rheu Rennes, France, [3]Iowa State University, Ames, IA, United States, [4]California State University, Chico, CA, United States.

The evolutionary and genomic history of polyploid *Spartina* species will be reviewed, with a special interest in the role of reticulate evolution and genome duplication in the success of newly formed hybrid and allopolyploid lineages. *Spartina* species are tetraploid, hexaploid or dodecaploid perennials, most of them native to the New World. Recent (19th century) hybridisation and polyploidisation events involved hexaploid species, following introduction of the east-American *S. alterniflora* into Western Europe. Two independent hybridisation events with the Euro-African *S. maritima* resulted in hybrids that differ dramatically in morphology, i.e., *S.* x *neyrautii* (in France) and *S.* x *townsendii* (in England), both with *S. alterniflora* as the maternal parent. Chromosome doubling of *S*. x *townsendii* resulted in a particularly successful new allopolyploid species, *S. anglica*, which has rapidly expanded in range and has now invaded several continents. We use this system to explore the genetic, epigenetic and expression dynamics of recent hybrids and allopolyploid taxa in Western Europe.

1.6.4. Genomic and transcriptomic changes during and following allopolyploid speciation in *Senecio*

R. J. Abbott[1], M. J. Hegarty[2], G. Liu[1], K. J. Edwards[2], S. J. Hiscock[2];
[1]St Andrews University, St Andrews, United Kingdom, [2]Bristol University, Bristol, United Kingdom.

The discovery of new allopolyploid species in the wild provides an opportunity to examine what changes in genome structure and gene expression accompany allopolyploid speciation. The Welsh groundsel, *Senecio cambrensis*, is one of five new allopolyploid species known to have originated within the past 100 years or so. It originated independently at two different sites in the United Kingdom following hybridization between diploid *S. squalidus* and tetraploid *S. vulgaris*. We have found that the Welsh lineage of this allohexaploid species contains high levels of AFLP genotypic diversity indicating that intergenomic recombination is common. A genomic map of *S. cambrensis* has been constructed for comparison with maps of the parent species to assess levels of intergenomic exchange. In addition, we have developed and used an anonymous cDNA microarray to examine genome-wide alterations to gene expression between parents, the triploid hybrid and the allohexaploid using wild and synthetic material. Dramatic differences in expression were recorded between the four taxa demonstrating the impact of hybridization and polyploidy on gene expression in higher plants.

1.6.5. The genetic consequences of polyploidy in *Nicotiana*

A. R. Leitch[1], M. W. Chase[2], J. Clarkson[2,1], S. Knapp[3], Y. Lim[1], R. Matyasek[4], A. Kovarik[4];
[1]Queen Mary University of London, London, United Kingdom, [2]Royal Botanic Gardens, Kew, United Kingdom, [3]Natural History Museum, London, United Kingdom, [4]Institute of Biophysics, Brno, Czech Republic.

Here we report on the genetic consequence of polyploidy from ancient to recent in Nicotiana. Polyploidy has been associated with a number of genetic events, these include: (i) homogenisation of rDNA; (ii) transcription silencing of rDNA; (iii) loss and gain of DNA sequence; (iii) stabilising chromosome translocations; (iv) genome “downsizing” and (v) rapid evolution of paternal genomes. These phenomena are studied using recently made synthetic Nicotiana allotetraploids. Data are compared with natural polyploids from Nicotiana sections of widely different ages and hence periods of time for genetic divergence (thousands to million of years). We find rapid changes in the first few generations, these include the amplification and spread of a novel rDNA family across and between loci and the loss of tandem and dispersed repeats. Thereafter, over long-time scales (>20,000 years old) we observe genome diploidisation processes including the divergence of repetitive sequences and the loss of rDNA loci.

1.6.6. Genetic and genomic consequences of recent and recurrent allopolyploidy in *Tragopogon* Asteraceae

J. A. Tate[1], Z. J. Chen[2], P. S. Soltis[3], D. E. Soltis[1];
[1]University of Florida, Gainesville, FL, United States, [2]Texas A&M University, College Station, TX, United States, [3]Florida Museum of Natural History, Gainesville, FL, United States.

Tragopogon mirus and *T. miscellus* are allopolyploids that formed repeatedly during the past 80 years following the introduction of three diploids (*T. dubius*, *T. pratensis*, and *T. porrifolius*) from Europe to western North America. Because the parentage and time of formation of these polyploids are well documented, this system provides a unique opportunity to study the consequences of recent and recurrent polyploidization. We summarize the cytogenetic and genomic aspects of polyploidy in *Tragopogon*, emphasizing our recent studies of gene expression in the newly formed allopolyploids. Specifically, cDNA-AFLPs reveal differences in gene expression between *T. miscellus* and its diploid parents, as well as between populations of *T. miscellus* of reciprocal origin. These differences include novel expression and gene silencing, with some patterns of gene silencing corresponding to maternal and paternal effects. The recent generation of artificial F_1 hybrids between the diploid progenitors will allow us to explore the impact of hybridization versus polyploidization on the genomes of the tetraploid species.

1.6.7. Independent ancient polyploidy events in the sister families Brassicaceae and Capparaceae

M. Schranz, T. Mitchell-Olds;
Max Planck Institute of Chemical Ecology, Jena, Germany.

Recent studies have elucidated the ancient polyploid history of the *Arabidopsis thaliana* (Brassicaceae) genome. The studies concur that there was at least one polyploidy event, identifiable by numerous duplicated gene pairs in syntenic blocks, which occurred some 20 to 60 mya and near the divergence of the Brassicaceae from its sister family, the Capparaceae. Using a comparative genomics approach, we have asked the question of whether this polyploidy event was unique to members of the Brassicaceae or if it was shared with the Capparaceae. We have isolated and sequenced three genomic regions from diploid *Cleome spinosa* (Capparaceae) that are homologous to a duplicated region found on At3 and At5. The three genomic regions in *Cleome* are each unique and are mosaics of At3 and At5 specific genes, with no clear orthology/ paralogy gene pair relationships. Genes found in duplicate in *A. thaliana* also tend to be replicated in *Cleome*. Surprisingly, molecular evolutionary analyses found that the triplication in *Cleome* occurred more recently, and independently, of the duplication event in *A. thaliana*, but that the rate of gene loss is higher in *Cleome*.

1.7.1. Research on *Orobanche*: what do we know and what should we get to know?

D. M. Joel, **D. M. Joel**;
Agricultural Research Organization, Ramat-Yishay, Israel.

Orobanche spp. (broomrapes) are parasitic plants that develop multicellular haustoria, which connect to the roots of various dicots. Their tiny seeds germinate only after perceiving a host stimulus. Some species are weedy and cause severe damage to agriculture. The globalization of these parasitic weeds, the evolution of new races, and the gradual increase in their virulence pose threat to many crops worldwide, while means to control them are scarce. Studies of key developmental mechanisms of the parasitic interaction, regarding germination, attachment, haustorium penetration and host resistance, are needed for the understanding of their evolution. Proteomics and genomics should provide data on the genes involved in host-parasite interaction. Manipulation of developmental and metabolic pathways, which are involved in the parasitic interaction in both host and parasite, may provide protection against parasitic weeds. New sources for resistance in host plants may also be developed, employing specific antibodies, gene silencing, local release of toxins, and false signals.

1.7.2. Molecular phylogenetics and taxonomy of *Orobanche*s. l. (Orobanchaceae)

G. M. Schneeweiss[1], J. Park[1], J. Manen[2], A. Colwell[3];
[1]Institute of Botany, Vienna, Austria, [2]Conservatoire et Jardin Botaniques, Genéve, Switzerland, [3]US Geological Survey, Seattle, WA, United States.

Phylogenetic analyses of DNA-sequence data have greatly changed our understanding of circumscription of Scrophulariaceae and allied families, e.g., Orobanchaceae, traditionally comprising exclusively holoparasitic taxa, now include both hemi- and holoparasitic members. In a similar way, recent molecular phylogenetic analyses suggest substantial re-definition of the genus *Orobanche*, which is the largest of the holoparasitic genera in Orobanchaceae. One group, with chromosome base number of $x = 12$, contains the each monophyletic sections *Gymnocaulis*, *Myzorrhiza*, and *Trionychon*. The second group, with chromosome base number of $x = 19$, contains *Diphelypaea* and *O.* sect. *Orobanche*, the latter again comprising three distinct lineages. The relationships between these two major groups and those to other genera are unclear. As already suggested by previous authors, recognition of the sections of *Orobanche* as separate genera would allow to better reflect the phylogenetic patterns in a taxonomic system.

1.7.3. *Orobanche*-host plant interactions: ecological and physiological aspects

J. A. C. Verkleij;
Institute of Ecological Science, Amsterdam, The Netherlands.

Among the various Orobanche species, a large difference in host range exists from very small to extremely wide. Because the *Orobanche* lifecycle is highly specialized for parasitism, the first stages of host-parasitic interactions seemed to be essential in determining host specificity. Orobanche seed germination is dependent on several abiotic and biotic factors as shown in various ecological and physiological studies. Although this first stage can be considered as the most discriminating one in terms of host selection, the germination process is too complex to draw definitive conclusions. The next stages crucial for the development of Orobanche are haustorium initiation, host tissue penetration and physiological compatibility. Progress in understanding these processes have been made in recent years using host plant-parasite model systems. After successful infection Orobanche relies completely on its host for the supply of both reduced carbon, nitrogen and also minerals. The response of the host to infection by the holoparasite can be explained by just source -sink relations and will be discussed with respect to other parasitic angiospermhost systems.

1.7.4. Predictive empirical modelling of *Orobanche* life cycle and seed ecology

A. J. Murdoch[1], E. Kebreab[2];
[1]The University of Reading, Reading, United Kingdom, [2]The University of Guelph, Guelph, ON, Canada.

Dormancy in *Orobanche* seeds is removed as a two-stage process. First, after shedding from the mother plant, populations of dry *Orobanche* seeds after-ripen (lose primary dormancy). Increasing the temperature results in a faster after-ripening rate of the seed population. The second stage - conditioning - occurs at water potentials close to full imbibition. The rate of conditioning in the seed population also increases with increase of temperature. Secondary or even tertiary processes may interfere with dormancy loss. For example, prolonging the conditioning period beyond about 21 days decreases the subsequent germination response due to a) induction of secondary dormancy and b) at temperatures over about 25°C, loss of viability. Germination of conditioned seeds depends on chemical stimulation from host's roots, temperature and water stress. The thermal time for germination is strongly affected by water potential. Non-linear probability models account for these processes and provide predictive empirical models to describe the germination behaviour of the seed population. The impact of these results is discussed for *O. aegyptiaca* parasitising tomato.

1.7.5. Population genetics in *Orobanche* species

Z. Satovic[1], D. M. Joel[2], D. Rubiales[3], J. Cubero[4], B. Roman[5];
[1]Faculty of Agriculture, Zagreb, Croatia, [2]Newe-Ya'ar Research Center, Agricultural Reserach Organization, Ramat-Yishay, Israel, [3]IAS - CSIC, Cordoba, Spain, [4]ETSIAM - UCO, Cordoba, Spain, [5]IFAPA - CIFA, Cordoba, Spain.

The studies of population genetics of *Orobanche* species are of great importance since the understanding of the variability within and between pathogenic populations is essential if selection programmes need to target sources of resistance in different areas and suitable breeding strategies need to be developed. The use of morphological markers in *Orobanche* has been difficult because holoparasitism resulted in a reduced number of suitable characters even for taxonomical purposes. The distribution of genetic variation in *O. aegyptiaca*, O. *crenata*, *O. cumana*, *O. foetida* and *O. ramosa* populations has been reviewed based on available molecular marker data. It is shown that by using simple DNA marker systems (e.g. RAPDs and ISSRs) the intraspecific variability can be assessed and problematic issues such as the differentiation between botanical taxa, geographical differentiation, and host-differentiation can be addressed.

1.7.6. Evolution of Ty1-*copia* and Ty3-*gypsy* retroelements in holoparasitic *Orobanche* (Orobanchaceae)

J. Park, G. M. Schneeweiss, H. Weiss-Schneeweiss;
Institute of Botany, University of Vienna, Vienna, Austria.

Retrotransposons (RTNs) are mobile genetic elements, which transpose via an RNA intermediate. The transposition of RTNs is replicative, i.e., the existing elements are not excised but the newly formed copies re-integrate into new positions in the host genome. This feature, among others, such as ubiquity and high copy number, renders RTNs excellent molecular markers. We amplified and sequenced *rt* gene of Ty1-*copia* and Ty3-*gypsy* RTNs (at least 20 clones for each RTN type) from 13 *Orobanche* accessions. These accessions are (i) the economically most important weeds *O. aegyptiaca* and *O. ramosa* of sect. *Trionychon* and *O. cernua* and *O. crenata* of sect. *Orobanche*, and (ii) one close wild relative of each of these four taxa. While in sect. *Trionychon* RTN diversity is higher with many small unique RTN families, fewer RTN families are found in sect. *Orobanche*, some of them comprising numerous and very similar *rt* sequences. This suggests that species in sect. *Orobanche* might have experienced a recent burst of RTN activity. Additionally, we found indication of horizontal gene transfer for Ty1-*copia* and Ty3-*gypsy* RTNs, both from sect. Trionychon to sect. Orobanche and vice versa.

1.7.7. *Orobanche* species as weeds and their management in sustainable agriculture

D. Rubiales[1], M. Fernández-Aparicio[1], B. Román[2], J. C. Sillero[2], J. I. Cubero[3];
[1]CSIC, Córdoba, Spain, [2]IFAPA, Córdoba, Spain, [3]UCO, Córdoba, Spain.

About 3500 flowering plant species have lost their autotrophic way of life during evolution and parasitise other plants in order to supply themselves with water and nutrients. They are more than a fascinating group of plants as a few of them are severe constraints to major crops. By far the most economically damaging parasitic weeds are members of the genera *Striga* (witchweeds) and *Orobanche* (broomrapes). The most damaging *Orobanche* species are *O. crenata* that causes huge damage to legume crops, *O. cumana* that threatens sunflower, *O. ramosa* that attacks potato, tobacco, tomato and hemp, and *O. aegyptiaca* has very severe effects on legumes and vegetables, but also other species might gain importance. The spread of these parasitic weeds, and the gradual increase in their virulence pose threat to many crops worldwide, while means to control them are scarce. In the present work we revise their importance and re-evaluate control methods in the light of recent developments in crop breeding and molecular genetics.

1.8.1. Species concepts and biodiversity in *Trichoderma* and *Hypocrea*: evolution of a versatile fungal genus

C. P. Kubicek;
Forschungsbereich Gentechnik und Angewandte Biochemie, Institut für Verfahrenstechnik, Umwelttechnik und technische Biowissenschaften, Technische Universität Wien, Vienna, Austria.

Trichoderma/Hypocrea is a genus of soil-borne or wood-decaying fungi, which can make up a high portion of fungal propagules in soil. It contains members that are important to mankind as producers of industrial enzymes and biocontrol agents against plant pathogens, but also as opportunistic pathogens of immunocompromised humans. Most recently, endophytic

Trichoderma spp. have also been found. Species identification, while essential in view of the controversial properties of taxa of this genus, has been problematic by traditional methods, therefore rendering the species identity of isolates studied in older literature uncertian. In this lecture, I will demonstrate how the Genealogic Concordance Phylogenetic Species Recognition Concept (GCPSR), when combined with Bayesian models of evolution, provides insights into the biodiversity, modes of speciation and evolution of ecological characters in this ubiquitous fungal genus.

1.8.2. New aspects on ecology and biodiversity of the Sebacinales (Hymenomycetes, Basidiomycota), plant associates with a uniquely wide spectrum of mycorrhizal interaction types

M. Weiß[1], M. A. Selosse[2], S. Setaro[1], F. Glatard[3], F. Oberwinkler[1];
[1]Lehrstuhl Spezielle Botanik und Mykologie, Botanisches Institut, Universität Tübingen, Tübingen, Germany, [2]Equipe Co-évolution (CEFE-CNRS, UMR 5175), Université Montpellier II, Montpellier, France, [3]Institut de Systématique (IFR CNRS 1541), Muséum National d'Histoire Naturelle, Paris, France.

Within the basidiomycetes, the vast majority of known mycorrhizal species belong to homobasidiomycetes. It was therefore surprising that during the past years molecular and ultrastructural studies revealed a broad diversity of mycorrhizal associations involving members of the new heterobasidiomycetous order Sebacinales. It became evident that members of this order are involved in a wide spectrum of mycorrhizal types: ectomycorrhizas, orchid mycorrhizas (both with green and myco-heterotrophic orchids), ericoid mycorrhizas, and also in recently described associations with some members of the liverworts (Jungermanniales) that resemble mycorrhizas at the cellular level ('jungermannioid mycorrhizas'). A comparably broad diversity of mycorrhizal associations is known from no other fungal group. We give an overview over the present knowledge concerning phylogeny, morphology and ecology of the Sebacinales, particularly focussing on new results concerning associations with Ericaceae.

1.8.3. Molecular systematics of the Zygomycetes: organismal diversity, spore morphology and a multi-gene based phylogeny

K. Voigt[1], K. Hoffmann[1], E. Einax[1], H. Prillinger[2], M. Kirchmair[3], G. Newcombe[4], L. Olsson[5];
[1]University Jena, Fungal Reference Centre, Jena, Germany, [2]University of Natural Resources and Applied Life Sciences, Institute of Applied Microbiology, Vienna, Austria, [3]University Innsbruck, Institute of Microbiology, Innsbruck, Austria, [4]University of Idaho, Department of Forest Resources, Moscow, ID, United States, [5]University Jena, Institute of Systematic Zoology and Evolutionary Biology, Jena, Germany.

The Zygomycetes encompass microscopic fungi which form zygospores in sexual interactions. The most prominent and largest orders are the Mucorales and the Mortierellales, comprising in most cases saprotrophic but also facultatively parasitic species, which occupy a large variety of ecological niches. We investigated zygomycetous soil fungi from different natural habitats, e.g. from meadow land among the Danube river, alpine territories, domestic areas and forest biotopes. The goal was to assess the genotypic diversity in correlation with the phylogeny and systematics. To this end we generated multigene genealogies in conjunction with physiological and detailed sporangiospore morphology obtained by scanning electron microscopy. Phylogenetic analysis in the context of available sequence data (approx. 6,000 nucleotide positions per species) strongly supports sporangiospore morphology and thermophilic growth as suitable distinguishing characters. Moreover, suggestions of a revised family nomenclature in zygomycete systematics will be discussed.

1.8.4. Conflicting evidences about the phylogeny of ascomycetous yeasts estimated by 18S rDNA sequences and cell wall carbohydrate composition

H. Prillinger[1], K. Lopandic[1], O. Molnar[1], M. Suzuki[2], W. Pinsker[3];
[1]Institute of Applied Microbiology, University of Natural Resources and Applied Life Sciences, Vienna, Austria, [2]Japan Collection of Microorganisms, RIKEN, Wako, Saitama, Japan, [3]Institute for Medical Biology, Genetic Working Group, University of Vienna, Vienna, Austria.

Small subunit rRNA gene sequences (18S), urease-activity and cell wall carbohydrate composition were analysed within a larger number of ascomycetous yeasts and filamentous fungi to validate their congruence in predicting phylogenetic relationships. Three carbohydrate patterns, glucose-mannose, mannose-glucose-galactose-rhamnose and glucose-mannose-galactose-rhamnose-(fucose), characterise the Hemiascomycetes, the Euascomycetes and the Protomycetes, respectively. In addition, the glucose-mannose-galactose carbohydrate profile can be found in representatives of all the three classes. Chemotaxonomic studies coupled with additional cytological and co-evolution studies support the idea that the Hemiascomycetes occupy a basal position in the phylogeny of Ascomycota.These results are not in line with the phylogenetic studies based on the sequences of 18S rRNA encoding gen. The maximum parsimony analysis indicated that Hemiascomycetes and Protomycetes might represent sister groups. The term Protomycetes was introduced reflecting much better the properties of the whole class.

1.8.5. New anamorphic Basidiomycota filling gaps in fungal diversity studies

R. Kirschner;
Botanisches Institut, Frankfurt am Main, Germany.

Anamorphic Basidiomycota provide essential data for understanding the life-cycle (saprobic stage vs. biotrophic stage), ecology (geographic distribution, substrates, vectors etc.), and systematics (morphological, molecular, and other characteristics) as well as the general diversity of the Basidiomycota. In this contribution, this significance of anamorphs is illustrated with examples of new anamorphic taxa (hyphomycetes and yeasts) connected with the Cryptomycocolacales (*Colacosiphon*), Atractiellales (*Leucogloea*), Agaricostilbomycetidae (*Kurtzmanomyces*), Dacrymycetales (*Dacryoscyphus*), Auriculariales (*Helicomyxa*), Tremellales (*Sterigmatosporidium*), as well as the Agaricales (anamorphic *Marasmius*) and other homobasidiomycetes (*Cruciger*). The new taxa are based on morphological, ultrastructural, physiological, and molecular findings in collections made in Middle Europe, China, and Taiwan.

1.8.6. Utility of chemotaxonomy for assessment of phylogenetic relationships and generic concepts within the Xylariaceae

M. Stadler;
Bayer Health Care AG, Wuppertal, Germany.

The biological and chemical diversity of *Xylariaceae* with emphasis on genera with *Nodulisporium*-like anamorphs (e.g., *Daldinia*, *Hypoxylon*) was evaluated by a HPLC-based chemotaxonomic survey of ca. 2000 specimens and cultures, accompanied by extensive morphological studies and SEM. Conspecificity of recent records with old type specimens by comparison of HPLC profiles was safely established in many cases, since the characteristic metabolites may remain stable for over 200 years. Several of them constitute novel natural products that were identified from stromata of *Xylariaceae* in the course of concurrent "mycochemical" studies. These results were found largely in agreement with those of concurrent molecular studies, involving 5.8S/ITS nrDNA sequences. While anamorphic morphology and metabolism of cultures agreed well at generic level and above, a combination of chemical and morphological traits appears suited better than even molecular data for differentiation of these fungi at subgeneric level. A polythetic approach is most likely to result in a stable phylogeny of these fungi, as well as for attempts to estimate their biological diversity.

1.8.7. Tuberculina " Helicobasidium: cheating fungi" killing plants

M. Lutz, R. Bauer, F. Oberwinkler;
Universität Tübingen, Spezielle Botanik & Mykologie, Tübingen, Germany.

Helicobasidium species (Urediniomycetes) are serious plant pathogens causing the economically important violet root rot. In its sterile stage, the fungus is known as Rhizoctonia crocorum or Thanatophytum, respectively. In contrast, Tuberculina species are mycoparasites of rust fungi. The strong inhibitory effect of Tuberculina on rust spore production has resulted in extensive research dealing with Tuberculina as a biological agent in rust control. Recently, we demonstrated that rust-parasitic Tuberculina species and plant-parasitic Helicobasidium species are stages of the life cycle of one holomorph. Combining the results of infection experiments, molecular analyses, and morphological and ecological characters, we show that there are at least six monophyletic lineages within the Tuberculina/Helicobasidium-group that can be unambiguously distinguished. The thereby revealed diversity opens up new perspectives on the evolution of this exceptional mycoparasitic-phytoparasitic fungal group.

1.9.1. Ecological speciation in an East Maui endemic *Dubautia* (Asteraceae) species flock

E. A. Friar[1], L. M. Prince[1], M. McGlaughlin[1], E. H. Roalson[2];
[1]Rancho Santa Ana Botanic Garden, Claremont, CA, United States,
[2]Washington State University, Pullman, WA, United States.

The process of adaptive radiation has been the subject of considerable debate. Several hypotheses have been proposed to explain the rapid diversification of taxa into varied habitats. The ecological theory of adaptive radiation postulates that divergent natural selection drives rapid speciation and phenotypic diversification. One recently evolved example of a monophyletic species radiation into a small species flock is the East Maui endemic Dubautias: D. menziesii, D. platyphylla, D. reticulata, and D. waianapanapaensis. Despite the close genetic relationships, these species are morphologically and ecologically distinct. These four species, therefore, represent a recent ecological diversification into different niches, apparently based upon fine-level partitioning of ecological habitats. They are capable of interbreeding where they come into contact, but typically inhabit different habitats and maintain their morphological distinctness. Here, we examine variation within and among populations of the East Maui endemic species of Dubautia using microsatellite, DNA sequence, leaf morphometric, and ecological data.

1.9.2. Current Trends in Western Balkan *Campanula L.* Research

S. Kovacic;
Department of Botany and Botanical Garden, Faculty of Science, Zagreb, Croatia.

Genus *Campanula* is traditionally considered to be very complicated from a taxonomic point of view, due to its phenotypic plasticity, ontogenetic variation and polyploidy. Flora of the Western Balkans comprises up to 100 *Campanula* taxa, out of which more than 30% endemic. Mutual relations of these taxa puzzle taxonomists for centuries: today, using comparative morphological, chorological and ecological data, in combination with the results of extensive cytological, isoenzyme and molecular (chloroplast and nuclear DNA) approaches, we are closer than ever to finally understand the obscure relationships among the Balkan-*Campanula* taxa lineages, and to other campanuloids, their ways of surviving the Ice Ages and possible paths of re-colonisation, followed by fast evolution of taxa. Several indigenous endemic lineages (Isophylla, Waldsteiniana, Pyramidalis, Rotundifolia) are discussed closely, to demonstrate promising comparative approaches in solving mutual relations inside this perplex genus.

1.9.3. Large scale AFLP screening of natural populations provides the basis for the analysis of the molecular mechanisms underlying biodiversity - the case of *Melampyrum* (Orobanchaceae)

J. Wunder[1], M. Li[1], G. Bissoli[1], H. Saedler[2], C. Varotto[1];
[1]CSBT, Center for the Study of Biodiversity – Trentino, San Michele all'Adige, Italy, [2]Max-Planck-Institut for Plant Breeding Research, Cologne, Germany.

Analyses of mutants and “ecotypes” using mainly seedbank material cover only a small part of the variation present in natural populations. By contrast, in nature there is a large range of variation, encompassing an unknown number of distinct ecotypes, varieties and mutants. Within the 6 species of *Melampyrum* known in Trentino/Italy, AFLP analyses revealed considerable genetic distances within and between populations as well as differences between species concerning population- and meta-population structure. Beside several morphological and ecological traits varying between populations and species also a flower-mutant independently appearing in different populations was discovered. Furthermore there is a lack of correlation between morphological and genetic distances between the species to the point that even a 7th species was found. While genomic-based AFLP provides the basis to define the populations or species to be compared, other techniques, like cDNA-AFLP are used to identify the genes involved in the traits analyzed. A summary of our approach to trace the molecular mechanisms underlying biodiversity by analysing natural populations is given.

1.9.4. Within-population genetic variation of the distylous *Primula veris* : does morph ratio matter in fragmented habitats?

F. Van Rossum, **L. Triest**;
Vrije Universiteit Brussel, Brussel, Belgium.

In Flanders (northern Belgium), *Primula veris* (Primulaceae), a distylous self-incompatible perennial herb, mainly occurs in fragmented habitats of the intensively used agricultural landscape. We investigated within-population and within-morph genetic variation and structure for 30 allozyme loci in 24 populations of *P. veris* from two distant regions (Westhoek and Voeren), in relation to population morph bias and morph frequencies. Enzyme polymorphisms indicate that the Wright’s inbreeding coefficient (F_{IS}) values were negatively correlated to the proportion of pin individuals in the population. Three populations showed a significant genetic differentiation between pin and thrum morphs. Contrasting fine-scale spatial genetic structure patterns were found for pin and thrum morphs. The results are discussed in the light of demographic stochasticity, morph-specific differences in self-compatibility levels and reproductive fitness, historical factors (bottlenecks), and pollination patterns.

1.9.5. Deleterious mutation in plant species with contrasting mating systems

D. J. Schoen;
McGill University, Montreal, PQ, Canada.

The genus Amsinckia (Boraginaceae) is a group of western North American annual plants that exhibit remarkable interspecific and intraspecific variation in the rate of self-pollination, variation that is closely tied to the presence of distyly in populations. Phylogenetic studies of this group suggest that extant homostylous and distylous populations are often very closely related. Here we present the results of studies designed to estimate deleterious mutation parameters in two closely related species of the genus with contrasting mating systems. The results show there are no marked differences in the rates and effects of deleterious mutation affecting a major fitness component, flower number per plant, implying that mutation rate does not evolve with the mating system. This observation may help account for the apparent pattern of recent mating system diversification within this plant group.

1.9.6. Evolution of herbivore-induced resistance in wild mustard (*Sinapis arvensis*)

T. Fabbro, T. Steinger;
University of Fribourg, Department of Biology, Ecology & Evolution, 1700 Fribourg, Switzerland.

Induced responses of plants to herbivore feeding play an important ecological role in plant-herbivore interactions. Several chemical, morphological, and life-history traits can be induced and their inducibility may be under selection by herbivores. An evolutionary response to selection may be constrained by a lack of genetic variation or by negative genetic correlations. We used a quantitative genetic approach with controlled crosses, that allowed the estimation of additive genetic variances and covariances. In a experiment the responses of Sinapis arvensis to feeding by a specialist herbivore, Pieris rapae, were investigated. We measured a number of resistance traits and performed bioassays to determine resistance against Mamestra brassicae, Spodoptera littoralis, and Pieris rapae. We present estimates of the heritability of constitutive and induced resistance traits, and explore the pattern of genetic correlations among these traits in order to predict their evolutionary potential.

1.9.7. The effects of selection on a polyploid series

P. A. Ashton;
Edge Hill College of HE, Ormskirk, United Kingdom.

The development of an array of molecular markers in the last twenty years has enabled evolutionary relationships between taxa to be precisely determined. Consequently a large number of such studies have been carried out, focussing on such modes of speciation as progenitor-derivative pairs and polyploid series. At the same time the effects of natural selection have been less likely to be investigated, although this was the predominant area of research in the early days of ecological genetics. Where evolutionary pathways are known, a return to a more precise consideration of the effects of selection following speciation can be undertaken. In particular the classical effects of polyploidy leading to increase in cell size has implications for the fitness and niche of a plant. This talk outlines how selective forces can influence the legacy of polyploidy on simple characteristics within a polyploid series such as *Senecio*.

1.10.1. Ecophysiological aspects of desiccation tolerance in Angiosperms

D. F. Gaff;
School of Biological Sciences, Monash University, Clayton, Australia.

A majority of vascular plants are killed by drought if the foliage water potential falls to -15MPa. Others have leaves that survive -300MPa or even <-600MPa.

Even if some desiccation tolerant angiosperms occupy a restricted habitat, they occur over a wide range of climates, latitudes, altitudes, insolation, topography & substrates. DT mechanisms are compatible with almost the full scope of eco. adaptation. Taxonomic distribution of foliar DT ranges broadly across angiosperms, but the tolerance is expressed in only a small proportion of the monocots & even fewer dicots. Aspects of taxonomic spread of DT imply existence of predisposition in certain taxa to evolve desiccation drought tolerant foliage. In some taxa mature & immature leaf tissue are desiccation tolerant; in others only immature leaf tissue is tolerant, being consistent with the view that in the evolution of the phenomenon in angiosperms DT spread from young to mature tissue. Senescence compromises any potential for DT in vascular plants. Interspecific hybrids of “resurrection” species are also desiccation tolerant and mechanisms of DT are phenotypically compatible between species and even genera.

1.10.2. Desiccation tolerance in Bryophytes: the primitive strategy for land plants?

A. J. Wood[1], M. J. Oliver[2], B. D. Mishler[3];
[1]Southern Illinois University, Carbondale, IL, United States, [2]USDA-ARS, Lubbock, TX, United States, [3]UC-Berkeley, Berkeley, CA, United States.

Green plants are believed to have colonized the land from a fresh water origin requiring adaptive mechanisms that permit avoidance or survival of dehydration. We hypothesize that primitive plants were vegetatively desiccation tolerant and that the primitive tolerance mechanism is reflected in the way modern day bryophytes survive drying. Evidence is consistent with bryophytes employing a strategy of constitutive cellular protection coupled with the induction of a repair mechanism upon rehydration. Proteins synthesized following rehydration (rehydrins) are important components of desiccation tolerance in bryophytes. Genomic studies reveal that some prominent rehydrins are similar to seed LEA proteins, classically ascribed a protective function during drying. The role of LEA proteins during rehydration is unknown but recent data suggests a function in stabilization and reconstitution of membranes. Phylogenetic rehydrin mapping studies led to a re-examination of the evolution of desiccation tolerance in land plants. The new phylogeny suggests that vegetative desiccation tolerance may have evolved from a mechanism first seen in propagules.

1.10.3. Mechanisms of dealing with mechanical stress associated with water-deficit in a range of desiccation-tolerant and -sensitive species

J. M. Farrant[1], N. Algar[1], C. Vander Willigen[1], R. A. Balsamo[2];
[1]University of Cape Town, Cape Town, South Africa, [2]Villanova University, Philladelphia, PA, United States.

Vegetative tissues of resurrection plants are desiccation tolerant. Mechanical damage caused by drying is avoided. In desiccation-sensitive plants it is manifest by plasmalemma tearing and wall collapse. We examined tensile properties in leaves of several resurrection and sensitive species during drying in relation to subcellular changes. Tensile strength was greater in wet tissues of tolerant relative to sensitive plants and decreased (dicots) or remained unchanged (monocots) in the latter during drying. In tolerant species, it increased on drying in all species except grasses, where it remained unchanged. When tolerant plants are rapidly dried, so that protection does not accumulate, tensile properties are similar to sensitive species. Mechanical stabilisation in *Craterostigma* spp occurs by wall folding, explaining increased tensile properties when dried. In *Xerophyta* spp walls remain unchanged anatomically and stabilisation occurs by maintaining cell volume though filling of vacuoles with compatible solutes. In grasses a combination of wall folding and vacuole filling occurs, the counteracting effect enabling unchanged tensile properties.

1.10.4. Programmed cell death in desiccation tolerant and intolerant seeds

I. Kranner, S. Birtic, H. W. Pritchard;
Royal Botanic Gardens Kew, Wakehurst Place, United Kingdom.

Hardly any animals and higher plants can survive desiccation, but the majority of the latter have desiccation tolerant ‘orthodox’ seeds. Free radicals, formed during water removal, impair metabolism and necessitate protection and repair during desiccation and rehydration, respectively. Consequently, desiccation tolerance and prolonged longevity in the desiccated state depend on the ability to scavenge free radicals, using antioxidants such as glutathione, ascorbate and tocopherols. The major intracellular antioxidant consistently found in all desiccation tolerant life forms is glutathione, making it essential to survive desiccation. However, if the antioxidant system eventually fails during long-term desiccation, substantial amounts of glutathione are oxidized and its redox potential increases towards more positive values. We present a model of biochemical pathways, suggesting that glutathione redox potential acts as a signal that initiates programmed cell death. Meta-caspase acitivated DNAses finally cleave DNA into inter-nucleosomal fragments, restraining recovery, in both desiccation tolerant and intolerant seeds.

1.10.5. Desiccation tolerance of epiphytic bryophytes in relation to microclimate in a Venezuelan cloud forest

Y. Leon[1], M. C. F. Proctor[2], S. Engwald[3];
[1]Universidad de Los Andes, Merida, Venezuela, [2]Department of Biological Sciences, University of Exeter, U.K., Exeter, United Kingdom, [3]Dep. of Horticulture, Philipp-Holzmann-Schule, Frankfurt am Main, Germany.

The forests of the northern Andes are a major centre of epiphytic bryophyte diversity and abundance. We analyse wet and dry-season data for temperature, PAR, r.h., and periods with and without precipitation, in relation to data on desiccation tolerance and light responses of some epiphytic species. Most wet and dry periods lasted no more than a few hours; the longest dry periods recorded in the lower canopy were c. 199 h in February (dry season) and 56 h in August (wet); a quarter of all dry periods were >15 h in February and >8 h in August. Relative humidity was mostly >70% and often >90%, especially at night. With high r.h. and temperature around 15 °C, saturation deficits are small and evaporation slow, so mosses will generally retain turgor over dry periods up to a few hours. All the species examined tolerated at least a few days’ desiccation, but all survived and recovered best if desiccated at r.h. >70%; light responses were consistent with measured lower-canopy PAR levels.

1.10.6. Photosynthetic activity of *Haberlea rhodopensis* dehydrated to different extent in natural conditions

K. M. Georgieva[1], L. Maslenkova[1], V. Peeva[1], S. Petkova[1], Z. Tuba[2];
[1]Institute of Plant Physiology, Sofia, Bulgaria, [2]Szent István University, Gödöllő, Hungary.

Photosysthem II (PSII) function was studied in the leaves of resurrection plants *Haberlea rhodopensis* during desiccation in natural conditions and the subsequent rehydration. Thermoluminescence (TL) measurements showed a clear correlation between the changes in the intensity of B- and A- band in TL glow curves with increasing dehydration. The Tmax of the two bands however were practically not changed. The observed stabilization of charge storage in PSII was accompanied by a strong reduction of the TL B-band amplitude, showing a reduction of the number of the operating PSII centers starting at the beginning of dehydration. The rate of oxygen evolution and electron-transport activity dropped more slowly and a threshold at 35-40 % RWC was observed. At this state of dehydration the non-photochemical quenching showed maximal values and sharply decreased with increasing water deficiency. After rehydration of the detached leaves in the dark the PSII functioning was quickly restored. Possible mechanisms for the protection of the photosynthetic apparatus in Haberlea were discussed.

1.10.7. Landscape patterns of vascular resurrection plants: examples from the Western Ghats of India

A. Watve[1], S. Porembski[2];
[1]Agharkar Research Institute, G. G. Agarkar Rd. Pune 411 004. India., Pune, India, [2]Institute of Biological Sciences, Department of Botany, Wismarsche Str. 8, D – 18051 Rostock, Germany, Rostock, Germany.

Desiccation tolerance is a rare adaptive trait in vascular plants. Only about 300 species of angiosperms are known to withstand complete desiccation with monocots outnumbering dicots. Desiccation tolerant plants occur preferentially on rock outcrops in the tropics. Contradictory to the expectation of these plants being rare or unimportant, they form dominant vegetation type in some landscapes. Compared with other regions, sparse information is available on desiccation tolerant species in India. Tripogon (Poaceae) is most important amongst Indian resurrection plants with five species, of which three are endemic. An association of poikilohydric Tripogon lisboae dominates vertical cliffs of Northern Western Ghats which are characterized by highly seasonal climate. The potential habitat of cliff dwelling Tripogon sp. was mapped using slope analysis and extent of distribution was estimated. Western Ghats cliffs are the largest known example of landscape level dominance of resurrection plants where they form a dense vegetation cover on steep vertical cliffs.

1.11.1. Identifying new components in the guard cell signalling network

A. M. Hetherington[1], Y. Liang[1], X. Xie[1], D. Worrall[1], C. Tagliavia[1], S. Clements[2], J. Gray[2];
[1]Lancaster Environment Centre, Lancaster, United Kingdom,
[2]University of Sheffield, Sheffield, United Kingdom.

Guard cells are an excellent model in which to investigate signalling in plants. Their responses to hormonal and environmental signals are easy to measure and provide a highly robust readout against which to test the effects of genetic manipulation of, or pharmacological intervention in, guard cell signalling. A complex signalling network involving changes in guard cell turgor, gene expression, membrane trafficking, cytoskeletal organization and sugar metabolism underlies stomatal movements. The best understood signalling system in guard cells is the closure response stimulated by ABA. Currently we know rather little about how the components involved in ABA signalling are organised in guard cells. Evidence will be presented that guard cell signalling exhibits properties that reminiscent of the emergent properties found in scale free networks (Barabasi and Oltvai 2004, *Nature Reviews Genetics* 5, 101-113) and that increases $[Ca^{2+}]_{cyt}$ might represent a "hub" in this system. In addition recent results concerning the identification of novel components involved in guard cell signalling will be presented.

1.11.2. Guard cell signal transduction from genomics to membrane signaling

J. I. Schroeder[1], J. Young[1], I. Mori[1], D. Mackesy[1], N. Leonhardt[1], Y. Murata[2], J. M. Kwak[3];
[1]University of California, San Diego, La Jolla, CA, United States,
[2]Okayama University, Okayama, Japan, [3]University of Maryland, College Park, MD, United States.

Guard cells have been developed as a model system for dissecting early signal transduction mechanisms. Previous studies have shown that two classes of Ca^{2+} - induced stomatal closing can be separated: rapid Ca^{2+} reactive and long term Ca^{2+} programmed stomatal closing (Allen, et al., *Nature,* 2001 411:1053). However, no genetic evidence exists for Ca^{2+} sensors that function in stomatal movements. Plant genomes include many large gene families producing redundancy which can limit conventional genetic screens. To "narrow down" candidate Ca^{2+} sensor genes for functional characterization we have developed a "single cell-type genomics" approach using guard cells (Leonhardt, Kwak, et al., 2004, *Plant Cell* 16: 596). Using this platform we show important roles for guard cell-expressed Ca^{2+} dependent protein kinases that function in ABA - and Ca^{2+} - activation of anion channels and interestingly also in ABA activation of Ca^{2+} permeable channels. In addition to ABA, high CO_2 concentrations close stomata, but the CO_2 signaling production mechanisms remain less well understood. Data will be presented showing new CO_2 signal transduction mechanisms.

1.11.3. MJ and ABA signaling cascades in guard cell

D. Suhita[1], A. S. Raghavendra[1], **A. Vavasseur**[2];
[1]School of Life Sciences, Hyderabad, India, [2]CEA, St Paul lez Durance, France.

Signalling events during abscisic acid (ABA) or methyl jasmonate (MJ)-induced stomatal closure were examined in Arabidopsis. Stomata of jar1-1 mutant plants are insensitive to MJ, but able to close in response to ABA with a lesser sensitivity to ABA than wild type plants. Reciprocally, the stomata of ost1-2 are insensitive to ABA, but able to close in response to MJ despite to a lesser extent than wild type plants. Both MJ and ABA promote H2O2 production in guard cells, while exogenous application DPI, an inhibitor of NAD(P)H oxidases, results in the suppression of ABA/MJ-induced stomatal closure. ABA elevates H2O2 production in jar1-1 guard cells but not in ost1-2, whereas MJ induces H2O2 production in ost1-2 guard cells, but not in jar1-1. MJ-induced stomatal closing is suppressed in the NADPH oxidase double mutant atrbohD/F and in the outward potassium channel mutant gork1. Analyses of the kinetics of cytosolic pH changes and reactive oxygen species (ROS) production show that the alkalisation of cytoplasm precedes ROS production during the stomatal response to both ABA and MJ.

1.11.4. Protein phosphorylation and dephosphorylation in blue light response of stomata

K. Shimazaki, T. Kinoshita, A. Takemiya;
Faculty of Science, Fukuoka, Japan.

Phosphorylation and dephosphorylation played an important role in blue light response of stomata. Blue light perceived by phototropins, a blue light receptor, is transduced into activation of the plasma membrane H^+-ATPase via phosphorylation. However, the mechanism by which the signal from phototropins is transmitted to the H^+-ATPase is unknown. We report here that protein phosphatase 1 functions as a positive regulator in this process in guard cells. We cloned protein phosphatase 1 from *Vicia* guard cells and determined its predominant expression in guard cells. We constructed the mutant protein of phosphatase 1 that lacked activity, and the mutant was transiently expressed in *Vicia* guard cells. Overexpression of the mutant in guard cells specifically inhibited blue light-dependent stomatal opening in the epidermis. The results suggest that protein phosphatase 1 functions as a positive regulator in blue light signaling. We will provide other supporting data for this result.

1.11.5. Nitric oxide is a signaling component during stomatal closure induced by methyl jasmonate or bicarbonate

V. A. Kolla[1], D. Suhita[1,2], A. Vavasseur[2], **A. S. Raghavendra**[1];
[1]University of Hyderabad, School of Life Sciences, Hyderabad 500046, India, [2]CEA/Cadarache-DSV-DEVM, Laboratoire des Echanges Membranaires et Signalisation, 13108 St Paul Lez-Durance Cedex, France.

Nitric oxide (NO) participates in stomatal responses to abscisic acid (ABA). We report the importance of NO during also methyl jasmonate (MJ) or bicarbonate induced stomatal closure, in epidermal strips of *Pisum sativum* and *Commelina benghalensis*. The presence of SNP (a generator of NO) promoted stomatal closure by MJ or bicarbonate. Suppression of NO levels, by c-PTIO (NO-scavenger) or L-NAME (inhibitor of NO synthase) reversed stomatal closure by ABA or MJ. Real time monitoring with fluorescent DAF-DA indicated that NO production in guard cells peaked at 18 min, compared to 30 min in case of ROS and 15 min in case of pH. The changes in the NO-levels of guard cells and responses to NO-modulators were more pronounced in case of MJ than that of ABA. Our results suggest that changes in guard cell pH and NO are related. However, EGTA reversed stomatal closure, despite the increase in NO-production by MJ or bicarbonate.

1.11.6. ABA signalling in guard cells revisited - New insights from electrophysiological studies in intact plants

R. Hedrich;
Julius-von-Sachs-Institut für Biophysik, Würzburg, Germany.

Fast ABA responses - exemplified by half times of stomatal closure around 5-10 min - is believed to not involve gene activation. Instead stomatal closure is accomplished by the release of potassium ions and chloride as well as the metabolic degradation of the major organic anion malate. In search for ABA signalling intermediates the response of ion channels of guard cells in epidermal peels as well as guard cell protoplasts and vacuoles have been challenged with well-characterized modulators effective in signal transduction pathways of animal cells. Isolated, experimentally well controlled guard cell preparations, however, often lack communication with neighbouring cells, turgor or cytosolic components. Current models, gained from observations on different guard cell preparations, species or not even guard cells are very complex and most likely wrong. To online record changes in ion fluxes across the plasma membrane of guard cells in intact plants, we have developed a method, based on multi-barreled microelectrodes introduced into the cytoplasm of these sensory motor cells. This approach in previous studies was successful in exploring blue- and red light as well CO_2-signalling. Using this online, *in planta* approach together with ABA signalling mutants, we have been able to identify signalling elements required for fast ABAinduced stomatal closure. A model on the ABA-based regulation of guard cell ion transport will be presented at the meeting.

1.12.1. What controls diversity in broad-leaved forests?

E. O. Box, M. Manthey;
University of Georgia, Athens, GA, United States.

Despite climatic relations at broad scale, biodiversity at finer scales is more variable and sensitive to substrate and biotic factors that are hard to identify and quantify. Diversity in relevés in eastern North America is high at intermediate moisture but erratic in warmer areas; woody and non-woody groups respond differently. Existing hypotheses are examined, especially for niche width and range size. Warming responses by broad-leaved forests might include: - initial increases due to weedy invaders, slower increases with less vagile invaders - increases as forest canopies open, but possible decreases as forest microclimates dry out - gradual decrease as long-living canopy trees die out and are not replaced - decreases as populations of sensitive forbs die out faster than they can recolonize. There is evidence for most of these responses, but will insight into diversity controls predict responses to change? This may require more physiological and other knowledge than we possess.

1.12.2. Global gradients of vascular plant diversity

J. Mutke, G. Kier, H. Kreft, W. Küper, D. Rafiqpoor, W. Barthlott;
Nees Institute, University of Bonn, Bonn, Germany.

For the first time we present analyses of latitudinal gradients of species richness for a group as large as the vascular plants on a global scale. The analyses are based on species richness figures for some 2460 operational geographical units such as countries, islands, mountain ranges, or national parks. The comparison of different species richness gradients in different continents is used to demonstrate the variety of trends and influences mixing up in the overall pattern. One of the most important results is that there is no universal latitudinal gradient of plant diversity. However, in accordance with the water-energy hypothesis, constraints imposed by the physical environment, such as the length of the thermal vegetation period or water availability, show high correlations to large scale trends of biodiversity. These trends are modified by historical influences such as long term climatic stability as well as areas with a high diversity of the abiotic parameters - the geodiversity. Highest species richness values can be found in the Tropical and subtropical moist broadleaf forests followed by tropical and subtropical coniferous forests.

1.12.3. The advantages of being evergreen

G. Walther;
Institute of Geobotany, Hannover, Germany.

Conspicuous changes in the composition of deciduous broad-leaved forests have been observed in recent years at the southern foot of the Alps (i.e. in southern Switzerland and northern Italy). Since the early 1970s, the number and frequency of evergreen broad-leaved species is steadily increasing suggesting that this particular plant functional type may profit from changing environmental conditions. In this presentation, possible advantages of evergreen versus deciduous broad-leaved species are presented and discussed in the context of climate change and the global exchange of persons and goods. The trend towards milder winter conditions and prolonged growing season in areas with a temperate climate seems to favour evergreens and to increase their competitiveness against deciduous species. A shift from the deciduous broad-leaved to evergreen broad-leaved vegetation type is presented and exemplified on the species, community and biome level.

1.12.4. Does global change contribute to diversity in broad-leaved forests or is it only a "disturbance"?

K. Fujiwara, T. Yoshino;
Yokohama National University, Graduate School of Environment & Information Sciences, Yokohama, Japan.

There are two main types of temperate broad-leaved forest, evergreen (warm-temperate to subtropical) and deciduous (typical or cool-temperate, plus some warm-temperate). These are separated by various aspects of winter temperature, as related also to moisture and topography. There is already evidence of evergreen broad-leaved species moving into nearby deciduous forests -- and even more into conifer plantations (that stay warmer in winter). The invading species, however, may be native trees of adjacent forests or escaping planted exotic species. Dispersal mechanisms (e.g. birds) and germination ability suggest which kinds of both smaller and larger species that might be relatively mobile under warming. On the other hand, will the newcomers likely represent a real augmentation of natural diversity, as "new native" species, or will the newcomers mostly be exotics taking advantage of a new kind of disturbance? Some insight may be gained from the so-called Jomon Period in Japan (about 6000 years ago), when southern species moved north and some still remain, as relicts.

1.12.5. Forecasting biodiversity response to global change in broad-leaved forests: a role for plant functional types

A. N. Gillison;
Center for Biodiversity Management, Yungaburra, Australia.

A generic method of vegetation classification using a plant functional grammar and a minimum set of plant functional attributes was applied to a representative series of broadleaved forest sites from high to equatorial latitudes. Analyses reveal predictible changes in suites of plant functional types (PFTs) along defined physical environmental gradients. These studies suggest sieving out of certain PFTs under changing physical environments may have irreversible consequences for biodiversity. Case studies from complex humid tropical forest mosaics in Sumatra and the Western Amazon basin illustrate how PFTs used in association with plant vascular species can enhance the prediction of certain faunal groups. These suggest that (a) a radically new approach to vegetation typology may be required for biodiversity management and (b) biodiversity assessment of forests should include contextual, gradient-based sampling of other vegetation types. It is argued that methods of forest typology that include PFTs rather than relying solely on plant species and structure may provide a more efficient basis for forecasting biodiversity response to global change.

1.12.6. Bioclimatic and historical aspects of biodiversity in the broadleaved forests of mainland Northeast Asia

P. V. Krestov[1], J. Song[2];
[1]Institute of Biology & Soil Science, Vladivostok, Russian Federation,
[2]Andong National University, Andong, Republic of Korea.

An analysis is presented of biodiversity in the world's richest temperate-zone deciduous forests, dominated by broad-leaved species of *Acer*, *Fraxinus, Kalopanax, Quercus, Tilia, Ulmus* and by temperate coniferous species of *Pinus* and *Abies*. The vegetation in cold-temperate maritime regions belongs to the Tilio amurensis-Pinetalia koraiensis, in cool-temperate maritime to the Aceri pseudosieboldianae-Quercetalia mongolicae (both Quercetea mongolicae), in cold-temperate continental to the Querco mongolicae-Betuletalia davuricae, and in cool-temperate continental to the Lespedezo bicoloris-Quercetalia mongolicae (both Querco mongolicae-Betuletea davuricae). The cause of the high biodiversity is a strong drying during the late Pleistocene cooling 18,000 BP. Montane refugia with mesic conditions, in combination with the immigration of drought-tolerant species, created a mixture of ecologically contrasting floristic elements linked to different geographical regions. The occurrence of a seasonal period of moisture deficit in late spring is the most important climatic factor dividing forest classes in temperate mainland Northeast Asia.

1.12.7. Potential habitat suitability changes for 135 tree species in the Eastern United States following climate change

L. R. Iverson, A. Prasad, S. Matthews;
USDA Forest Service, Delaware, OH, United States.

Evidence mounts for biological shifts underway due to climate change, and these shifts will increase over this century. Our analysis of 135 tree species in the Eastern United States, using two scenarios of climate change and over 30 climate, soil, and landscape predictors, shows the potential for substantial shifts in species ranges. Our statistical model, DISTRIB, has been modified to use three classification and regression tree processes for best model generation, prediction, and understanding. Regression tree analysis (RTA) produces one tree with drivers of distribution clearly elucidated; bagging trees (BT) essentially averages 30 RTA models via subsets of observations to attain better prediction and allows multiple statistics to evaluate the model; and random forests (RF) essentially averages 1000 RTA models with random subsets of observtions and predictors to create the best prediction. Results of the 135 species runs shows northward migration of habitat, calculated via a statistic of 'optimum latitude' for a large proportion of the species. The habitat shifts also produce concomitant changes in tree biodiversity across the region.

1.13.1. Harmful algal blooms: from molecular processes to global ocean phenomena

G. M. Hallegraeff;
School of Plant Science, University of Tasmania, Hobart, Australia.

Algal blooms range from harmless water discolorations, to species that cause mortalities of finfish in aquaculture, and those that produce neurotoxins which can kill human consumers of seafood. Since many blooms are nearly monospecific, correctly assessing the taxonomic and genetic identity of the organisms is crucial in deciding whether knowledge from similar blooms can be applied to the local conditions. Evidence for an alarming global increase in the past three decades in the frequency, intensity and geographic distribution of HABs has been partly attributed to increased public awareness and increased utilisation of coastal waters for aquaculture. However, coastal eutrophication, global climate change and ship ballast water are contributing to the increasingly detrimental effects of algal blooms on fisheries, aquaculture, human health, tourism, marine environment and regional economies. Molecular approaches and remote sensing are now providing us with the forensic tools to resolve the key mechanisms responsible for algal blooms, allowing human society to make well-informed decisions on adequate control, management and mitigation strategies.

1.13.2. Long-term effects of coastal blooms on phytoplankton community structure

R. J. Livingston;
Florida State University, Tallahassee, FL, United States.

We used a 16-year multidisciplinary database in the Perdido River and Bay system (NE Gulf of Mexico) to determine responses of phytoplankton assemblages and associated coastal food webs to natural and anthropogenous nutrient loading. Orthophosphate and ammonia loading from a pulp mill generated a series of plankton blooms dominated by diatoms, raphidophytes, dinoflagellates and cyanobacteria. Blooms followed species-specific seasonal patterns. Interannual phytoplankton trends were associated with nutrient loading and rainfall cycles. Initial diatom blooms were replaced by raphidophytes and dinoflagellates in time. Bloom effects on phytoplankton assemblages included initial reductions of species richness and diversity, competitive exclusion of various species, direct and indirect replacement processes, and altered nannoplankton trends. Long-term changes indicated complex adaptive processes that led to non-linear responses to nutrient loading and time-based alterations of interspecific relationships. Changes in phytoplankton composition were associated with damaged food webs, population losses and reduced secondary productivity.

1.13.3. Eutrophication trends and consequences in the inshore-offshore system of the Aegean Sea, Eastern Mediterranean

L. Ignatiades;
Institute of Biology, National Research Center 'Demokritos' Ag. Paraskevi, Attikis, Athens, Greece.

The Aegean Sea is one of the most oligotrophic areas of the eastern Mediterranean but certain inshore regions within the Aegean Sea were characterised as mesotrophic and eutrophic on the basis of environmental and phytoplanktonic parameters recorded during the period 1996 - 2003. A total of 35 stations were sampled from the northern to the southern open waters and from inshore to offshore waters of the Aegean Sea. Data of nutrients, chlorophyll Ŭ, and primary production were analysed statistically on the basis of probabilistic statistics in order to classify the trophic status of the examined regions. The levels and limits of the values of each one of these parameters were defined, scaled and summarized by the expression 'open oligotrophic'<'offshore mesotrophic'<'inshore eutrophic' waters. Underwater light penetration, and phytoplankton cells (quantitatively and qualitatively) also were recorded. The effect of the trophic status of the water on phytoplankton community structure was evaluated on the basis of the patterns of seasonality, species composition and diversity, and the development of harmful algal blooms.

1.13.4. How do harmful raphidophyte blooms occur predominantly over diatoms in coastal sea?

I. Imai[1], S. Itakura[2], M. Yamaguchi[2];
[1]Kyoto University, Kyoto, Japan, [2]National Research Institute of Fisheries and Environment of Inland Sea, Hiroshima, Japan.

Raphidophytes such as *Chattonella* spp. and *Heterosigma akashiwo* have recurrently caused harmful algal blooms accompanying mass mortalities of cultured fish in coastal waters. Diatoms also form red tides with no harmful effects usually. Diatoms generally show faster growth rates than raphidophytes; still raphidophytes cause red tides. How can they? Raphidophytes and diatoms have benthic cysts and resting stage cells in their life cycles, respectively. It is empirically known that raphidophyte blooms have been observed when diatoms are scarce in water columns. Diatoms tend to form resting stage cells under nutrient-deficient conditions, and rapidly sink to bottom and disappear from the water columns. In addition, Raphidophyte cysts can germinate in the dark, whereas diatom resting stage cells require light for germination. Thus the predominance of raphidophytes might be related to the disappearance of diatoms and subsequent failure of germination of their resting stage cells under low light conditions. The selective germination of cysts at the sea bottom is presumably a significant factor for the initiation and success in raphidophyte red tides.

1.13.5. Bacterioplankton community structure as affected by different harmful algal bloom events in W Mediterranean coastal waters

E. Garcés[1], M. Vila[1], A. Reñe[1], L. Alonso-Sáez[1], M. Masó[1], A. Lugliè[2], P. Gasol[1];
[1]Institut de Ciències del Mar, CSIC, Barcelona, Spain, [2]Dipartimento di Botanica ed Ecologia vegetale, Sassari, Italy.

The CARD-FISH protocol was used to assess the spatial and temporal variation in abundance and composition of dominant groups of bacterioplankton during different harmful dinoflagellate bloom events in the littoral of the W Mediterranean Sea. The composition of the bacterial community differed considerably during the different bloom phases studied. *Cytophaga/Flavobacteria* (CFB) were abundant in the development phase and comprised 47% of total cells assigned to the main bacterial groups (CFB plus Ŭ- and ɔ-proteobacteria). During the maintenance phase, the proportion of CFB decreased, whereas *Ŭ-Proteobacteria* increased. The *Ŭ-Proteobacteria* became the most important group (71%) during the non-bloom period. The ɔ-*Proteobacteria* maintained low proportions (7-11 %) at all time. During the spatial variability study, *Ŭ-Proteobacteria* dominated the bacterial community (51 %), followed by CFB (35 %), while ɔ-*Proteobacteria* comprised substantially lower proportions (13 %). This community structure was similar to that observed during the maintenance phase of the bloom in the temporal study, which suggested that this bacterial community structure is typical for dense phytoplankton blooms in the studied coastal waters.

1.13.6. Potential effects of global climate change (elevated CO_2, temperature and UVB) on phytoplankton population composition

S. Stojkovic[1], J. Beardall[1], J. A. Raven[2];
[1]Monash University, Clayton, Australia, [2]University of Dundee at SCRI, Scottish Crop Research Institute, Dundee, United Kingdom.

We are living in an era of rapidly changing climatic conditions with CO_2 set to at least double in the next 100 years, sea surface temperatures to rise by an average of 2-3 ^{o}C and with an increase in UVB fluxes at high latitudes. Using data from the literature, we will present physiologically based predictions, substantiated where possible with available data on aquatic systems, about the likely consequences of climate change on phytoplankton composition. For example, microalgae show species specific responses of photosynthesis and growth to elevated CO_2 and UVB - might we then see changes in population structure related to these factors? Since individual species have distinct temperature ranges, even small increases in temperature could have significant effects on population composition, as well as causing earlier onset of spring blooms. Temperature changes can also affect the onset of stratification in the water column- indirectly this can influence community structure through effects on the supply of nutrients from deeper water. All aspects of predicted climate change are thus likely to have major effects on the function of aquatic ecosystems.

1.14.1. Evolutionary systems theory as transdisciplinary methodology. The legacy of Ludwig von Bertalanffy

W. Hofkirchner[1,2];
[1]ICT&S Center, University of Salzburg, Salzburg, Austria, [2]Bertalanffy Center for the Study of Systems Science, Vienna, Austria.

Ludwig von Bertalanffy is known as founding father of the General System Theory (GST). When he created his GST amidst the last century, he was able to overcome the deep cleft between the controversial theoretical approaches to biology - mechanicism and vitalism. He formulated laws of organisation ruling biota and after generalising them he successfully applied them to different domains such as medicine, psychology, psychotherapy. His main concern was the fate of the human civilisation and the new way of thinking necessary for the survival of mankind. Evolutionary systems theory - as a theory about evolving systems and as a theory that is the result of the merger of systems theory and evolutionary theory - is the most recent elaboration of Bertalanffy's original GST-ideas. It revolves around the notion of self-organisation. It provides a transdisciplinary framework for consilience throughout science.

1.14.2. Scientific and 'Non-Scientific' Ways of thinking

K. W. Kratky;
Institute of Experimental Physics, Vienna, Austria.

First various aspects of language and communication are addressed. Then we consider worldviews and scientific theories, which will lead us to four perspectives or ways of thinking: the systematic, systemic, symbolic and symbiotic views, with which we can look at the world. In our Western society, especially the logical/ systematic perspective is common (motto: 'either - or'), which corresponds to classical natural science. Additionally, also the cybernetic/ systemic view (motto: 'as well as') can be found in the social sciences, and the constructivistic/ symbolic view (motto: 'on one hand - on the other hand') refers to the humanities. However, the holistic/ symbiotic view (motto: 'two sides of ONE coin') fits in better with the spiritual realm that plays an important role in traditional societies. Altogether, these considerations encourage a transdisciplinary perception.

1.14.3. Monte Grande, disturbed forest: a semiotic explanation

J. A. Escutia[1], N. Estrada[2];
[1]Departamento de Ecología y Recursos Naturales, Facultad de Ciencias, México, D. F., Mexico, [2]Facultad de Ciencias Políticas, UNAM, México, D. F., Mexico.

The aim of this work is to show how the ecological research and the production of meanings are similar. The knowledge of the world is through the interpretation of the representations and models of the reality, for example, the structural analysis of vegetation to study Monte Grande's cloud forest (Hidalgo, Mexico). Data of flora, basal area, density, vertical and diametric structure, from the perspective of Semiotics will be representations of the forest. After the interpretation of these elements and their relationship, and after the structural comparison: minimal value of basal area, poor density of tall trees with large BHD, high density of multistem trees, and the increase of the relative value of favored species. These findings indicated that this is a damaged forest. The only possible way to arrived at this conclusion was by the study of representations of the forest and their comparison with representations of other forests. As we can see, the study of a ecological problem and the production of meanings are similar because ecological knowledge, as well as knowledge of the world, is result of the analysis of forest' representations not of the forest itself.

1.14.4. Therapeutic Horticulture in Austria

N. Fahnl, **M. Putz**;
Austrian Association of Horticulture, Vienna, Austria.

Historically gardening and horticulture constituted important components of work therapy programs operating in mental health institutions. The main orientation was food production. Since the late 1970's there was a paradigm shift towards programs providing more positive, value added and reinforcing experiences. In the last years horticultural therapy has bees developed as a special domain in public health.

In 2002 the first international congress on therapeutic horticulture took place in Vienna - organised by Austrian Association of Horticulture. It took occasion to celebrate it's 175'th anniversary by supporting the development of therapeutic horticulture.

Research on therapeutic horticulture is still scare in Austria. There are treatises from various aspects which should be connected in the future: landscape architecture, sociology, botanic and agriculture, occupational therapy, education and psychology, medical and health care. The need for applied research is central in gaining recognition and acceptance.

Since October 2004 a group of experts of the different science and occupations work at the specification of horticultural therapy.

1.14.5. The influence of radiesthetic phenomena on growth, yield and fruit quality of strawberries (*Fragaria ananassa*)

R. Brunmayer, H. Keppel, A. Spornberger;
Institute of Horticulture, Fruit Growing and Viticulture, Vienna, Austria.

The effect of radiesthetic phenomena on plants is a less known subject. Plants react to radiesthetic influence with stunting, shifted growth, devitalized constitution and sometimes even with dying. In 2004 a field trial experiment in eastern Austria should clear up this phenomena on growth, yield and susceptibility to pests and diseases of strawberries. In addition fruit quality characters were analysed: P-value (pH-value, conductivity, redox potential), dry matter content, emission of biophotons, fruit-shape-index, mechanical strength of fruit and others. While there were no differences in growth and yield characters, analysis of biophoton-emission showed a higher vitality of fruits on plants with radiation up to a certain level. A relationship between healthy leaves and dry matter content of leaves was also found. Data from P-value and biophoton-emission were comparable. Experiments to check the influence of radiesthetic phenomena on other fruit species are planned.

1.15.1. Biodiversity in organic agriculture (OA)

U. Köpke;
Institut für Organischen Landbau, Bonn, Germany.

OA generates goods benefits through contributing significantly to the conservation and enhancement of agricultural biodiversity. Historically, farmer-designed biodiversity is represented by crops and livestock integrated and linked to a diversified crop rotation that is considered as the key element of OA. The broader spectrum of associated biodiversity including weeds and beneficial plants, soil fauna, herbivores, carnivores and composers is mediated through diversified planned biodiversity. These respond with increased abundance and/or species richness. Biodiversity in OA provides agroecosystem services beyond the production aspects, such as regulation of abundance of undesirable organisms, pests and pathogens, better use of natural resources and agroecosystem stability in general. Better knowledge of the interdependencies of the organisms and habitats involved will lead to more precise agroecosystem management, thus benefiting the biodiversity components supporting sustainability. The associated biodiversity will thus become a more and more productive and planned biodiversity.

1.15.2. Biodiversity in some organic farms, Thailand

A. Duangpaeng, S. Chamratpan;
Udon Thani Rajabhat University, Udon Thani, Thailand.

Biodiversity of three organic farms in Thailand was surveyed in 2004. After harvesting rice, pumpkin (*Cucurbita pepo*), *Sesbania* sp., sword bean (*Canavalia gladiata*) and melon (*Cucumis melo*) were grown in 'Poa Man Samsee' rice organic farm and were tilled into the soil to improve soil fertilizer. The liquid bioextract made from fish, vegetable, and microorganisms was filled into farmland. It increased high yield and small animal in puddle fields. The mixed crop farm of 'Poa Prayong' cultivated rice (*Oryza sativa*) as the main crop. Many kinds of bamboos (*Bambusa membranacea, B.nutans, Dendrocalamus asper*) were grown as natural guard rows. Mango (*Mangifera indica*), calamus (*Calamus diepenhorstii*) and banana (*Musa sapientum*) were grown around rice puddle. Many kinds of vegetable such as papaya (*Carica papaya*), cow pea (*Vigna unguiculata*), egg plant (*Solanum melongena*), and rose apple (*Syzygium malaccense*) were cultivated in the organic vegetable farm of 'Rai Ton Nuei'. Soil microorganism was mainly sprayed with irrigation. Indian hemp (*Crotalaria juncea*) seeds were sow in bed during vegetable rows for fixing nitrogen and improvements in pest management.

1.15.3. Biological control of apple blue mold with *Pseudomonas fluorescens*

H. R. Etebarian[1], P. L. Sholberg[2], K. C. Eastwell[3], R. J. Sayler[4,5];
[1]Abourayhan Institute, Tehran University, Tehran, Islamic Republic of Iran, [2]Pacific Agri-Food Research Centre, Agriculture and Agri-Food Canada, Summerland, BC, Canada, [3]Washington State University – IAREC, Prosser, WA, United States, [4]Department of Plant Pathology, Univeristy of California, Davis, CA, United States, [5]Department of Biological Sciences, University of Arkansas, Fayetteville, AR, United States.

Pseudomonas fluorescens isolate 1100-6 was evaluated as a potential biocontrol agent for control of apple blue mold caused by *Penicillium expansum* or *P. solitum.* Both the wild-type isolate 1100-6 and a genetically modified derivative, labeled with the gene encoding the green fluorescent protein (GFP) were compared. The *Ps. fluorescens* isolates with or without GFP equally reduced growth of *Penicillium* spp. and produced large zones of inhibition in dual culture plate assays. Cell free metabolites produced by the bacterial antagonists reduced colony area of the *Penicillium* isolates by 17.3 to 78.4%. *Ps. fluorescens* with or without GFP significantly reduced apple decay severity and percent incidence of infected wounds caused by two *P. expansum* isolates after 11 days at 20°C and by *P. expansum* and *P. solitum* after 25 days at 5°C when the biocontrol agents were applied in wounds 24 or 48 hours before challenging with *Penicillium* spp. These results indicate that *Ps. fluorescens* isolate 1100-6 could be an important new biological control for apple blue mold and should be considered for commercialization.

1.15.4. Diversity and importance of arbuscular mycorrhizal fungi (AMF) in organic farming

M. J. Gollner, J. K. Friedel, B. Freyer;
Division of Organic Farming, Wien, Austria.

AMF are symbionts in most agroecosystems, colonizing the roots of the majority of crop plants. They absorb mineral nutrients by their extended hyphal network from nutrient poor soils and deliver them to their host plant in exchange for carbohydrates. AMF can also enhance the resistance to root pathogens and abiotic stresses, such as drought. Furthermore, AMF play an important role in the formation of stable soil aggregates that prevent soil erosion. Because of these beneficial effects, it is a challenge to develop management strategies beneficial to AMF and applicable for sustainable agricultural systems such as organic farming (OF). Industrial farming practices are apparently detrimental for AMF, as recent studies indicate declining AMF performance with agricultural intensification. However, little is known about the effect of agricultural practices in OF on the diversity of AMF. An overview over the current knowledge and results of our own studies about the effect of agricultural practices in OF on the diversity and root colonisation of AMF will be presented and discussed.

1.15.5. Scenarios for the development of biodiversity in organic farms Uganda

C. Walaga;
Institute of Organic Farming, University of Natural Resources and Applied Life Sciences, Vienna, Austria.

The current status of the biodiversity - field crops and accompanying biotopes - in Organic Farms in Uganda can be characterised by a high competition between limited farm land and overgrazing. Further more there is a lack of training and extension, which introduces the organic farmers into the significance of biodiversity in both a diversified cropping system and the integration of biotopes into the farming system, as a basic management tool to offer predators and beneficials suitable habitats. The study is therefore discussing scenarios focussing the potential of establishing biodiversity in Organic Farming. The status quo of biodiversity in Organic Farms is described, based on expert interviews of advisers and researchers. In a second step, the perspectives of biodiversity in Organic Farms are described with scenario technique. The key factors are identified by a systems analysis and an impact- and SWOT- analysis is acquired by stakeholders of the Organic Farming product chain. The scenarios show, the endogen potential to drive the biodiversity by farmers and their limiting factors. A policy paper summarises the perspectives to strengthen the biodiversity in Organic Farms under the specific conditions in Uganda.

1.15.6. Biodiversity in organic smallholder farms of Nakuru District, Kenya

R. N. Onwonga, B. Freyer;
Institute of Organic Farming, University of Natural Resources and Applied Life Sciences, Vienna, Austria.

To get basic information on the management status of organic smallholder farms, but also their biodiversity status, a study was carried out in Molo, Lare and Gilgil administrative divisions of Nakuru district, Kenya, from January 2003 to January 2005. A total of 36 farmers, twelve from each study site representative of the socio-economic classes were involved in the study. Besides several analysis on cropping system, nutrient management, organic matter balance and economy of the farms, an investigation on crop diversity, biotopes, their structures and plant species was carried out. The study shows site, management and individual preferences based diversity of biotopes and species. Where as several studies discuss the potential of biodiversity in organic farms in humid zones, concrete investigation of the biodiversity status in organic farms in tropical environments are scarce. Therefore the overall value of this study is to get first data on biodiversity as a basis for the evaluation of the sustainability of organic farming practises in tropical environments.

1.16.1. Plant fibres for composites: promises, problems and strategies for effective utilisation

G. Jeronimidis;
Centre for Biomimetics, The University of Reading, Reading, United Kingdom.

Plant fibres are a valuable source of high quality renewable and biodegradable materials. Paper and paper-based products owe their success to wood fibres made by trees. Similarly, non-wood fibres with their the combination of high-modulus, high-strength cellulose microfibrils, layered cell walls and low density can compete successfully with many synthetic technical fibres in a wide range of applications, composite materials being particularly important because of their added value. One of the main perceived obstacles to a greater acceptance of plant fibres is their variability. This is the result of intrinsic plant variability, agronomic practices, etc. and also of poorly developed extraction methods. Solution to this problem requires better understanding of the factors which control fibre structure formation, and hence properties, in plants and development of extraction technologies which take more account of the biological design of these fibres, with its advantages and limitations.

1.16.2. Wood-based nanocomposites

L. A. Berglund;
KTH, Stockholm, Sweden.

Nanocomposites based on microfibrillated cellulose, MFC, represent a new way of utilizing the inherently high modulus and strength of cellulose. MFC is obtained by disintegration of cellulose in, for instance, animals, wood, fruits, vegetables or algae.

Bacterial cellulose can also be used. A typical lateral dimension of such fibrils is 30 nm whereas the lengths could be several micrometers. The Young's modulus of cellulose is comparable with high-performance fibers such as aramide (Kevlar™). This is due to the highly packed, extended chain conformation of cellulose in its crystalline forms in nature. The model studies performed, predominantly in France, are likely to inspire an expansion of this research area. One interesting possibility is new nanocomposites mimicking the plant cell wall. In order for materials based on microfibrils to make the transition into industrial technology, consideration of cheap disintegration routes from the cell wall is required. In this context, wood pulp and waste products from the food industry in the form of vegetable and fruit pulp (or cattle feed pellets based on those pulps) are of interest as sources of cellulose.

1.16.3. Structure-property relationships in the loblolly pine cell wall: Interaction with synthetic polymers

T. G. Rials[1], W. Tze[1], S. Wang[1], S. Kelley[2], G. Pharr[1];
[1]The University of Tennessee, Knoxville, TN, United States, [2]National Renewable Energy Laboratory, Golden, CO, United States.

While engineered wood composites continue to make great strides in properties and performance, durability of the adhesive bond remains of utmost concern. To address this issue, as well as other performance characteristics of wood-based composites, progress must be made toward understanding the fundamental nature of cell wall polymer-synthetic resin interaction. This presentation builds on earlier reports by applying nanoindentation to loblolly pine specimens varying in age and microfibril angle. Comparing results from this experimental approach and conventional mechanical bending tests, surprisingly consistent trends were observed for both hardness and modulus. Additionally, experiments on adhesive bond lines prepared with phenol-formaldehyde and isocyanate adhesives, revealed little difference in hardness between resin, wood, and interphase. However, dramatic effects were seen in the time-dependent, rheological properties as distance from the bond line increased.

1.16.4. Bio-nanocomposites based on cellulose nanofiber

H. Yano[1], A. N. Nakagaito[1], S. Iwamoto[1], M. Nogi[2];
[1]Research Institute for Sustainable Humanosphere, Kyoto University, Uji, Japan, [2]International Innovation Center, Kyoto University, Kyoto, Japan.

A completely new kind of high strength composite was manufactured using microfibrillated cellulose (MFC) derived from kraft pulp. Because of the unique structure of nano-order-scale interconnected fibrils and microfibrils greatly expanded in surface area that characterizes MFC, it was possible to produce composites that exploit the extremely high strength of microfibrils. The Young's modulus and bending strength of composites using phenolic resin as binder achieved values up to 19GPa and 370MPa, respectively, with a density of 1.46g/cm2. To evaluate how the degree of fibrillation of pulp fiber affects the mechanical properties of the composites, kraft pulp subjected to various levels of refining and high pressure homogenization treatments was used as raw material with different phenolic resin contents. It was found that fibrillation solely of the surface of the fibers is not effective in improving composite strength, though there is a distinct point in the fibrillation stage at which an abrupt increase in the mechanical properties of composites occurs. The increase was attributed to the complete fibrillation of the bulk of the fibers.

1.16.5. Cellulose Fibrils: Isolation, characterisation and technical application

K. Richter, T. Zimmermann, E. Poehler, T. Geiger, J. Schleuniger;
Swiss Federal Laboratories for Materials Testing and Research, Duebendorf, Switzerland.

Agglomerated cellulose fibrils embedded in a lignin matrix in the cell wall are a predominant reason for the outstanding specific tensile strength of wood. In order to convert these mechanical properties to practical use for polymer composites, fibrils were isolated out of sulphite pulp and characterised by Scanning Electron (SEM) and Transmission Electron Microscopy (TEM). Depending on the disintegration method, the fibrils have diameters in the nanometer and lengths in the micrometer range. Homogeneous, transparent fibril films and polymer composites with two water soluble polymers were prepared. Tensile tests as well as nanoindentation experiments were carried out to determine the mechanical properties of the composites. The addition of fibrils led to a significant increase of the Young`s modulus, the tensile strength, the elongation to rupture and the hardness. Atomic Force Microscopical (AFM) and TEM investigations provide evidence for a homogeneous distribution and network formation of the fibrils within the polymers. The results of this study and the perspectives of producing new bio-based nanomaterials are promising.

1.16.6. Cell-wall Mimicking Cellulose-xylan Nanocomposites

P. Gatenholm, S. Damström;
Chalmers University of Technology, Göteborg, Sweden.

The wood secondary cell wall exhibits a hierarchical organisation where the distribution and interactions of the constituents on different scales strongly affects the overall performance and particularly mechanical properties. In this study we have prepared cell wall-like, nanostructured materials by assembly of microfibrillar cellulose, produced by *Acetobacter Xylinum*, and xylans extracted from wood and annual plants. Nanocomposites were characterised by several different techniques including atomic force microscopy (AFM), scanning electron microscopy (SEM) and the properties were evaluated by mechanical testing. AFM analysis shows that the materials were composed of a network of randomly oriented microfibrils with xylans in shape of aggregates between and/or covering the cellulose microfibrils. We found a strong effect of the molecular structure of xylan onto mechanical performance of nanocomposites, particularly with regards to effect of moisture. The effect of other hemicelluloses, as well as refinements of the spatial arrangement of the components of the composite, are currently under evaluation

1.16.7. Nanocomposites of cellulose whiskers and biopolymers

K. A. Oksman, A. P. Mathew, D. Bondeson, L. Petersson, I. Kvien, B. Tanem;
Dept. of Engineering Design and Materials, Trondheim, Norway.

New nanostructured composites, where both the reinforcement as well as the matrix are bio based are interesting materials for medical and packaging applications. Cellulose is the most abundant natural polymer on the earth and combined with natural polymers like starch, cellulose acetate or poly lactide acid will lead to development to new type of biodegradable and environmental friendly bionanocomposites. This new family of nanocomposites is expected to have remarkable improvement of material properties when compared with the matrix polymers or conventional micro- and macro-composite materials. Such improvements can include a higher modulus and strength, a decrease in gas permeability, increased heat distortion temperature, and an increase in the biodegradability rate of biodegradable polymers. The first phase of our work has been to study the separation techniques of micro crystalline cellulose to be able to obtain cellulose whiskers and processing of nanocomposites. The second phase has been to characterize the nanostructures with atomic force microscope (AFM) and transmission electron microscope (TEM) and study the composites thermal and mechanical properties. Our results show that cellulose whiskers can be obtained from microcrystalline cellulose. These cellulose whiskers are 10-20 nm in diameter and the length varies between 300-500 nm. The prepared composites have a nanostructure and shows improved properties compared to pure polymer matrix.

1.17.1. In the future, botanical information will be everywhere

R. A. Morris;
UMASS-Boston, Boston, MA, United States.

Google and rough computations suggest that at least 25,000 institutions serve botanical data, a number probably growing rapidly. In the future, botanical information will be everywhere. How will information from this vast store be discovered, evaluated and integrated? One contemporary answer is a divide-and-conquer technology known as Service Oriented Architecture in which "middleware," imposed between databases and users, provides a single kind of data, so one service might provide digitized specimen records, another taxonomic history for the names in those records, etc. Integrating the results is facilitated by a number of international data exchange standards. I'll describe some of these and give two examples from our Electronic Field Guide Project. One is "guided" taxonomic id keys which, at decision points, make calls to remote databases for data to assist the decision, and at terminals, make calls to produce descriptive species pages. Second is a kind of “data mule” in the form of JPEG2000 image files, copies of which travel to different human and software agents via the internet to obtain, annotate or deliver images from the field, lab, garden or museum.

1.17.2. The metaherbarium - benefits for data providers as well as users

M. A. Lane, L. Speers;
Global Biodiversity Information Facility (GBIF), Copenhagen, Denmark.

Collectively, the 6000 herbaria that are distributed around the world provide the most complete view available of the historical and current distribution of the flora of the planet. But, because of the generally opportunistic way each collection has expanded through its history, it is difficult for potential users, without physically visiting a given collection, to fully ascertain the coverage of its holdings from either a temporal, spatial or taxonomic perspective. However, the enormous value of these collections’ collective holdings -- what may be called the global MetaHerbarium -- can be realized via digital sharing of specimen information. Use of common Global Biodiversity Information Facility (GBIF)-endorsed standards for data exchange brings visibility to otherwise unknown collections, and allows participating herbaria to receive attribution for sharing data from any of their holdings that respond to user queries of many types, thus validating institutional and societal support.

1.17.3. Automated georeferencing for natural history collections

R. S. Beaman, Y. Guo, A. Green;
Peabody Museum of Natural History, New Haven, CT, United States.

Quantitative geospatial references are critical elements of botanical collection data, because they enable us to integrate information within and beyond the biological domain. Of the various classes of information linked to biological specimens, geospatial coordinates used for mapping species distributions are among the most widely demanded by the scientific community and the general public. Geospatial referencing provides the means to link specimen data to the rapidly growing body of spatial environmental data for interdisciplinary research into complex phenomena. For example, access to geospatially referenced data from specimens provides a quantitative basis for biodiversity analyses and predictive niche modeling and for determining sampling densities of various sites. Providing spatial coordinates for collections has proven a significant challenge. Nearly every specimen is associated with a textual representation of the place from whence it came, but few carry with them quantitative geospatial coordinates. We address here advances made in automating the task of geospatial referencing for biological collections.

1.17.4. Integrating geospatial and natural history collections data in a web-accessible database for New Mexico

C. K. Frazier;
Institute of Natural Resource Analysis and Management, Albuquerque, NM, United States.

Digitizing herbaria specimen information can facilitate collection management processes (e.g., label generation, annotation history tracking, and transaction documentation), make the collection’s holding more widely known and easier to access, and provide basic data of utility to science and the general public. Over the past two decades, herbaria and other biological museum collections throughout the world have initiated numerous, largely independent digitization projects that differ in technical complexity, data model, and basic functionality. In this talk, I will discuss our efforts to provide support for digitization, georeferencing and electronic data access to small to medium-sized collections (10 - 200k specimens) in New Mexico. I will feature aspects that allow collections to become involved even with limited technical capabilities and resources and which allow them to participate in larger data accumulation projects at the state, national and international levels.

1.17.5. Virtual herbaria: challenges and goals

G. F. Guala;
USDA-NRCS, Baton Rouge, LA, United States.

Although long dreamt of, and debated in many forms, at the time of the last IBC, the Virtual Herbarium as a fully realized entity was in its infancy. In the intervening years a large number of virtual herbarium projects have sprung up. Significant efforts are now being directed at large scale integration so that the dream of a globally integrated Virtual Herbarium is within reach. In this presentation, an overview of some of the various types of virtual herbarium efforts will be given. The challenges and potential payoff of some technologies unique to those efforts, and for massive integration of them, will be examined. The role of a *de facto* global virtual herbarium in other enabling science such as automated keys and earth observing systems will be examined. Finally, the very special place of virtual herbaria among the rapidly expanding plethora global biodiversity data will be discussed.

1.17.6. Rapid digital specimen image and data capture: a web services solution

N. Cellinese[1], R. Beaman[1], B. Heidorn[2], A. Green[1], Y. Guo[1];
[1]Peabody Museum of Natural History, Yale University, New Haven, CT, United States, [2]University of Illinois, Urbana-Champaign, Champaign, IL, United States.

The technology required for digital image capture of specimens has become affordable, if not yet commonplace. Digital imaging projects often do nothing more with images than make them available for web display. However, an image can serve the additional purpose as the basis for label data capture. Along with specimen images, label data, particularly georeferenced label data, is a valuable public product for collections. Our ultimate goal is to reduce the total cost of digital collection data capture by significantly reducing human labor required and total project duration. Clicking the shutter on a digital camera initiates a sequence that culminates with the population of label data and a specimen image into a structured collection database. Significant gains can be achieved by developing appropriate protocols and methodologies, then packaging them as web services. We are using open source and commercial solutions, and are developing solutions where necessary that accelerate the herbarium specimen data capture process. Each of these solutions is embedded into web services, providing benefits such as cross-platform interoperability and scalability.

1.17.7. Georeferencing primary biological collections - validation, cleaning and quality control

A. D. Chapman;
Australian Biodiversity Information Services, Toowoomba South, Queensland, Australia.

The introduction of the World Wide Web opened up the possibility of exchanging primary species data (specimens, observations and survey data) between institutions and for making them available to researchers and others via the Internet. One of the key aspects of making those data useful is the geocoding associated with them - their coded location, for example latitude and longitude. The process of adding georeferencing information is a major source of error and badly georeferenced records can lead to real loss of quality and thus usefulness. Examination of data currently being exchanged via the Global Biodiversity Information Facility Data Portal, shows great variation in the quality of the georeferencing, and that very few institutions have introduced detailed data quality control procedures for validate the data and their georeferencing. Techniques for checking, validating and cleaning the georeferencing or records have, and are being, developed and refined. This paper examines a range of methods - some stand-alone, some via the use of Web Services - and recommends ways that institutions may introduce these into their Data Quality Control procedures.

2.1.1. The bread of polyploidy

A. A. Levy, F. Belinky, A. Shperberg, C. Bessudo-Melamed, N. Barkai;
Weizmann Institute of Science, Rehovot, Israel.

Wheat and yeast both represent contrasting models to study the genetic and epigenetic changes that occur upon polyploidization. The wheat group contains diploid, tetraploid and hexaploid species. Polyploidization occurred ~ 0.5 Mya for tetraploid wheat (genome BBAA) and only ~9,000 Years ago for hexaploid bread wheat (Genome BBAADD). Bread wheat is a young allopolyploid with a very large genome and relatively limited amount of genomic infrastructures. By contrast, yeast is an ancient allopolyploid with a small and fully sequenced genome and with extensive expression data publicly available. With the recent sequencing of the whole genome of several yeast species, including six sensu stricto

Saccharomyces species that can be hybridized to form interspecific hybrids and allopolyploids, yeast has become a paradigm to study the genetic and epigenetic changes that occur during speciation via allopolyploidization. We describe recent studies on the reprogramming of the wheat and yeast genomes as a result of interspecific hybridization and allopolyploidization.

2.1.2. novel phenotypes, genomic rearrangements, and epigenetic changes in resynthesized Brassica polyploids (Brassicaceae)

C. Pires[1], R. Gaeta[1], E. Leon[1], L. Lukens[2], T. Osborn[1];
[1]University of Wisconsin, Madison, WI, United States, [2]University of Guelph, Guelph, ON, Canada.

Brassica is a fascinating model for plant domestication because of its spectacular variation in vegetative forms. Key questions that emerge: do ancient and recent polyploidy events contribute to morphological variation? Are genome structure and gene expression changes associated with polyploidy directed or random? By synthesizing 50 lines of allopolyploid *Brassica napus* from the same homozygous diploid parents, we are ‘replaying the evolutionary tape’ to find out if resynthesized polyploids are similar to each other and to natural polyploids. It appears that both chromosomal rearrangements and epigenetic events play a major role in the generation of new phenotypes in polyploids. The results of these studies suggest that polyploidy is an evolutionary mechanism that leads to dynamic changes in phenotype, genotype, and transcriptome at the early stages in polyploid evolution.

2.1.3. Chromatin organisation and methylation in polyploid and hybrid plant species

T. Schwarzacher[1], J. P. Bailey[1], A. Contento[1], S. Kubis[1], F. Noreen[2], K. Richert-Poeggeler[2], C. H. Teo[1];
[1]University of Leicester, Leicester, United Kingdom, [2]University of Basel, Basel, Switzerland.

We are studying the interaction of genomes in old and new polyploid and hybrid cereals, petunias and bananas. Our work concentrates on repetitive sequences, their distribution and evolution, and their epigenetics as evidenced by chromatin organisation and methylation. Activation of integrated, but dormant pararetroviruses (EPRVs) can be caused by the introduction of wide hybridization and can lead to disease outbreaks through tissue culture or environmental stresses as has been shown for banana. Complex patterns of chromatin methylation result in different inducibility and expression levels of EPRVs in Petunia and vary between accessions. Differences in methylation patterns at symmetrical CpG and CpNpG and asymmetrical sites of a widespread repetitive sequence family were observed in diploid and polyploid *Triticeae* genomes. Diploid species of rye and wheat show uniform methylation signals while allopolyploids have more unevenly distributed methylation patterns indicating *de novo* methylation and demethylation mechanisms when genomes are combined in polyploid and hybrid species.

We thank NERC and the EU- framework 5 programme Paradigm for support.

2.1.4. Silencing of duplicated genes in polyploid cotton

K. L. Adams[1], Z. Liu[1], R. Percifield[2], J. F. Wendel[2];
[1]University of British Columbia, Vancouver, BC, Canada, [2]Iowa State University, Ames, IA, United States.

Hybridization followed by genome doubling (allopolyploidy) is a prominent mode of speciation in plants and it can lead to phenotypic novelty. Polyploidy can have considerable effects on gene expression, resulting in gene silencing and adjustments in transcript levels. Molecular techniques were used to screen the expression of over 2000 transcripts and to assay in detail expression levels of 50 genes duplicated by polyploidy, using multiple organs and genotypes of natural and synthetic cotton polyploids. Silencing of one copy was documented for several duplicated gene pairs and silencing of many genes is organ-specific. Some genes show partitioning of expression patterns between duplicates, with one duplicate copy being silenced in some organs and the other copy being silenced in other organs, indicating subfunctionalization. Comparisons of expression patterns in different synthetic polyploid genotypes suggest that silencing of some genes is directed, but it is stochastic for other genes. These results provide a detailed portrayal of gene expression changes that occur following allopolyploidy and suggest epigenetic causal factors.

2.1.5. Differential expression of homoeologous loci in allotetraploid cotton

J. A. Udall, J. M. Swanson, R. A. Rapp, J. F. Wendel;
Iowa State University, Ames, IA, United States.

The two genomes of allotetraploid cotton, *Gossypium hirsutum* (AD_1), were derived from an evolutionarily recent merger of two divergent, diploid progenitors closely resembling extant *G. raimondii* (D_5) and *G. arboreum* (A_2). Single-strand conformational polymorphism analyses have demonstrated that many duplicated loci (homoeologs) that resulted from polyploid formation do not contribute equally to the transcriptome. To date, no large-scale survey duplicate gene expression has been conducted. Using a global assembly of 160,000 *Gossypium* ESTs, we identified 6605 pairs of polymorphisms, including both indels and single nucleotide polymorphisms, between the *Gossypium* A and D subgenomes in 2124 pairs of duplicated loci. Short (~25bp) oligonucleotide microarray probe-pairs targeting these polymorphisms were printed on NimbleGen microarrays and 672 loci homoeologous probe pairs were found to diagnostically distinguish both the A and D genomes of *Gossypium*. Preliminary results indicate that a majority of homoeologous loci are not expressed at equal levels and for many duplicate gene pairs, one homoeolog may be completely silenced.

2.1.6. Maintenance of epigenetic states and interaction of epialleles in diploid and tetraploid *Arabidopsis*

T. Baubec[1], M. Milos[1], B. Wohlrab[1], **O. Mittelsten Scheid**[1,2];
[1]Gregor Mendel Institute of Molecular Plant Biology, Austrian Academy of Sciences, Vienna, Austria, [2]University of Natural Resources and Applied Life Sciences, Vienna, Austria.

Natural or experimentally achieved polyploid formation is associated with genomic rearrangements and/or epigenetic changes in gene expression patterns. We investigate the nature of ploidy-related epigenetic modifications and the trans-interaction between genes in different epigenetic states. Several tetraploid Arabidopsis lines, derived from a diploid strain expressing a selectable gene, showed transcriptional gene silencing of the marker, forming inactive “epialleles”. Once established, the silent state was inherited to tetraploid and diploid progeny, accompanied by hypermethylation at the silent gene. Combining forward and reversed genetic approaches, we investigate which *trans*-acting factors are involved in maintenance of this ploidy-related silencing. The silent epiallele reduced the expression of an active allele if combined in the same tetraploid (but not in a diploid) genome. The suppressive effect is lasting even after genetic separation from the silencing allele, resembling paramutation, and converting a recessive into a dominant trait. Such mechanisms in freshly formed polyploids could contribute to their rapid evolution.

2.1.7. Transcriptome divergence and mechanisms of non-additive gene regulation in *Arabidopsis* allopolyploids

J. Chen[1], J. Wang[1], L. Tian[1], E. Wei[1], M. Chen[1], S. Rao[1], R. Doerge[2], H. Jiang[2], L. Comai[3], B. Watson[3];
[1]Texas A&M University, College Station, TX, United States, [2]Purdue University, West Lafayette, IN, United States, [3]University of Washington, Seattle, WA, United States.

Polyploidy has occurred throughout the evolutionary history of all eukaryotes. Reunification of the evolutionarily-divergent genomes in allopolyploids creates regulatory incompatibilities that must be reconciled. Here we show that transcriptome divergence between two Arabidopsis species and their new allotetraploids is not purely neutral. The diverged transcriptomes are reconciled by genome-wide genetic dominance and regulatory interactions leading to chromatin-mediated non-additive gene regulation in various biological pathways. Altered regulatory and epigenetic interactions between FRI and FLC mediate flowering time variation in Arabidopsis allopolyploids. We propose a general model that suggests genetic dominance as a mechanism for non-additive gene regulation and subfunctionalization of duplicate genes. Furthermore, microRNAs (miRNAs) play a role in post-transcriptional regulation of the duplicate genes, providing a mechanism for rapid phenotypic and developmental changes in new allopolyploids.

2.2.1. Arbuscular mycorrhiza: general introduction and basic concepts

J. M. Barea, N. Ferrol, C. Azcón-Aguilar;
CSIC, Granada, Spain.

Arbuscular mycorrhiza (AM) is a widespread mutualistic symbiosis between roots of most land plants and Glomeromycota microbial fungi known to improve plant growth and nutrition and to protect the plant against biotic/abiotic stresses. AM fungi (AMF), obligate biotrophs dated back to 600 Ma, played a key role in land colonization by early plants. AMF are now present in all terrestrial plant systems to impact on their diversity, stability and/or productivity. Biotechnological applications are feasible. Spore morphology-based taxonomy was classically used but molecular tools, based on PCR amplification and rDNA fingerprinting and sequencing are currently applied for diversity/phylogeny analyses. The intraspecific variation of AMF multinucleate spores is being considered with regard to both genetic and functional diversity studies. Recent advances on AMF genomics include: (i) genomic sequencing; (ii) EST sequencing; (iii) expression of genes involved in AMF development; (iv) idem of those involved in nutrient acquisition and metabolism; (v) functional analysis of expressed genes (vi) proteomics and (vii) AM-induced changes in plant gene expression

2.2.2. The role of mycorrhizal fungi in reclamation of degraded ecosystems

M. Vosátka, J. Rydlová, D. Püschel, M. Janoušková, J. Albrechtová;
Institute of Botany, Academy of Sciences of the Czech Republic, Pruhonice, Czech Republic.

Mining and coal-fired power stations have led to the build-up of fly ash deposits and spoil banks. Succession on these sites is slow due to low abundance and biodiversity of the microbial populations. The research aims to find out the possibilities to accelerate succession on degraded sites and to develop sustainable revegetation by the use of Phyto-Microbial Complexes (PMC's) tolerant to edaphic stress. The concept is based on introduction of suitable plant species, mycorrhizal symbionts and their bacterial associates with the aim to establish vegetation and microbial community of desirable biodiversity. Arbuscular and ectomycorrhizal fungi together with plant growth-promoting rhizobacteria have shown various positive effects on the nutrient uptake, growth and fitness of the majority of plant species tested. Laboratory and field research is building up knowledge on ecophysiology of plant-microbes associations and further research remains essential for the vital use of PMC's on industrial base. Acknowledgement is given to Ministry of Education, Youth and Sports of the Czech Republic for support of the Research Centre Bioindication and Revitalisation.

2.2.3. Isoprenoid metabolism in arbuscular mycorrhizal roots

D. Strack;
Institute of Plant Biochemistry, Halle (Saale), Germany.

Development of arbuscular mycorrhizal (AM) roots is correlated with accumulation of various isoprenoids, i.e. C13 cyclohexenone derivatives and acyclic 'mycorradicin', the latter being a major component of the long-known 'yellow pigment'. Marked increase of transcript levels of the two pivotal enzymes of the corresponding methylerythritol phosphate (MEP) pathway, 1-deoxy-D-xylulose 5-phosphate (DXS) and 1-deoxy-D-xylulose 5-phosphate reductoisomerase (DXR), is induced by the fungal symbiont, e.g. Glomus intraradices. Two distinct classes of DXS-like cDNAs have been identified. DXS1 genes are preferentially expressed in many developing plant tissues except roots, whereas expression of DXS2 genes is strongly stimulate in roots upon colonization by mycorrhizal fungi. This is accompanied by a dramatic increase of root plastids and the formation of dense plastid networks covering the arbuscules. DXR has been immunolocalized in plastids around the arbuscules, tightly correlated with arbuscule development. These observations point to an important role of root plastids and (apo)carotenoids in the functionaing of AM symbiosis.

2.2.4. Role of arbuscular mycorrhizal fungi in phytoremediation - practical and theoretical aspects

K. Turnau, P. Ryszka, A. Jurkiewicz, T. Anielska, S. Gawronski;
Institute of Botany of the Jagiellonian University, Krakow, Poland.

Diverse human activities resulted in the creation of large areas contaminated by heavy metals. Bioremediation is an alternative to traditional technologies. Considerable attention was focused on the potential use of plant rhizosphere to remediate contaminated soil, however, the role of mycorrhizal fungi, which are an important component of soil microbiota has been almost neglected. Properly developed mycorrhizal symbiosis may enhance the survival of plants in polluted areas by improving nutrient acquisition, water relations, pathogenic resistance, phytohormone production, etc., thus supporting the success of bioremediation. In addition, mycorrhizal fungi were found to play an important role in heavy metal detoxification and vegetation establishment on strongly polluted soils. The effectivity of the bioremediation techniques depends on the appropriate selection of both partners. The experiments carried out on industrial wastes in Poland pointed out that plants conventionally introduced in such places disappear relatively soon, while those appearing during natural succession are better adapted for harsh conditions.

2.2.5. Arbuscular mycorrhizal fungi and heavy metal and salt stress

H. Bothe, U. Hildebrandt, P. Wilde, A. Manal;
Botanisches Institut, Universität Köln, Köln, Germany.

Colonization by arbuscular mycorrhizal fungi makes plants more resistant to stresses. In heavy metal stress, an isolate of the AMF *Glomus intraradices* from the zinc violet effectively transfers heavy metal tolerance to plants in heavy metal soils. Inside the roots, heavy metals are concentrated in the inner parenchyma cells with most of the fungal structures. Northern analyses, Real-time PCR experiments and in situ hybridizations showed that plant genes are differentially expressed upon heavy metal stress and mycorrhizal colonization. In particular, the transcript level of a root specific metallothionein is drastically upregulated upon heavy metal stress but downregulated upon AMF colonization. A SSH library constructed from fungal hyphae grown either in high or low concentrations of zinc did not provide any fungal counterpart of plant genes. In constrast, genes of enzymes which detoxify reactive oxygen species were found. Thus the fungal cells in the symbiosis may primarily have to cope with the heavy metal-induced oxidative stress. Plants from salt marshes are also strongly colonized by AMF. Results on AMF and salt will also be presented.

2.2.6. The arbuscular mycorrhizal and the rhizobial symbiosis: similarities and differences

H. Vierheilig;
Institut für Pflanzenschutz, Wien, Austria.

Legumes can form a symbiosis not only with nodule-forming rhizobial bacteria, but also with arbuscular mycorrhizal fungi (AMF). Abundant information is available on the regulation of the legume-rhizobium interaction, whereas in the understand of the regulation of the arbuscular mycorrhizal symbiosis several steps still remain unclear. Ample evidence indicates that the rhizobial host can control the extent of nodulation, the so-called autoregulation of nodulation. An autoregulatory mechanism has also been postulated for the AM symbiosis. Moreover, an established mycorrhizal association can systemically suppress not only further mycorrhization but also nodulation and the application of Nod factor to one side of a split-root system suppresses mycorrhization on the other side. These results point towards certain similarities in the autoregulatory mechanisms of the two associations. Recent results strengthen this hypothesis, showing that in supernodulating soybean mutants where nodulation is not autoregulated, also mycorrhization is not autoregulated. The regulation in the rhizobial and the arbuscular mycorrhizal association is discussed.

2.2.7. Mechanisms and interactions in mycorrhizal phosphate transport

M. Bucher;
ETH Zurich, Institute of Plant Sciences, Lindau, Switzerland.

The arbuscular mycorrhiza represents an ancient symbiosis, thought to have originated at least 460 million years ago, in the roots of plants pioneering the colonization of terrestrial habitats. In these associations, a key process is the transfer of phosphorus as inorganic phosphate to the host plant across the fungus-plant interface in exchange for plant-based carbohydrates. Phosphate transport across the cell boundary is mediated by transport proteins. The first mycorrhiza-specific phosphate transporter gene, named *StPT3*, was recently cloned from potato (Rausch et al., 2001). Using molecular-genetic tools, the regulatory mechanism involved in *StPT3* expression was subsequently shown to be conserved in phylogenetically distant plant species, and to be selectively induced by fungal species from the phylum *Glomeromycota* (Karandashov et al., 2004; Schüssler et al., 2001). Novel tools to unravel the molecular interactions involved in symbiotic phosphate transport are presently being established in the group. Recent progress in understanding the regulation and functional role of mycorrhiza-specific phosphate transporters will be presented.

2.3.1. The mesozoic context for the origin of angiosperm plant-insect associations and floral syndromes

C. C. Labandeira;
Smithsonian Institution, Washington, DC, United States.

The presence of insect associations on various crown groups of Mesozoic seed plants increasingly place Early Cretaceous flowering plants in a dynamic and comprehensive ecological context. These plant-insect associations extend back to the Middle Triassic, 100 m.y. before the earliest angiosperm fossils, and indicate that host-specific leaf miners, gallers, wood borers, and seed predators were efficiently partitioning foliar, stem, and reproductive tissues of seed plants in both Gondwana and Laurasia. Some endophytic associations likely induced both accommodationist and highly defended strategies to ward off herbivory. Major Mesozoic seed-plant groups, including Ginkgoopsida, Bennettitales, Voltziaceae, Cheirolepidaceae, Pentoxylaceae and Corystospermaceae harbored diverse feeding guilds that set the stage for herbivore colonization of early angiosperms, perhaps by lateral transfer. Additionally, gymnospermous pollination is documented by fossil data from insect gut contents, mouthpart structure, plant fructification damage and reproductive biology, and temporally overlaps with early angiosperm pollination styles.

2.3.2. Multiple meanings and modes: on the many ways to be a “generalist” flower

J. Ollerton;
University College Northampton, Northampton, United Kingdom.

Describing a species of plant as being a pollination “generalist” or “specialist” is not straightforward. There are a number of different ways of defining “generalized” and “specialized” and some important conceptual issues in relation to the ecological quantification and evolutionary meaning of generalization. Apparently generalized species may be cryptically specialized (pollinated by only a few species, despite a large diversity of flower visitors), or pollinated by a single functional group of related taxa. In addition, plants that possess phenotypically specialized flowers may in fact be ecological generalists in their interactions with pollinators. Finally, sampling effort in the field is an important consideration, both within a population and across populations. In this paper I illustrate these issues and concepts using case studies from my own work on genera such as *Ceropegia, Xysmalobium* and *Lotus.* A more detailed, critical appreciation of generalized plant-pollinator interactions is necessary to our understanding of the ecology and conservation of this important ecological process.

2.3.3. The problem of generalized flowers - morphological aspects

F. H. E. Weberling;
Arbeitsgruppe Biosystematik, Ulm, Germany.

Certain groups of flowers characterized by similar physiognomy are preferably visited by a diverse group of animals. These flowers have passed a process of mutual specialization to their pollinators. The question for the initial forms of this evolution remains unanswered, but a broad spectrum of visitors is assumed. We prefer to designate them as ‚generalized´ instead of ‚non-specialized´, since each organism needs to be adapted to its environment in any way. Generalized flowers even occur in otherwise highly evolved families. They may have developed secondarily from specialized types combining plesiomorphic with secondarily achieved characters. Thus ‚generalized´ & ‚specialized´ are relative terms. Asking for the generalized flower does not imply the question for the early primitive flower! Neither in fossil records nor among the extant primitive Angiosperms we find a model organism for a flower with a broad spectrum of visitors, displaying all the organs in their plesiomorphic state. The Winteraceae, however, present members coming close to this ideal with primitive features and open generalized flowers, visited by a broad spectrum of pollen-vectors.

2.3.4. The top-10 most generalized flowering plants in the world

J. M. Olesen;
Inst. Biol. Sciences, Univ. Aarhus, Århus C, Denmark.

The ‘pollination generalization level’ L_n of a flowering plant species *n*, here defined as number of flower-visiting animal species attracted to the flowers of *n* in a given study site, varies enormously among plant species. I have compiled information about *L* from the literature and my own studies for more than 1800 plant species throughout the world. The frequency distribution of *L* is very skewed. In about half of all species *L* = 1, whereas a few species are visited by an extremely diverse fauna. Within study site, *L* increases with number of flower-visitor species *A*. In order to correct for this, I express *L* relatively, as the proportion of the total flower-visitor fauna in a study site that visits a given plant species (*L*/*A*). In my talk, I list the top-10 most generalized (*L*/*A*) species in the “world”, i.e. out of a sample of +1800 plant species. I discuss why they are on the list: Is it because of flower morphology, abundance, habitat, study methodology etc.?

2.3.5. Generalist flowers and phytophagous beetles in two tropical canopy trees: resources for multitudes

F. Ã˜degaard[1], **D. M. Frame**[2];
[1]Norwegian Institute for Nature Research (NINA), Trondheim, Norway,
[2]Herbarium, Institut de Botanique, Montpellier, France.

Using the STRI Fort Sherman canopy crane, Panama, we studied beetle visitors to flowers of Tapirira guianensis (Anacardiaceae) (Tp) and Nectandra purpurea (Lauraceae) (Np) over 2 flowering seasons. In these unrelated short (Np) and tall (Tg) canopy trees, the superficial morphology of the flowers and inflorescences are similar. Flowers are five-parted, minute (to 2 mm), cream to slightly purplish (Np) and last 1 to 2 days. Inflorescences bloom for about 3 days in Tg and 1-2 weeks in Np. The white floral sprays (inflorescences) in both plants are emergent above the parent tree leaf layer and are visited by numerous beetles. Total number of phytophagous beetles collected from inflorescences was 122 species (841 individuals) and 122 species (723 individuals) for Tg and Np, respectively. Beetles were sorted into 3 functional groups: general flower visitor, species that develop in buds and seed predators. Of the general flower visitors, 96 species and 99 species were collected from Tg and Np, respectively. There were 66 species of beetles in common between the two trees. Such numbers clearly imply that in the tropics generalist flowers are important resources for beetles.

2.3.6. Generalized versus specialized pollination modes in tropical floras: the case of the cerrado vegetation in Brazil

G. Gottsberger, I. Gottsberger;
Abteilung Systematische Botanik und Ökologie, Universität Ulm, Ulm, Germany.

The prevailing view of plant-pollinator interactions assumes that most tropical communities exhibit higher specificity than in temperate zones. All angiosperms in a one hectare plot of cerrado vegetation in São Paulo State, were investigated with respect to pollination mode and pollinators. The majority of the 301 species were either bee pollinated (38%) or generalists (37%); in addition, 13% were anemophiles, 3% cantharophiles, 2% each ornithophiles, sphingophiles and phalenophiles, and 1% each chiropterophiles, psychophiles and myiophiles. A relative measure of importance of an agent with respect to a particular plant species was obtained by considering the visiting animals as exclusive, principal or additional pollinators. Of the 261 zoophilous species, 51 are "specialized", that is, are exclusively pollinated by a single animal group. The great majority (210) are effectively pollinated by at least two groups, which act either as principal or additional pollinators. Flowers of these oligo- to polyphilic plants have a relatively low level of floral specialization. Detailed studies of other tropical vegetations might well reveal a similar pattern.

2.3.7. A floral ecologist´s past fifty years: Some personal thoughts and experiences

S. P. Vogel;
Faculty Center of Botany, Vienna, Austria.

After a first flourishing in the 19th century, floral ecology fell into relative dormancy for almost 50 years, although some important innovations were achieved during that time. In the mid-20th century, the field became revitalized, mainly through interdisciplinary impulses: insect and vertebrate biology, physiology, genetics, floral morphology, new interest in tropical floras, and modern methods. Floral ecology is now so expanded and divergent in topics that no single scholar can maintain a full overview. Two different motivations of research prevail: the Post-Darwinian approach involving the evolutionary perspective, guided by causative and reductionist reasoning, and the comparative functional interpretation of floral structure, maintaining the narrative culture of documentation and explanation of existent conditions. In the present contribution, the author outlines his own involvement in pollination science and recalls the circumstances that led him to his findings concerning adaptive radiation into floral syndromes, the actual role of bat pollination, novel types of floral reward, and deceptive attraction.

2.4.1. Reflections on the ultrastructure of softwood fibres

L. Salmén;
STFI-Packforsk, Stockholm, Sweden.

The ultrastructure and interaction of the wood polymers in the fibre wall of softwood tracheids is of high interest for understanding the mechanical properties of wood fibres. The cell wall structure in terms of cellulose aggregates and the distribution of the hemicelluloses, glucomannnan and xylan, will be discussed based on measurements using Atomic Force Microscopy as well as Dynamic FTIR spectroscopy. The cellulose aggregates are shown to have a large variation within the cell wall, however uniform across the cell wall. When processed or subjected to different environments large aggregate size changes are shown to occur. For softwood fibres FTIR showed that of the two hemicelluloses, glucomannan was closely connected to the cellulose while the xylan seemed to be more freely arranged. Taking into account the swelling behaviour of the cellulose aggregates it was likely to assume that the glucomannans are making up some of the structure of the cellulose aggregates being strongly bonded to these. Based on these studies a model for the ultrastructure of the cell wall and how it may change by processing is discussed.

2.4.2. Characterization of the gelatinous layer (G-layer) as origins of the xylem properties peculier to the tension wood

H. Yamamoto, Y. Arakawa, K. Abe, M. Yoshida;
Sch. Bio-agr. Sci., Nagoya, Japan.

Origins of the mechanical properties peculiar to the tension wood (TW) in the arboreal dicotyledon were clarified in relation to the gelatinous layer (G-layer) formation. [Materials] Tested species were (1) *Quercus sp.,* and *Zelkova sp.,* forming a very thick G-layer, (2) *Acer* spp., forming a thin but clear G-layer, and (3) *Magnolia spp*. forming no G-layer. Eight to ten points were set peripherally in a leaning stem of each tested tree, and the growth stress (*GS*), the drying shrinkage (*SH*), and the Young's modulus (*MOE*), along the fiber direction, were measured. Afterward, area ratio of the G-layer was determined at each point. In *Magnolia spp*., cellulose content and average microfibril angle were measured. [Results] Intensities of *GS*, *SH*, and *MOE* became larger with increase of the area ratio of the G-layer, which suggests that origins of the TW properties were attributed to the nature of the G-layer. In *Magnolia sp*., large cellulose content and small microfibril angle produced the similar effect as forming the G-layer. Intrinsic properties of the G-layer were estimated quantitatively by applying the observed results to the simulation using a multi-layered fiber model.

2.4.3. Probing cell wall characteristics of mild compression wood

A. Singh[1], R. Möller[1], Y. S. Kim[2];
[1]New Zealand Forest Research Institute Limited, Rotorua, New Zealand, [2]Chonnam National University, Gwangju, Republic of Korea.

Compression wood forms in gymnosperm trees in response to gravity mediated stimulus. The form of compression wood varies greatly, ranging from very mild to severe. This review focuses on cell wall characteristics of mild compression wood, which also occurs in a wide range of forms. Recent investigations employing a combination of various microscopy techniques have provided information that forms an important basis for distinguishing various forms of mild compression wood and also mild compression wood from normal wood. The single most distinguishing feature, which can be used to differentiate the mildest forms of compression wood from normal wood, is the greater lignification of the outer S_2. However, in some cases the outer S2 is only marginally more lignified than the corresponding cell wall region of normal wood, and the experience has shown that distinguishing such mild forms requires the use of high resolution microscopy, such as transmission electron microscopy. This and other features of mild compression wood will be described with suitable illustrations during presentation.

2.4.4. The effect of latitude and impact of fertilisation on tracheid dimensions and wood density of Norway spruce (*Picea abies* (L.) Karsten)

R. M. Piispanen[1], M. P. Sarén[2], P. T. Saranpää[1];
[1]Finnish Forest Research Institute, Vantaa, Finland, [2]University of Oulu, Measurement and Sensor Laboratory, Kajaani, Finland.

Tracheid diameter, cell wall thickness and wood density were studied in two long-term nitrogen fertilisation experiments of Norway spruce. The purpose was to compare a northern growth site (66°51'N, 27°07'E) to a southern growth site (61°10'N, 26°03'E), with a respect to a fertilisation treatment. Solid nitrogen fertiliser was given every five years during years 1961-2000 and led to 992 and 1306 kg of total N deposition per ha in both sites. Five 60-year-old unfertilised control trees and five fertilised trees were selected in year 2002 from both sites. The fertilisation increased annual ring width significantly in the northern location, but similar effect was not seen in the southern site. Transverse wood sections (thickness 15 µm) were cut with a cryo-microtome at 10 year intervals for cell size measurements. According to our preliminary results, nitrogen fertilisation decreased tracheid size in both sites. The impact of the interaction of northern vs. southern growth site and fertilisation on tracheid properties with respect to wood density will be discussed.

2.4.5. Cell wall formation and polymer topochemichal assembly in the developing xylem

K. C. Ruel;
CERMAV-CNRS, Grenoble, France.

Secondary wall organization is in large part responsible for the mechanical and physiological properties of wood. Using high resolution of transmission electron microscopy (TEM) together with the specificity of immunological probes, we investigated the deposition *in muro* of hemicelluloses and lignins from the early stage of differentiation to the mature fibre and vessel walls in growing plants of *Arabidopsis thaliana* and poplar. TEM examination of differentiating cells as well as various wood and wood-derived materials and genetic mutants brought multiple evidence of the lamellar organization of the secondary walls. Immunogold labelling suggested that two different types of lignin molecules differentially polymerised at different steps of the wall formation, and two structurally different xylan types, had specific functions in the cohesion of cellulose microfibrils (CMFs). This process may be modified in response to environmental factors. A model of the spatio-temporal relationships between hemicelluloses, lignins and CMFs during secondary wall assembly is proposed.

2.4.6. Immunolocalization of enzymes involved in synthesis of syringyl lignin

K. Takabe[1], T. Nishihara[1], M. Fujita[1], V. L. Chiang[2];
[1]Graduate School of Agriculture, Kyoto, Japan, [2]North Carolina State University, Raleigh, NC, United States.

Immunocytochemistry is a powerful tool to reveal the localization of enzymes at cellular and subcellular level. Lignification is thought to occur in three steps. Monolignols are synthesized in the cell, transported towards the cell wall, and polymerized dehydrogenatively within the cell wall. Many enzymes are involved in the synthesis of monolignols. We investigated the enzymes involved in syringyl lignin. Immunolabeling of coniferyl aldehyde 5-hydroxylase catalyzing the conversion of coniferyl aldehyde to 5-hydroxy coniferyl aldehyde is mainly observed in the fibers of aspen during the secondary wall formation. It is localized mainly on rough endoplasmic reticulum. Sinapyl alcohol dehydrogenase catalyzing the conversion of sinapyl aldehyde to sinapyl alcohol is also localized in the fibers during secondary wall formation. It is localized mainly on the cyto-sol. Taken together, accumulation of syringyl lignin in aspen is discussed.

2.4.7. The process of xylem cell diferentiation in relation to wood properties.

J. R. Barnett, M. Kumar, M. J. Wilkinson;
The University of Reading, Reading, United Kingdom.

The physical properties of wood depend on the cell types present, their relative proportions, their distribution (anatomical arrangement), their morphology and structure, and the structure and composition of their cell walls. Whilst these parameters are under genetic control, they are also sensitive to environmental variation. Key factors during development of xylem cells which affect the quality of wood formed are the degree and direction of cell enlargement, the orientation of deposition of cellulose microfibrils in the secondary wall of fibres and the amount of lignification which takes place. This presentation will describe some of the microscopic structural changes which take place during differentiation of fibres, tracheids and vessel elements. In particular, we examine the role of plasmodesmata and the cytoskeleton in cell commitment, enlargement and wall formation. We also present initial results on the differential expression of genes, in particular tubulin genes, in cambium tissues during the formation of juvenile and mature wood.

2.5.1. Genome Size Matters

M. D. Bennett;
Jodrell Laboratory Royal Botanic Gardens Kew, Richmond, Surrey, United Kingdom.

Genome size is a key biodiversity character which amazingly varies more than 1000-fold between plant taxa. Interest in plant genome size evolution and its significance has increased greatly with a recent upsurge in the number of size estimates published, including the first values based on ‘complete’ genome sequencing. Comparative genomics based on robust phylogenies have provided exciting new insights into the molecular mechanisms responsible for genome size gain (obesity) and loss (down-sizing), and have provoked new ideas about the evolutionary forces driving such changes. Knowledge of species DNA amounts has many important uses, given its nucleotypic effects, and recent studies provide the first telling evidence that genome size can be a key predictor of species extinction, and survival in polluted environments. Linking widely diverse perspectives on genome size variation at levels from DNA sequences to ecosystems will be an important driver for progress in many botanical fields.

2.5.2. Mechanisms of plant genome size evolution: insights from comparative genome analysis

B. G. Murray;
School of Biological Sciences, The University of Auckland., Auckland, New Zealand.

Developments in the analysis of plant genomes over the past 5-10 years have begun to provide much clearer insights into the processes involved in changes in genome size. The variation within groups such as the angiosperms is very large, with an approx. 1000-fold variation, and it is likely that several mechanisms are involved. Genetic mapping of many species and sequencing of a few has revealed that duplication of whole or parts of the genome is probably ubiquitous. This is a powerful method for genome size increase, polyploidy doubles C-value whereas segmental duplications will have smaller effects. Polyploidy and hybridization may also be accompanied by deletion or proliferation of DNA sequences that may also contribute to C-value variation. Transposable elements, particularly retrotransposons, are also key elements in genome size variation, though they do not necessarily proliferate unchecked as recent studies in *Arabidopsis* have shown. The dynamic nature of genome size variation has been highlighted by the application of phylogenetic methods which that both increase and decrease in size occurs within phylogenetic lineages.

2.5.3. Genome obesity and downsizing across the Tree of Life

I. J. Leitch, M. D. Bennett;
Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

Polyploidy and transposon amplification are widely accepted as the predominant mechanisms for generating genome obesity in angiosperms. These observations, coupled with proposals that most genomes are palaeopolyploid, suggest that large genomes should be the rule rather than the exception. However, superimposing genome size data onto a well supported phylogeny shows that species with large genomes are exceptional and restricted phylogenetically. Further, data showing that C-values in some polyploids are lower than the expected sum of their parental genomes, and molecular evidence showing elimination of DNA in some polyploids suggest that polyploidization may also triggers genome downsizing. Analysis of C-value data across a broad angiosperm sample confirmed that genome downsizing following polyploidy may indeed be a widespread phenomenon of considerable biological significance. Extending these approaches to other plant groups (e.g. gymnosperms, ferns, mosses and algae), although often limited by scarcity of data, further highlights the rarity of large genomes, and suggest that genome downsizing operates over large phylogenetic distances.

2.5.4. Nuclear DNA content estimates in green algal lineagaes: Chlorophyta and Streptophyta

D. F. Kapraun;
University of North Carolina Wilmington, Wilmington, NC, United States.

An ancient divergence separates eukaryotic green algae into two major monophyletic lineages: Chlorophyta and Streptophyta, and a residium of green algae, including *Mesostigma* (Prasinophytes). The present investigation expands our database of C-values to 135 species, emphasizing Streptophyta and the charophycean lineage which is sister group to land plants. The DNA-localizing fluorochrome DAPI (4', 6-diamidino-2-phenylindole) and RBC (chicken erythrocytes) standard were used to estimate 2C values with static microspectrophotometry. In Chlorophytes, 2C DNA estimates range from 0.2 - 6.1 pg. For Streptophytes, 2C nuclear DNA contents range from 0.2 - 2.1 pg, excluding the highly polyploid Desmidiales and Charales, which have genome sizes of up to 20.7 and 39.2 pg, respectively. These data will help pre-screen candidate species for the on-going construction of Bacterial Artificial Chromosome (BAC) nuclear genome libraries for the Ancestral Green Flagellate (AGF). It is proposed that the ancestral genome for both the Chlorophyta and the Streptophyta lineages is small (*c*. 0.05 - 0.1 pg).

2.5.5. Genome size - pollution and survival

B. Vilhar[1], T. Vidic[1], J. Greilhuber[2];
[1]University of Ljubljana, Biotechnical Faculty, Department of Biology, SI-1000 Ljubljana, Slovenia, [2]University of Vienna, Institute of Botany, A-1030 Vienna, Austria.

In eukaryotes, nuclear genome sizes vary by more than five orders of magnitude. This variation is not related to organismal complexity, and its origin and biological significance are still disputed. We assessed the adaptive value of genome size with a comparative study of grassland plant communities occurring on a gradient of environmental conditions caused by pollution from a former lead smelter. The concentration of Pb in the soil on the five investigated plots ranged from 0.01% on the unpolluted reference plot to 3% on the most polluted plot close to the smelter stack. The number of vascular plant species correlated negatively with the level of metal contamination and ranged from 106 to 20. Analysis of genome sizes of 70 herbaceous dicot perennial species occurring on the investigated plots revealed a negative correlation between the concentration of contaminating metals in the soil and the proportion of species with large genomes in plant communities. These results represent the first direct evidence, based on a field study, that genome size is associated with differential survival of species in extreme environmental conditions.

2.5.6. Does insular environment affect genome size? An evidence from Macaronesian flora.

J. Suda[1,2];
[1]Charles University, Department of Botany, Prague, Czech Republic,
[2]Institute of Botany, Academy of Sciences, PrŢhonice, Czech Republic.

Genome sizes for 239 endemic Macaronesian species from 111 genera and 39 families were estimated using propidium iodide flow cytometry. Surprisingly narrow variation in 1C-values was revealed, ranging from 0.19 pg to 9.52 pg (ca. 50-fold difference, thus less than several plant families). Majority of endemic species (67.8%) possessed very small genomes (1C Ò 1.40 pg), while small (1C = 1.41-3.50 pg) and intermediate (1C = 3.51-14.0 pg) genomes were much less frequent (20.5% and 11.7%, respectively). These proportions dramatically differ from the world flora figures. Moreover, minimum values hitherto known for major phylogenetic lineages have often been approached or even passed in Macaronesia. Similarly, for nearly all genera and families, endemic members had significantly lower C-values than their non-Macaronesian counterparts. Marked prevalence of very small genomes among unrelated angiosperms indicates that genome miniaturization might be a common evolutionary strategy in insular conditions. Relationship between rapid burst of speciation and genome size is also suggested.

2.5.7. The large genome constraint hypothesis: evolution, ecology, and phenotype

C. A. Knight;
California Polytechnic State University, San Luis Obispo, CA, United States.

If large genomes are truly saturated with unnecessary "junk" DNA, it would seem natural that there would be costs associated with accumulation and replication of this excess DNA. Here we examine the available evidence to support this hypothesis, which we term the "large genome constraint". We examine the hypothesis at three scales: evolution, ecology, and the plant phenotype. In evolution, we found that genera with large genomes are less likely to be highly specious - which suggests a large genome constraint on speciation. In ecology, we found that species with large genomes are underrepresented in extreme environments - which suggests a large genome constraint on the distribution and abundance of species. Ultimately, if these ecological and evolutionary constraints are real, the genome size effect must be expressed in the phenotype. Therefore, we review data on the physiological correlates of genome size. Most notably, we found that species with large genomes have reduced maximum photosynthetic rates. These correlations may help explain why species with large genomes are trimmed from the evolutionary tree and have restricted ecological distributions.

2.6.1. Phytogeography and epiontology of floras

D. Uzunov, N. G. Passalacqua;
Museo di Storia Naturale della Calabria ed Orto Botanico, Rende (CS), Italy.

Patterns of the distribution of the plants over the earth can be demonstrated to be non-random. The Phytogeography has evolved in order to explain the non-randomicity of plant distribution in terms of the historical and ecological processes. Since of the origin of this scientific field, the central question was the definition of the flora concept, as a means for studying the taxa (or the whole of local populations) inhabiting a given territory, and the delimitation of the spatial scale in which the floras originated and evolved as natural phenomena. The presentations discus different qualitative and quantitative methods applied for evaluating the floristic diversity and representativeness, for defining the phytogeographical division at regional level and for laying out hypotheses of the flora genesis (epiontology). The open question is: is it possible to find principle and well shared approaches for phytogeographical analysis of floras?

2.6.2. Defining and delimiting choronomic units: methods and problems in the phytogeography of Calabria (S Italy).

N. G. Passalacqua, L. Peruzzi, D. Gargano;
Museo di Storia Naturale della Calabria ed Orto Botanico, Aracavacata di Rende, Italy.

The Calabria region is the southernmost part of Italian peninsula, extending ca. 350 km north to south from 39° 54' to 38° 42' N in the centre of Mediterranean sea; the area is widely mountainous raising to about 2000 m a.s.l. many times throughout its latitudinal range. Often included in the Mediterranean region by a phytogeographical point of view, instead recent works assigned the upper part of mountains to the European region. Our research started from distribution of endemic and relictual taxa for definition of choronomic units and geographic elements, while auto- and synecological data were used as comparative to test their consistence and define their boundaries. Moreover, the distribution analysis of relictual and vicariant taxa, compared to paleogeographical and palynological data, was used to find possible historical pathways that outlined the present choronomic units.

2.6.3. Biogeography of plants of the Guiana Shield: Inferences from seven florulas from Northern South America

D. Clarke;
University of North Carolina at Asheville, Asheville, NC, United States.

The florulas of seven well-collected locations in northern South America were tested for floristic similarity. Checklists from Kaieteur Falls National Park, Mabura Hill, and Iwokrama (Guyana), Reserva Ducke (Brazil), Saül (Central French Guiana) and Guaramacal and Ávila National Parks (Venezuela) were first synonymized and then the relationship between Sorenson's dissimilarity and geographic distance between florulas was examined using the Mantel Test at the species and genus level. The distribution of species over the sites was influenced by the distances between sites. However, there was no evidence that the distribution of genera between sites was influenced by the distances between sites. The results support a model of floristic similarities determined by the distribution of white sand and sandstone substrates in the three florulas from Guyana while the flora of Saül, although located on the Guiana Shield, lacks white sand substrates and shows more generalized similarities to the other florulas from Northern South America.

2.6.4. Phytogeographic regions of NW Russia, with connection of distribution of the apomictic *Hieracium* species

A. N. Sennikov;
Komarov Botanical Institute, Saint-Petersburg, Russian Federation.

The system of phytogeographic regions of NW Russia (Saint-Petersburg, Pskov and Novgorod Regions) is based on the characters of species distribution, landscape and climate. The territory is situated in Southern Boreal and Hemiboreal zones separated by the northern limit of oak and some species of its suite. It belongs to the oceanic sector O1 with three subsectors within (a detailed version of the "Finnish" phytogeographic system). 21 regions (with subregions) are separated on the basis of presence of characteristic (mainly forest, especially thermophilous) species and landscape peculiarities. These regions may be grouped in large-scale traditional provinces (Fennoscandia, Baltia, Belorussia, Middle Russia) with intermediate areas between them. The most diverse apomictic genus *Hieracium* was taxonomically treated anew and the microspecies distribution according to the phytogeographic regions was analysed. The distribution of 55 native *Hieracium* species generally follow the main trends in flora, dividing the territory into 5 "*Hieracium* regions": Maritime East Fennoscandia, Continental East Fennoscandia, Baltia, North Russia, Central Russia.

2.6.5. The origin and evolution of the Socotran flora - evidence from molecular data

M. Thiv[1], H. P. Linder[2];
[1]Staatliches Museum für Naturkunde, Stuttgart, Germany, [2]Institute of Systematic Botany, Zurich, Switzerland.

This study aims at the analysis of biogeographic patterns among the flora of the Indian Ocean archipelago of Socotra. Hitherto, Socotran endemics were purported to have biogeographic relationships to Africa, Arabia, Asia and/or the Canary Islands. The origin of the Socotran flora and the biogeographic history of the Eritreo-Arabian subregion is here reconstructed using molecular phylogenies of seven dicotylous genera with taxa endemic to Socotra. Invasion events from E Africa and/or Arabia are indicated for *Thamnosma* (Rutaceae), *Echidnopsis* (Apocynaceae), *Campylanthus* (Plantaginaceae), *Kleinia* (Asteraceae) and *Aerva* (Amaranthaceae). So far, close relationships to the Somalo-Ethiopian and South Arabian floristic provinces are obvious, and direct connections to the Canary Islands or Asia can be ruled out. Vicariant patterns possibly caused by the geological separation of Socotra from Arabia 35-15 mya could not be detected by creating general area cladograms.

2.6.6. Qinghai-Tibet Plateau Uplift and its impact on Tethys Flora

H. Sun[1], Z. M. Li[2];
[1]Kunming Institute of Botany,Chinese Academy of Sciences, Kunming, China, [2]Life Science School, Yunnan Normal University, Kunming, China.

Paleobotanical data had showed that the beginning flora of Qinghai-Tibet Plateau was a part of Tethyan Tertiary "paleotropical flora". After late Paleogene, along with climate of the Mediterranean gradually become aridity, the "laurophyll" or "paleotropical geoflora" gradually replaced by temperate sclerophyllous forest, semiarid or arid the modern Mediterranean flora. In Neogene, Himalayas uplifted caused the semiarid or arid modern Mediterranean flora turning to adapt to different alpine environments. Through analysis of the origin of sclerophyllous oaks forest in these region and Eurasian and North temperate disjunction, as well as endemic and relic, in some examples: *Helleborus, Incarvillea, Kelloggia, Thermospideae, Acanthochlamys, Meconopsis, Notholirion, Coriaria, Hippophae,* and *Arenaria,* showed that dominant modern floristic elements in Qinghai-Tibet Plateau such as Temperate of Old world, North temperate, Sino-Himalayan, Central Asia, and endemic were mostly origination from Tertiary Mediterranean flora. Furthermore, these analysis also demonstrated the dispersal pathway of the Tethys tertiary flora along Tethys.

2.7.1. From genetics to phylogenetics: shifting continents and paradigms in the evolution of seed-free vascular plants

C. H. Haufler;
University of Kansas, Lawrence, KS, United States.

About 20 years ago, a revolution began in evolutionary studies of seed-free vascular plants. Whereas common wisdom averred that minute spores diminished barriers to long distance dispersal, genetic analyses demonstrated outcrossing breeding systems that require two spores for each successful migration event. Since that discovery, vicariance has taken on renewed significance, and new data on the recent origins of major groups require fresh consideration of biogeographic assumptions. The Polypodiaceae yield phylogenetic insights through an exemplar integration of DNA sequence analysis and biogeography. New evidence shows separate yet parallel radiations in the New and Old Worlds. By combining sequence data, continental drift, and a reassessment of morphological features, a sometimes radical realignment of generic boundaries is obtained. Subsequent presentations in this symposium further promote a paradigm shift in the systematics and biogeography of seed-free vascular plants.

2.7.2. Possible long distance dispersal of ferns between Madagascar and Southeast Asia

N. Murakami;
Graduate School of Science, Kyoto University, Kyoto, Japan.

Madagascar is well known as a large island containing many endemic plant species. During our attempts to find cryptic species using nucleotide sequence data of the rbcL gene, we collected members of the Asplenium nidus and Hymenasplenium unilaterale complexes widely from the Old World tropics including Madagascar. We found many cryptic species that have distinct rbcL sequences and are reproductively isolated as shown by crossing experiments. Even though we could find some amount of rbcL sequence variations in the cross-fertile plants from Southeast Asia, plant samples with the identical or similar rbcL sequences were detected from Madagascar. For example, H. unilaterale from Madagascar, Java, and Borneo, and those of H. exisum from Madagascar and Sumatra showed the same rbcL sequences, and A. nidus from Madagascar and Vietnam also had similar rbcL sequences. These results suggest long distance spore dispersal between Madagascar and Southeast Asia, which are at least 6000km apart.

2.7.3. Phylogeny of the fern genus *Elaphoglossum* (Elaphoglossaceae) and its implications for biogeography

G. Rouhan[1,2], K. Abdul-Salim[3], T. J. Motley[3], J. T. Mickel[3], F. Rakotondrainibe[1], J. Dubuisson[2], R. C. Moran[3];
[1]Muséum National d'Histoire Naturelle, Paris, France, [2]Université Paris 6, Paris, France, [3]New-York Botanical Garden, New-York, NY, United States.

We performed phylogenetic analyses of *Elaphoglossum* using morphological characters and sequences from cpDNA regions. The sampling included species from the Neotropics and Paleotropics. The wide distribution of *Elaphoglossum* makes it appropriate to study floristic relationships between Africa/Madagascar and the Neotropics, and to test hypotheses about relative contributions of long-distance dispersal versus vicariance. Results show the Paleotropical species are polyphyletic and suggest multiple, independent long-distance events in three out of the four major clades recognized in the genus. Given this and the fact that 75% of the species occur in the Neotropics, it appears that *Elaphoglossum* migrated from the Neotropics to Africa. The distribution of the genus is examined in the Indian Ocean area and the Hawaiian islands. Preliminary studies postulate four separate colonization events of which a single introduction resulted in a radiation of six Hawaiian endemic species, and in the Indian Ocean at least 13 colonization events are involved for explaining the distribution.

2.7.4. Molecular biogeography and origins of the Hawaiian fern flora

T. A. Ranker[1], J. M. O. Geiger[2], J. M. Ramp[1], S. T. Klimas[1];
[1]University of Colorado, Boulder, CO, United States, [2]Carroll College, Helena, MT, United States.

We are conducting a phylofloristic investigation of the geographical origins of the fern flora of the Hawaiian Islands through the application of molecular phylogenetics. Groups that we are presently studying include *Hypolepis* (Dennstaedtiaceae), *Dryopteris* & *Nothoperanema* (Dryopteridaceae), *Cibotium* (Dicksoniaceae), *Diplopterygium* (Gleicheniaceae), and *Adenophorus*, *Grammitis*, & *Lellingeria* (Grammitidaceae). For each group we have developed explicit, testable hypotheses of their historical biogeography based on pre-existing ideas and/or on our preliminary data. By comparing the results across groups, we are testing the broad hypothesis that diverse, unrelated lineages share common pathways of dispersal to the Hawaiian Islands. Preliminary results from several groups suggest that the jetstream serves as a major vehicle of spore dispersal from the Indo-Pacific region. Our results have important implications for the origins of all wind-dispersed groups of organisms in Hawaii and for the processes of community assembly.

2.7.5. Origin and diversification of African ferns with special emphasis on polygrammoid ferns

T. Janssen[1,2], H. P. Kreier[1], H. Schneider[1];
[1]Albrecht-von-Haller-Institut für Pflanzenwissenschaften, Georg-August-Univesität, Göttingen, Germany, [2]Muséum National d'Histoire Naturelle, Dépt. de Systématique et Evolution, Paris, France.

A phylogenetic approach is applied to infer the relationships of African ferns belonging to the highly diverse polygrammoid fern lineage. Recent studies have revealed the global relationships of these ferns and found evidence for distinct New World and Old World clades within this fern lineage. African and Madagascan polygrammoid ferns are related either to the Neotropical clades or to predominantly Asiatic Old World clades. We study six different groups (1) to identify the relationships among species occurring in Africa and Madagascar, (2) to detect the relationships of Afro-Madagascan taxa to species occurring in the Neotropics and Asiatic tropics, and (3) to find evidence for colonization of or departing from Africa. An African/Madagascan clade with a sister clade widespread in Asia and Australasia is found in drynarioid ferns and in the genus Platycerium. Both clades also show a split into an African and a Madagascan subclade. Evidence for colonization of Africa by Neotropical taxa is found in the genera Microgramma and Pleopeltis.

2.7.6. The age of New Zealand's ferns

L. Perrie, P. Brownsey;
Museum of New Zealand Te Papa Tongarewa, Wellington, New Zealand.

New Zealand has long been geologically isolated, with its separation from Gondwana beginning some 80 million years ago. However, evidence is accumulating from both molecular and fossil studies that much of the New Zealand flora originated only recently, seemingly via long distance dispersal. To investigate the age of New Zealand's ferns, we applied molecular dating analyses to DNA sequence data from 30 monilophyte and lycophyte genera. Each sampled genus comprised a pair of one species from New Zealand and one from elsewhere. The reconstructed divergence ages for the majority of these genera were much less than 80 million years ago. These results will be discussed within the context of the uncertainty surrounding the geological history of the region, the New Zealand fossil fern record, and the testing of hypotheses of origins for these fern genera in New Zealand (i.e., long-distance dispersal versus vicariance; direction of dispersal; one versus multiple colonisation events).

2.8.1. Measuring selection and constraints: how phenotypic space is shaped

M. Pigliucci;
Dept. of Ecology & Evolution, SUNY, Stony Brook, NY, United States.

Modern evolutionary theory is a complex ensemble of concepts and theoretical constructs, some of which are articulated in mathematical fashion, and others are expressed as narratives. Some of the major concepts include, of course, natural selection, genetic drift, adaptive landscapes, fitness, species concepts, etc. This set of theoretical statements is associated with a bewildering array of empirical methods, including observational and experimental ones, that are meant to further our understanding of evolution in natural populations. This talk examines some of the key concepts in evolutionary theory and how well (or not) they square with the methods commonly employed to study questions related to those concepts. It will emerge that in some cases we are in need of either a re-conceptualization of some of our key ideas, or of new empirical approaches, or both.

2.8.2. Moderator's comments: Understanding adaptation in plants

S. E. Sultan;
Wesleyan University, Middletown, CT, United States.

Understanding adaptation in plants poses both conceptual and methodological challenges. First, defining a putatively adaptive trait requires a conceptual distinction between the advantageous and the historically/ developmentally constrained aspects of any phenotypic feature. Second, although we often seek to test adaptation at the single-trait level, the adaptive value of any given trait is contingent on the suite of interacting traits that together consitute the phenotype. Similarly, the selective impact of any single environmental factor depends on the entire complex of environmental influences in the organism's natural setting, which is difficult to approximate experimentally. Finally, the measurement of fitness itself is far more complex than is indicated by the conventional reliance on total reproductive output. It is essential to consider additional traits that contribute to fitness in different ways, such as age at reproduction and quality of offspring.

2.8.3. Natural selection in relation to biotic and abiotic environments

M. A. Geber;
Cornell University, Ithaca, NY, United States.

Studies in wild populations and in experimental settings have compared the form and strength of the natural selection across environments that differ in either biotic or abiotic conditions. Recently, researchers in the field of "community genetics" have argued that genetic variation in interacting species (e.g., competitors) can lead to reciprocal evolution of both partners. However, we know little about the relative force of selection via biotic vs. abiotic conditions. If selection via biotic factors is weaker or more variable in time or space than abiotic selection, species interactions may have little long-term effect on phenotypic evolution. I review studies published since 1996 on patterns of selection to address the following questions. Do biotic or abiotic conditions exert stronger selection on phenotypic traits? How does the strength of selection differ across environments that vary in biotic (e.g., presence or absence of competing species) vs. abiotic (e.g., wet vs. dry environments) conditions? How variable is selection via biotic vs. abiotic conditions in time and space?

2.8.4. The contribution of maternal effects to adaptation in natural plant populations

L. F. Galloway[1], J. R. Etterson[2];
[1]University of Virginia, Charlottesville, VA, United States, [2]University of Minnesota Duluth, Duluth, MN, United States.

Environmental maternal effects may evolve as a source of adaptive plasticity between generations. This concept will be illustrated using *Campanula americana*, an herb that grows in understory and light-gap habitats. Estimates of seed dispersal suggest that offspring typically experience the same light environment as their mother. In a field experiment testing the effect of open versus understory maternal light environments, maternal light directly influenced offspring germination rate and season, and indirectly affected germination season by altering maternal flowering time. Germination season determines whether individuals grow as annuals or biennials, and results to date indicate that maternal effects on life history schedule are adaptive. Direct- and maternal-genetic variation for timing of germination (V_A and V_{Am}) will also be presented. In total, this provides a comprehensive assessment of the contribution of maternal light effects to life history evolution in this species. Evaluating maternal effects in an ecological context is necessary to demonstrate that they may provide phenotypic adaptation to local environments.

2.8.5. Issues in testing local adaptation - competition and environmental distance

A. Bischoff, L. Crémieux, T. Steinger, H. Mueller-Schaerer;
Unit of Ecology and Evolution, University of Fribourg, Fribourg, Switzerland.

Local adaptation is usually tested in reciprocal transplant experiments calculating the home versus away contrasts of the site by provenance interaction. Often, experiments are conducted under reduced competition, i.e. in weeded monocultures or in vegetation disturbed by planting of seedlings. Furthermore, a home-site advantage is commonly used to recommend close-by populations in restoration schemes - regardless of the habitat type in which populations occur. We set up a large-scale reciprocal transplant experiment with Swiss, Czech and UK populations of three grassland species. The effect of competition was tested by comparing spaced individuals in weeded monocultures and plants sown together with ten typical grassland species. At each site a close-by population from a contrasting habitat was compared to the two foreign populations. The home vs. away contrasts were largely affected by the competition treatment indicating that local adaptation under natural conditions cannot be predicted from plants grown without competition. Close-by populations from a contrasting habitat were often more different to the home population than foreign ones.

2.8.6. Quantitative evolution in natural populations: neutral markers and chemical defences in *Eucalyptus tricarpa*

R. L. Andrew;
The Australian National University, Canberra, Australia.

Neutral genetic markers can be useful tools for studying the evolutionary ecology of adaptive traits in natural systems. Marker-based investigations of natural populations and open-pollinated genetic trials have provided unique insight into the causes of defence trait variation in *Eucalyptus*. Formyl phloroglucinol compounds are the most effective and well-characterised defences of eucalypts and protect trees from both mammalian and insect herbivores. However, the high level of within-population variation requires explanation in such ecologically significant traits. Marker-based heritability methods in the wild, regression of progeny phenotypes on wild parents and family reconstruction in open-pollinated seedlots were gave estimates of natural quantitative genetic parameters. Despite substantial additive genetic variance, comparison of microsatellite divergence (F_{st}) with population differentiation in defence chemicals (Q_{st}) provides evidence for historical selective processes.

2.8.7. News in *Capsella* (Brassicaceae) - flowering ecotypes along a latitudinal transsect from the Kola Peninsula (67°N) to Astrakhan (46°N) in Russia

B. Neuffer;
Department of Systematic Botany, University of Osnabrueck, Osnabrueck, Germany.

Capsella bursa-pastoris (L.) Medik. is a self compatible tetraploid annual species with high colonizing success in all parts of the world and is mostly confined to man-made habitats. One reason for the success is the finescale differentiation in flowering ecotypes. 18 Populations of *C. bursa-pastoris* have been collected along more than 2500 km length from the Kola Peninsula to the Caspean See. The transsect includes short vegetation periods with extremely long days to hot and dry to salty conditions. The populations have been investigated in a common garden field experiment in order to differentiate between phenotypic plasticity and ecotypic differentiation of quantitative life history traits (flower begin, rosette diameter, leaf forms, plant height, branching and fruit characters). In addition, isozyme analyses have been performed. The most northern and most southern provenances belong to rather early flowering types, the provenances in between are medium to late flowering.

2.9.1. Response of northern forest trees to rising atmospheric CO_2 and tropospheric O_3: Mechanisms of altered forest productivity

D. F. Karnosky;
Michigan Technological University, Houghton, MI, United States.

Atmospheric concentrations of CO_2 and O_3 have increased dramatically since pre-industrial time. Since the impacts of these two co-occurring pollutants are diametrically opposite and because relatively few long-term studies of trees exposed to elevated interacting CO_2+ O_3 have been done, it is difficult to predict how forest productivity will be affected as these two pollutants continue to increase in the atmosphere. For the past 7 years, the Aspen Free Air CO_2 Enrichment (FACE) project has been examining the impacts of these co-occurring pollutants for two pioneer tree species (aspen and birch) and a later successional species (maple). In addition, many of the same aspen genotypes from Aspen FACE have been examined along a natural O_3 gradient in the Lake States region over the past 10 years. In this presentation, mechanisms controlling forest tree growth and productivity for these three species and two studies will be described under long-term exposure to elevated CO_2 and/or O_3.

2.9.2. Responses of *Pinus sylvestris* seedlings from four European populations to a polar light regime in a CO_2-enriched atmosphere

L. Llorens, M. Wentworth, E. Murchie, D. Beerling;
University of Sheffield, Sheffield, United Kingdom.

Ecosystem models predict the northwards migration of boreal forests over the next century as the climate warms and the atmospheric CO_2 concentration continues to rise. In future, therefore, boreal forests will experience a novel and poorly understood interaction between high CO_2 atmosphere and a polar light regime. We examined this interaction experimentally using four European ecotypes of *Pinus sylvestris* spanning a latitudinal transect from 40º to 68ºN grown under polar (70 ºN) light conditions with either ambient (400 ppm) or elevated CO_2 (800 ppm). Chlorophyll *a* fluorescence measurements indicated elevated CO_2 significantly enhanced photoinhibition in all four ecotypes at the growth irradiance (300 µmol PAR m^{-2} s^{-1}), and after a short-term exposure to high irradiance (600 µmol PAR m^{-2} s^{-1}), during the continuous light of the polar summer. In addition, we found no significant effects of elevated CO_2 on plant growth (height or stem diameter) in any of the four ecotypes. Thus, our results suggest that, at high latitudes, photoinhibition might offset the expected effects of CO_2 fertilization during *P. sylvestris* establishment.

2.9.3. Effects of season-long elevation of $[O_3]$ on leaf growth and photosynthesis of soybean in the field

M. M. Christ[1], E. A. Ainsworth[2], U. Schurr[1], A. Walter[1];
[1]ICG-III: Phytosphere, Research Center Juelich, Juelich, Germany, [2]USDA/ARS, University of Illinois, 147 ERML, 1201 W. Gregory Drive, Urbana, IL, United States.

Surface ozone concentration ([O-3]) has risen from an estimated pre-industrial value of 10 ppb to an average of ~60 ppb in the middle latitudes of the northern hemisphere, where it is predicted to rise by 20% in the next 50 years. The effects of elevated [O-3] (1.2 x ambient) on soybean (Glycine max cv. Spencer) leaf growth and photosynthesis were investigated under fully open-air conditions at the SoyFACE facility in Urbana-Champaign, IL, USA. The experiments were perfomed during pod-fill, when detrimental effects of O-3 would have the greatest impact on soybean yield. Photosynthetic carbon uptake was reduced in both growing and mature leaves by ~30% due to low stomatal conductance. Soluble leaf carbohydrate contents were lower under elevated [O-3]. Starch accumulation was observed in mature leaves, indicating altered sugar transport to sink organs. These changes in photosynthate availability appear to have reduced leaf growth rates, resulting in decreased leaf area at the end of pod-fill. However, the final yield was unaffected by elevated [O-3] suggesting photosynthate was preferentially allocated to reproductive sinks.

2.9.4. Pre-conditioning of alpine forest to tolerate ozone.

H. R. Bolhar-Nordenkampf[1], M. H. Meister[1], J. I. Haumann[1], F. Herman[2];
[1]Ecocenter, Department of Ecophysiology and functional Anatomy of Plants, Vienna, Austria, [2]Department of Forest protection, Vienna, Austria.

The ozone impact on forest growth does not directly correlate with the tropospheric ozone concentration, as calculated via the tree-specific critical level (spruce: 10 ppm.h, AOT40,), but it is supposed to correlate far better with the rate of O3 uptake (influx) and the formation of reactive oxygen species (ROS). Ozone risk maps of Austrian forest, based on this concept, showed large areas of alpine forest with growth reductions of 30%. These calculated findings were not confirmed by the forest stock inventory and/or tree physiological studies on the spot. In contrast this research showed, that the ozone influx, controlled by leaf conductance (gL) did not appropriately modify the obvious response of alpine forests to ozone. Whereas, with increasing altitude, trees seem to be pre-conditioned to tolerate higher ozone levels. This pre-conditioning was probably achieved by the adaptation to i. the “pre-industrial” ozone concentrations and/or by ii. a long-lasting adaptation the exposure to UV-B depending on latitude and altitude.

2.9.5. Does leaf photosynthesis of plants originating from natural CO_2 springs adapt to CO_2-enriched environments?

Y. Onoda, K. Hikosaka, T. Hirose;
Graduate School of Life Sciences, Tohoku University, Sendai, Japan.

To explore adaptation of leaf photosynthesis to CO_2-enriched environments, plants originating from three natural CO_2 springs (spring-plants; mean habitat CO_2 was 500-1000 µmol mol-1) and nearby control areas (control-plants; c. 370 µmol mol-1) were grown at two CO_2 treatments (ambient CO_2: 370, elevated CO_2: 700 µmol mol-1). We hypothesized that plants having a higher resource use efficiency at elevated CO_2 have been selected at natural CO_2 springs, because they may have higher competitive fitness in CO_2-enriched environments. This hypothesis was examined in the following three aspects: photosynthetic nitrogen use efficiency (PNUE), water use efficiency (WUE) and carbohydrate accumulation. The improvement of PNUE with a selective decrease in the amount of Rubisco, as predicted by theory, was not observed in all spring-plants. Lower stomatal conductance and higher WUE were found in spring-plants originating from one of the CO_2 springs, but not in those from the other two springs. Leaf starch accumulation tended to be lower in spring-plants originating from one of the CO_2 springs, which appeared to relieve down-regulation of photosynthesis.

2.9.6. A link between stomatal development and cuticular wax composition

J. E. Gray[1], G. Holroyd[2], J. Hunt[1], A. M. Hetherington[2];
[1]University of Sheffield, Sheffield, United Kingdom, [2]Lancaster University, Lancaster, United Kingdom.

The *Arabidopsis thaliana HIC* (for *High* CO_2) gene encodes a putative fatty acid elongase believed to be involved in the synthesis of very long chain fatty acids. Plants carrying a mutation in the *HIC* gene or engineered such that *HIC* gene expression is reduced display an increased number of guard cells when grown under elevated concentrations of carbon dioxide (Gray *et al.,* Nature 1990). As fatty acid elongases are involved in the production of very long chain fatty acids, which are components of the cuticular waxes, the stomatal index of several wax deficient mutants was investigated. *cer1* and *cer6,* which have mutations in decarbonylase and fatty acid elongase encoding genes respectively, were shown to have abnormally high stomatal indices. These results indicate a link between the control of stomatal number and the biosynthesis of cuticular waxes. The results of recent experiments on the possible involvement of waxes in the control of epidermal cell development at elevated atmospheric CO_2 will be presented.

2.9.7. Elevated Carbon Dioxide Concentrations Inhibit Nitrate Assimilation in the Shoots of C3 Plants

A. J. Bloom;
University of California, Davis, CA, United States.

Six independent methods affirmed that elevated CO_2 inhibits NO_3^- assimilation in shoots of C_3 plants (*Arabidopsis*, barley, *Flavaria pringlei*, giant redwood, tomato, and wheat), but not in NADP$^+$-ME C_4 plants (maize and *Flaveria bidentis*). These methods examined growth and protein content, shoot CO_2 and O_2 fluxes, NO_3^- uptake vs. accumulation, mutants deficient in NO_3^- reductase, ^{15}N discrimination, and ^{15}N partitioning after a $^{15}NO_3^-$ pulse. Several mechanisms may be responsible. 1) Photorespiration and the NADP$^+$-ME C_4 pathway may increase malate levels in the cytoplasm to generate the NADH required for NO_3^- reduction. 2) Elevated bicarbonate levels may interfere with NO_2^- translocation into chloroplasts. 3) NO_2^- reductase may obtain sufficient ferredoxin only when the C_3 pathway is CO_2 limited. These results explain several responses of plants to rising CO_2 levels including CO_2 acclimation and CO_2 suppression of respiration. They also suggest that as atmospheric CO_2 levels increase, shifts in the relative use of NH_4^+ and NO_3^- as N sources will influence the primary productivity of C_3 plants, thus altering species composition.

2.10.1. Growth and impact of measurements that do not perturb the plant. The example of tracer fluxes

W. J. Cram;
University of Newcastle, Newcastle upon Tyne, United Kingdom.

The annual number of publications using non-invasive techniques in plants rose exponentially from 1985 to 2000 and is still rising though more slowly. This parallels the increasing interest of investigators in functioning in the intact plant, in interactions between processes and in complex systems. A semi-systematic tabulation of non-invasive techniques will be considered in relation to major problems of plant biology in order to see what match there is. Tracer techniques for measuring fluxes and compartment contents in living cells will be reviewed in more detail. The critical considerations for appying a compartmental interpretation to a tracer exchange curve are: the system should be in a steady state, all compartments are fully mixed, there is no discrimination between tracer and traced ion or molecule. The experimenter must also ensure that the data cover the whole time course of exchange. Under these conditions it may be possible to estimate fluxes at plasmalemma and tonoplast.

2.10.2. Effect of nutrient stress on algae: a species comparison by FTIR-spectroscopy

K. Stehfest, C. Wilhelm;
Institute of Biology I, Leipzig, Germany.

The identification of nutrient limitation of phytoplankton growth is of considerable importance to our understanding of the ecology of aquatic systems. In addition, water quality of freshwater systems is controlled by the availability of nutrients limiting the aquatic primary productivity. As a response to nutrient stress phytoplankton cells undergo metabolic acclimation resulting in shifts of total C, N, and P quota. This was shown for e.g. nitrogen, phosphate, and silica limitation of algae. We employed Fourier Transform Infrared (FTIR) spectroscopy as a non-invasive technique to study changes in spectral features of several algae in response to nutrient stress. Monitoring changes of spectral band ratios and correlating the ratios with actual cellular C:N and C:Si quotients allowed the detection of species-specific shifts. Since the growth rate is known to depend on C, N, and P quota, FTIR can not only be used to detect the type of stress, but also its influence on growth and the competition capability of species. As an example FTIR spectroscopy was used to identify N-limitation of *Microcystis sp*. in a hypertrophic lake.

2.10.3. Relationships between leaf shape, leaf temperature, carbon gain and water use in South African Pelargonium species

A. B. Nicotra[1], M. J. Cosgrove[1], C. D. Schlichting[2], C. S. Jones[2];
[1]Australian National University, Canberra, Australia, [2]University of Connecticut, Storrs, CT, United States.

There is a tremendous range of variation in leaf shape among plants and we are only beginning to understand its functional significance. Theoretically, a divided or dissected leaf should track ambient temperatures more closely than an entire leaf of the same area. Because photosynthesis is optimum at a certain temperature, differences in leaf temperature will affect carbon gain. Transpiration also increases with temperature, thus, leaf-level water-use-efficiency (WUE) declines once temperature exceeds the optimum for carbon gain. We measured the thermal response of photosynthesis in Pelargonium plants grown at two temperature and water levels and asked whether leaves from species with different shapes varied in gas exchange traits. Results show that plants acclimated to growth temperatures and had very broad optimal temperature ranges. Thermal optima exceeded growth temperatures under both regimes, but optimum for WUE was significantly lower. Notably, dissected leaves had higher photosynthetic capacities than entire leaves, we propose that this may reflect a suite of correlated traits associating leaf shape, morphology and physiology.

2.10.4. Emergent Behavior and Information Processing by Stomatal Networks

K. A. Mott;
Utah State University, Logan, UT, United States.

Stomata must respond to environmental factors such that they open to admit enough CO_2 for photosynthesis, yet close sufficiently to prevent excessive water loss. Much of this regulation occurs at the level of the individual pore, through signal transduction pathways in the guard cells. However there is increasing evidence that stomata interact with each other over short distances and can therefore be said to form a locally-connected network. Chlorophyll fluorescence images and thermography can be used to show that stomatal conductance can often be patchy and that stomata can behave collectively. This collective behavior may indicate that stomatal networks are processing information in a manner similar to artificial networks that perform distributed emergent computation. This information processing may allow stomata networks to optimize gas exchange for an entire leaf or plant despite the fact that each individual stoma has only local information.

2.10.5. Non-invasive analysis of water and carbon transport and plant growth by nuclear magnetic resonance and positron emission tomography

U. Schurr[1], P. Blümler[1], S. Jahnke[1], G. Roeb[1], P. Minchin[1], J. Lindenmair[1], K. Füllner[1], K. Ziemons[2];
[1]Phytosphere, Jülich, Germany, [2]Central Institute for Electronics, Jülich, Germany.

Plant growth and transport processes are highly dynamic. They are characterized by plant-internal control processes and by strong interactions with the spatially and temporally varying environment. Analysis of structure-function relations of growth and transport in plants will strongly benefit from the development of non-invasive techniques. The paper will describe recent advances in the low- and high-field NMR imaging of plant transport in xylem and phloem as well as on root growth analysis in artificial soils. Non-invasive functional analysis of the dynamics of carbon transport is possible by using the short-lived isotope ^{11}C. In addition to standard detection techniques, the recently developed positron emission tomography system for plants (PlanTIS) allows imaging the flow of ^{11}C-labelled compounds in two and three dimensions. These techniques will provide a real insight into the dynamic nature of growth and transport processes of plants in variable environments.

2.10.6. Development of uniformly stable isotope labeling system in higher plants for hetero-nuclear NMR experiments *in vitro* and *in vivo*

J. Kikuchi;
Plant Science Center, RIKEN Yokohama Institute, Yokohama, Japan.

Novel methods for measurement of living systems are making new breakthroughs in life science. In the era of the metabolome (analysis of all measurable metabolites), a MS-based approach is considered to be the major technology, whereas a NMR-based method is recognized as minor technology due to its low sensitivity. Therefore, my laboratory is currently focusing to develop novel methodologies for an NMR-based metabolomics. This will be achieved by uniform stable isotope labeling of higher plants allowing application of multi-dimensional NMR experiments used in protein structure determination [1]. Using these novel methods, I will analyse the dynamic molecular networks inside tissues. Especially, use of stable isotope labeling methods has enormous advantage for discrimination of incorporated or *de novo* synthesized compounds. Furthermore, potentiality of *in vivo*-NMR metabolomics will be discussed in the conference. [1] “Stable isotope labeling of *Arabidopsis thaliana* for an NMR-based metabolomics approach.” *Plant Cell Physiol.* **45**, 1099-1104 (2004).

2.11.1. Noise-sustained patterns in excitable systems.

F. Moss;
University of Missouri at Saint Louis, Saint Louis, MO, United States.

The ability of excitable systems to generate and propagate patterns, or coherent structures, is well known. This property has been widely demonstrated in biological, chemical, physical as well as in ecological systems. In all such systems an inherent threshold mediates the excitation and propagation of the structures. In the absence of random fluctuations, or noise, structures can propagate only when generated by an excitation that exceeds the threshold. But when the excitation is sub threshold, the structures propagate only a short distance and then die out. It is nevertheless observed that sub threshold structures can propagate over long distances in the presence of noise. Such systems are modeled as networks of coupled nonlinear oscillators throughout which supra threshold and noise sustained sub threshold coherent patterns can propagate. Coupled noisy oscillators also exhibit stochastic phase synchronization, a closely related topic. Examples from a chemical, neural and biological system are presented.

2.11.2. Spatio-temporal pattern formation of photosynthesis from leaves to the canopy - do spatial variations really matter?

U. Rascher;
Research Center Jülich, Jülich, Germany.

Light use efficiency of photosynthesis dynamically adapts to a variety of internal and environmental factors often rendering photosynthesis heterogeneously distributed over single leaves or organs. These spatio-temporal variations reflect regulatory properties of photosynthesis and may have an constructive role for stability in metabolic pathways and during development. Natural canopies are complex 3-dimensional structures, exposed to a fluctuating light environment. The tropical rainforest mesocosm within the Biosphere 2 Center has been subjected to a series of 4-6-week drought treatments. Ecosystem CO_2 uptake rate declined 32% and ecosystem transpiration declined 50% in response to the drought, reflecting both morphological and physiological responses, including increased leaf fall, reduced maximum photosynthetic electron transport rate , and stomatal closure. Individual trees responded differently, expressing different levels of stress avoiding mechanisms. This functional diversity renders the individual response heterogeneous and has implications to scale leaf level responses to the dynamics of the ,,big leaf“ canopy.

2.11.3. Metabolite snapshot analysis reveals correlative biological fluctuation as a result of constant environmental perturbation in plant systems

W. Weckwerth[1], K. Morgenthal[1], R. Steuer[2];
[1]Max-Planck-Institut für Molekulare Pflanzenphysiologie, 14424 Potsdam, Germany, [2]Universität Potsdam, 14424 Potsdam, Germany.

For the analysis of plant systems we developed a technological platform based on snapshot metabolite profiling. For comprehensive analysis of representative compound classes gaschromatography coupled to time of flight mass spectrometry was used. Analytical precision is in the range of 10-30 % coefficient of variation. Biological fluctuation of independent samples exceeds this threshold several fold [1]. The metabolite variances are used for multivariate data analysis. Pairwise metabolite correlations are extracted from the data set and analysed with respect to correlation network topologies [2]. These dynamic changes in correlation networks are connected to underlying pathway networks [3, 4]. Numerical analysis of calvin cycle and sucrose metabolic pathways in leaf metabolism predict distinct metabolite correlation networks in dependence of environmental parameters and enzyme regulation. [1] Weckwerth et al. *Proteomics* 2004 [2] Weckwerth et al. PNAS 2004 [3] Weckwerth *Annual Review of Plant Biology* 2003 [4] Steuer et al. *Bioinformatics* 2003

2.11.4. Coupling of different oscillators in the circadian rhythm of Crassulacean acid metabolism (CAM)

T. P. Wyka[1], H. M. Duarte[2], U. E. Lüttge[2];
[1]Adam Mickiewicz University, Poznan, Poland, [2]Technische Universität-Darmstadt, Darmstadt, Germany.

In continuous light, the Crassulacean acid metabolism plant *Kalanchoë daigremontiana* undergoes a circadian rhythm of gas exchange. This rhythm, however, is not paralleled by the expression of CAM rhythmicity (i.e. storage and release of malate). Instead, a substantial proportion of the rhythm's amplitude is accounted for by C3 mediated uptake of CO_2. Experiments applying thermoperiodic entrainment have revealed the existence of an oscillator driving stomatal conductance which functions separately from the oscillator controlling CO_2 uptake by the mesophyll (Bohn et al. 2003 Biol. Chem. 384: 721-728). When stomatal conductance was eliminated by coating leaves with silicone grease, the mesophyll level rhythmicity was still expressed. Experimental analysis of the gas exchange rhythm in *Kalanchoë* has revealed a complexity of oscillating systems, including controls of CAM and C3 carboxylation pathways, as well as stomatal conductance working in a network to produce the overt CO_2 uptake rhythm.

2.11.5. “Functioning-dependent structures” (FDSs) in higher plants and fungi

M. E. Thellier[1], G. Legent[1], P. Amar[2], V. Norris[1], C. Ripoll[1];
[1]Laboratoire AMMIS, Mont Saint Aignan, France, [2]UMR CNRS 9023, Orsay, France.

Proteins involved in metabolic/signalling pathways are sometimes organised into multimolecular assemblies ranging from quasi-static complexes to dynamic associations only forming in an activity-dependent manner. These exist in all sorts of organisms and include the ATP- and pH-dependent association/dissociation of the V_1 and V_0 domains of the yeast vacuolar H^+-ATPases and the nucleotide-dependent pentameric/hexameric transition of the head structure of a higher plant V-type H^+-ATPase. We term *functioning-dependent structure* (*FDS*) any multimolecular structure in which proteins (or other molecules) associate due to the very fact that they are in the process of accomplishing their function and from which they dissociate when ceasing to function. Apart from the well-known advantages of protein assemblies compared with free proteins (better resistance to hydrolysis, channelling of intermediates), our modelling shows that, under steady state conditions, *FDSs* may display kinetic properties such as a prolonged linear response or a sigmoidal behaviour, even when their constitutive proteins do not display such properties when functioning separately.

2.11.6. Non-linear dynamics of plant photosynthesis in fluctuating light

L. Nedbal[1], Z. Benediktyova[1], K. Matous[1], J. Cerveny[2];
[1]Inst. Landscape Ecology ASCR & Inst. Physical Biology USB, Nove Hrady, Czech Republic, [2]Centre of Applied Cybernetics, Czech Technical University, Praha, Czech Republic.

Variable cloud cover and moving canopy are among the dynamic factors that have been shaping the photosynthetic regulation since the first ancestors of modern plants emerged. Plants developed regulatory feedbacks to sustain homeostasis of plant bioenergetics in fluctuating light. These feedbacks are responsible for emergent, systemic properties of plants that are observed in harmonically modulated irradiance. The non-linear, upper harmonic modulation of fluorescence emission and of CO_2 assimilation are measurable signatures of the dynamic regulation of photosynthesis during forced oscillations. We use the forced oscillations and frequency analysis of the reporter signals for systems identification of the photosynthetic regulatory motifs. An open-access, web-based modeling project aiming at this goal is presented. Molecular mechanisms with a potential of causing the non-linear dynamics are discussed. In parallel, we show that the forced oscillations and the analysis of the upper harmonic modulation of fluorescence emission can be used to detect regulatory mutants and plant segments affected by a biotic stress.

2.11.7. Dynamical complexity of gas exchanges and higher network connectance improves homeostasis of plants under water deficit

G. M. Souza[1], S. M. Pincus[2], **J. A. F. Monteiro**[3];
[1]University of Western Sao Paulo, UNOESTE, Presidente Prudente, Brazil, [2]Massachusetts Institut of Thechnology, Cambridge, MA, United States, [3]UniversitÃ¤t Basel, Basel, Switzerland.

We hypothesized that more irregular or complex temporal dynamics and a more interconnected overall network supports greater stability to gas exchange parameters (herein, CO_2 net assimilation and transpiration) in plants under water deficit. To test this hypothesis two genotypes of *Phaseolus vulgaris* were subjected to a period of absence of irrigation, and subsequent rewatering to achieve recovery. Gas exchanges parameters were measured each 10 s during 6 h to obtain time series to evaluate complexity by Approximate Entropy (ApEn) calculations, and network connectance in each water regime. Notably, the Jalo Precoce genotype showed significantly more stability than the Guarumbé genotype under system perturbation, coincident with greater irregularity in each gas exchange parameter and greater overall connectance for Jalo. This conclusion is consistent with other observations of greater homeostasis in more complex networks, seen in broad contexts such as cardiac rhythms and respiratory dynamics.

2.12.1. Molecular systematics and chemotaxonomy: The importance of molecular phylogeny to interpret phytochemical relationships

M. J. J. Wink;
Heidelberg University, Heidelberg, Germany.

The occurrence of secondary metabolites (SM) often agrees with taxonomic groups and has therefore been used to infer systematic relationships; even a new discipline “chemotaxonomy” had been established. This concept was based on the assumption that SM had no function and that they would strictly reflect phylogenetic relationships. However, presently we regard SM as defence and signal compounds, important for the plant’s survival and reproductive fitness. SM therefore represent adaptive characters that have been subject to natural selection. A closer look into the distribution of SM reveals that certain metabolites are absent (or present) in a given taxon, although all the neighbouring and ancestral taxa express or (do not express, respectively) the particular trait. The inconsistent SM profiles mean that the systematic value of chemical characters becomes a matter of interpretation in the same way as traditional morphological markers. Their occurrence apparently reflects adaptations and particular life strategies embedded in a given phylogenetic framework.

2.12.2. Review on taxonomy of the genus *Murraya* (Rutaceae) from chemosystematic viewpoints

T. Kinoshita[1], M. Shimada[1], H. Sato[1], N. Narita[1], T. Uji[2], K. Firman[3], F. M. Dayrit[4], D. A. Madulid[5];
[1]Teikyo University, Sagamiko, Kanagawa, Japan, [2]Herbarium Bogoriense, Bogor, Indonesia, [3]Bandung Institute of Technology, Bandung, Indonesia, [4]Ateneo de Manila University, Quezon, Philippines, [5]Philippine National Museum, Manila, Philippines.

The genus *Murraya* belongs to the orange subfamily (Aurantioideae) in Rutaceae, and comprises two sections: *Murraya* and *Bergera*. Section *Murraya* contains 4 species and 3 varieties, all of which are closely related each other from taxonomical viewpoints. *M. paniculata* is geographically the most wide-spread species of Section *Murraya* occurring in either the tropics or subtropics of Asia and Oceania. This species has found wide medicinal value throughout the area of distribution. Its ethnobotanical use varies outstandingly from one area to another, which is presumed to reflect botanical diversity of the origin at not only the infra-specific but also specific level. We have thus been induced to undertake intensive chemical investigation on this species of various localities, and have clarified chemical diversity of this species. A series of chemical studies revealed that *M. paniculata* should be divided into two species and several chemical races depending upon the types of prenylcoumarins contained. This paper deals with taxonomical review of both Section *Murraya* and genus *Murraya* from viewpoints of both morphology-based taxonomy and chemotaxonomy.

2.12.3. The systematic significance of isoflavonoids in the *Lecointea* clade (Leguminosae: Papilionoideae: Swartzieae).

A. F. Magalhães[1], A. C. Oliveira[1], **A. M. G. Tozzi**[1], C. A. Barbosa[1], E. G. Magalhães[1], V. F. Mansano[2];
[1]Universidade Estadual de Campinas, Campinas, Brazil, [2]Instituto de Pesquisas Jardim Botânico do Rio de Janeiro, Rio de Janeiro, Brazil.

Despite many morphological similarities, some molecular phylogenies indicated that the Lecointea clade, a basal group of Leguminosae, Papilionoideae, is not natural, but a recent molecular work suggested that this group is monophyletic. This paper aims to verify if the detection of flavonoids can be helpful in the classification of these Leguminosae taxa to see with which of the phylogenies the chemical data corroborate. For that it was accomplished a phytochemical study in roots of Harleyodendron unifoliolatum R.S.Cowan, Lecointea hatschbachii Barneby and Holocalyx balansae Micheli. This study resulted in the isolation of sixteen isoflavonoids. We detected four pterocarpans (two unpublished), three isoflavans and two isoflavanones (both are also unpublished) in Harleyodendron unifoliolatum; one pterocarpan, one isoflavone (unpublished) and three cumestans (two unpublished) in Lecointea hatschbachii; and two isoflavanones in Holocalyx balansae (also unpublished). The phytochemical evidences indicate that the members of Lecointea group have flavonoids and isoflavonoids that are not found in any member of the Vatairea group.

2.12.4. Using molecular phylogenies of the genus *Veronica s. str*. to assess iridoid and flavonoid characters

R. J. Grayer[1], D. C. Albach[2], R. M. Taskova[3], S. R. Jensen[4];
[1]Royal Botanic Gardens Kew, Richmond, Surrey, United Kingdom, [2]Institute of Botany, University of Vienna, Vienna, Austria, [3]Institute of Botany, Bulgarian Academy of Sciences, Sofia, Bulgaria, [4]Department of Chemistry, The Technical University of Denmark, Lyngby, Denmark.

Early systematic classifications of the genus *Veronica s. str.* (fam. Plantaginaceae, formerly Scrophulariaceae) were mainly based on macromorphological features such as the position of the inflorescence. Subsequent karyological, seed morphological and phytochemical studies suggested that these classifications did not reflect the phylogentic relationships within the genus. Recently several molecular studies have been carried out which have led to a new phylogenetic intrageneric classification of *Veronica*. This has provided us with a framework to assess the phylogenetic value of chemical characters for the classification of the genus. For example, unusual 8-hydroxyflavone glycosides, which according to previous classifications seemed to occur in unrelated groups in the genus, now appear to be characteristic of the new subgenera *Pocilla* and *Pentasepalae*, which are sister groups in the molecular phylogenetic analyses. Likewise, the iridoid glucoside mussaenoside appears to be a good phylogenetic character for the new subgenus *Veronica*.

2.12.5. Secondary metabolites in relation to molecular phylogenies in *Aloe* and related genera (family Asphodelaceae)

B. Van Wyk[1], **G. F. Smith**[2], A. M. Viljoen[3], J. Treutlein[4], M. Wink[4];
[1]Department of Botany and Plant Biotechnology, University of Johannesburg, South Africa, [2]Research Directorate, SANBI, Pretoria, South Africa, [3]Department of Pharmacy, University of the Witwatersrand, South Africa, [4]Institut für Pharmazie und Molekulare Biotechnologie (IPMB), University of Heidelberg, Germany.

Chemotaxonomic studies of *Aloe* and related genera of the family Asphodelaceae over the last 40 years have revealed a remarkable complexity of secondary metabolites. Most genera accumulate tetrahydroanthracenones in the roots and these metabolites show interesting discontinuities at generic level. Knipholone and related compounds appear to be confined to *Bulbine*, *Bulbinella* and *Kniphofia*, while asphodeline and related compounds are more widely distributed. 1-Methyl-8-hydroxyanthraquinones are present in the roots of most *Aloe* species (with further oxidation in *Gasteria*), while the leaves have anthrone-C-glycosides, chromones, phenylpyrones and rarely flavonoids. Nectar sugars are uniform within genera but show diagnostic differences amongst genera. General trends, congruence and inconsistencies in the presence of secondary metabolites will be highlighted, with reference to recently published molecular phylogenies. The overall pattern supports the hypothesis that hybridization must have played an important role in the phylogenetic history of the subfamily Alooideae.

2.12.6. Mapping of the distribution pattern of terpenoids on a molecular phylogeny inferred from ITS sequence data in *Nepeta* L.

Z. Jamzad[1], M. S. J. Simmonds[2], M. Ingrouille[3], F. Sefidkon[1], A. Jalili[1], G. C. Kite[4];
[1]Research Institute of Forests & Rangelands, Tehran, Islamic Republic of Iran, [2]Jodrell Laboratory, Royal Botanic Gardens Kew, Richmond, Surrey TW9 3AB, United Kingdom, [3]School of Biological and Chemical Sciences, Birkbeck College, Malet street, London, WCIE 7HX UK, London, United Kingdom, [4]Jodrell Laboratory Royal Botanic Gardens Kew, Richmond, Surrey TW9 3AB, United Kingdom.

The compositions of essential oils in *Nepeta* have been studied by GC-MS. The presence of terpenoids was interpreted on a molecular phylogeny based on the analysis of nucleotide sequences of the nrITS. The main components of the essential oil in most *Nepeta* species are monoterpenoids, 1,8-cineole and nepetalactone are major compounds, but rarely sesquiterpenoids are predominant. The results show that some of the monophyletic groups in the molecular phylogeny share the same class of compounds, for example, species of Sects. *Capituliferae, Micranthae* p.p. and *Micronepeta* p.p. are characterized with 1,8-cineol, transpinocarveol, pinocarvone, myrtenol and myrtenal. The species of Sect. Spicatae are characterzed by nepetalactone and 1,8-cineol as the major constituents, sabinene and beta- pinene in lower quantity. The species of sects. Nepeta, Micranthae p.p. and Macrostegiae p.p. are characterized by nepetalactone as the major constituent and a considerable number of sesquiterpenoids. In the species of Sect. Psilonepeta sesquiterpenoids are more frequent than monoterpenoids. The results provided data for a new infra-generic classification of *Nepeta.*

2.12.7. Sesquiterpenoids as chemosystematic markers in the subtribe Hypochaeridinae (Lactuceae, Asteraceae)

C. Zidorn;
Institut für Pharmazie, Universität Innsbruck, Innsbruck, Austria.

Molecular analyses are currently the gold standard within biosystematic research. However, many of the clades in phylogenies arising from molecular analyses are only weakly characterized by morphological data. In such instances, phytochemical data might help in phenetically defining clades found in molecular investigations. In contrast to the delimitation of the Lactuceae tribe from other tribes of the Asteraceae family, which is well established on the basis of morphological, phytochemical, and molecular markers, the borders of genera within the Lactuceae are not undisputed. Recent molecular analyses indicate that current generic limits within the Hypochaeridinae result in paraphyletic groupings. In this communication sesquiterpenoids are employed to phenetically characterize undisputed supra-specific entities within the subtribe Hypochaeridinae (Lactuceae, Asteraceae). The phytochemical data are congruent with recent molecular results and imply e.g. that the genus *Leontodon* will have to be divided into two separate genera.

2.13.1. Plant functional types as tools to bridge across scales

S. Lavorel;
Laboratoire d'Ecologie Alpine, Grenoble Cedex 9, France.

Plant functional research has soared for the last ten years as a result of the impetus given by global change questions. Recent research has explored the significance of plant functional traits to environmental response and ecosystem effects. One first achievement has been the production of standardised lists of the most significant and easily measurable traits. Based on these, and on large efforts to synthesise the literature, it has been possible to identify and explain plant functional response traits associated with response to resource gradients (esp. nutrients) and widespread disturbances such as grazing and fire. Current research is focussing on the challenge of linking these to effects on community structure and on biogeochemistry, showing the relevance of fundamental trade-offs that constrain the way plant manage their resources. These considerable advances will now allow us to refine functional classifications used in dynamic vegetation models, as well as contributing to the debate on the relationships between plant diversity and ecosystem function.

2.13.2. Scaling from traits to communities to ecosystems: the challenge of complexity at intermediate scales

K. N. Suding[1], S. Lavorel[2], F. S. Chapin[3], H. Cornellissen[4], S. Diaz[5], E. Garnier[6], D. Goldberg[7], D. Hooper[8], M. Navas[9];
[1]University of California Irvine, Irvine, CA, United States, [2]Université Joseph Fourier, Grenoble, France, [3]University of Alaska, Fairbanks, AK, United States, [4]University of Amsterdam, Amsterdam, Netherlands Antilles, [5]University of Cordoba, Cordoba, Argentina, [6]Centre d'Ecologie Fonctionnelle et Evolutive, Montpellier, France, [7]University of Michigan, Ann Arbor, MI, United States, [8]Western Washington University, Bellingham, WA, United States, [9]University of Montpellier, Montpellier, France.

Despite the potential importance of community dynamics, predictions of ecosystem responses to environmental changes are still often based on simple aggregations of individual plant responses. Regional-scale models often chose to ignore population and community-level phenomena on the grounds that this increased complexity does not add understanding. When does scaling need to incorporate community dynamics and when can it skip this level? Although higher-level responses to changing species and functional composition may often be modest and gradual, ignoring these dynamics may sometimes introduce large errors at higher levels of organization. We consider when it is necessary to deal explicitly with plant functional dynamics at the community level. First we outline the basic premises and assumptions of trait-based scaling, then present evidence that community-level phenomenon should be better incorporated into scaling approaches, and finally point to places where further research could help us better understand the importance of complexity at intermediate scales.

2.13.3. Can plant functional traits account for plant-plant interactions?

M. Navas, **M. L. Navas**;
UMR CEFE, Montpellier Cedex 1, France.

Much research has been devoted toward understanding how individuals of co-occurring plant species interact and how these interactions influence structure and dynamics of communities. Reviewing studies assessing inter-specific competition phenomena, a list of intuitive questions asked by researchers and experimental procedures employed to address these questions is proposed. Two groups of studies emerge: “individual-centered” studies characterizing short-term changes in performance and proportions of species; “community-centered” studies documenting species establishment and existence in communities. A trait-based approach is proposed to link “individual-“ and “community-centered” approaches. Effect traits acting on competitive intensity, are traits accounting for changes in local environmental conditions due to plant functioning. Examples of functional traits, involved in resource use trade-off, are given. Response traits characterize plant response to those environmental changes. They are related to plant growth, reproduction and longevity. Their relevance to assess changes in community structure and dynamics is discussed.

2.13.4. Response of plant functional traits to land-use changes in European mountain grasslands

M. Bahn, K. Bianchi, A. Cernusca;
Institut fuer Botanik, Innsbruck, Austria.

Land-use changes affect both the composition and the diversity of species in mountain grasslands. The related changes in plant functional traits, rather than species numbers *per se*, can be considered as major determinants of ecosystem biogeochemical cycles. Nine functional traits of more than 120 vascular plant species in 19 differently managed mountain grasslands across Europe were analysed as regards (i) their response to land use, (ii) their variation (i.e. the functional diversity of the ecosystems), and (iii) the definition of plant functional types and their relation to land use. It was found that with decreasing intensity of land management specific leaf area and mass-based leaf nitrogen concentrations (N_L) decreased, whilst leaf mass ratio and area-based N_L increased. The variation of canopy height, a measure of spatial heterogeneity, changed with land use and was closely related to the variation of plant height and carbon/nitrogen ratios, but not of biomass and leaf area. Based on a cluster analysis five plant functional types were distinguished, whose proportional contribution to the different grasslands varied in response to land use.

2.13.5. Generic functional descriptors as a basis for scale-free vegetation classification and analysis

A. N. Gillison;
Center for Biodiversity Management, Yungaburra, Australia.

A generic set of plant functional attributes and their elements is used to classify a plant as a unified functioning individual in terms of chlorophyll distribution, life form and aboveground rooting features. Any vascular plant can be readily described by combining the functional elements according to a specified rule set. While more than seven million combinations are theoretically possible, data from 1760 sites (40x5m transects) worldwide, suggests the real figure for the world's 250,000+ vascular plant species may be less than 4,000. Combinations of leaf adaptive features and supporting life form reflect both short and long-term plant response to environmental change and thus facilitate bridging scales of ecological analysis. Environmental, gradient-based case studies covering most of the world's key vegetation types are used to illustrate how data can be readily aggregated or disaggregated to target management or research needs at any specified environmental scale. Compared with purely species-based approaches, the method facilitates more meaningful cross-site ecological comparison and an improved basis for biodiversity assessment.

2.13.6. Plant functional traits capture changes in ecosystem functioning in response to land use changes

E. Garnier[1], T. VISTA Consortium[2];
[1]Centre d'Ecologie Fonctionnelle et Evolutive (UMR 5175), Montpellier Cedex 5, France, [2]Research Institutions and Universities across Europe, 10 cities in Europe, Czech Republic.

Although the structure and composition of plant communities is known to influence the functioning of ecosystems, there is as yet no agreement as to how these should be described from a functional perspective. We tested the biomass ratio hypothesis, which postulates that ecosystem properties should depend on species traits and on species contribution to the total biomass of the community, in 11 sites across Europe. These sites have undergone various land use changes, leading to changes in species composition and functional characteristics. Preliminary results suggest that ecosystem primary productivity and litter decomposition rate varied significantly with disturbance regime and availability of nutrients in several sites, and that these were correlated with community-aggregated - *i.e.* weighed according to the relative abundance of species - functional traits. We argue that some of the easily measurable traits tested provide simple means to scale-up from organ to ecosystem functioning in complex plant communities. These can be used to assess the impacts of community changes on ecosystem properties induced, in particular, by global change drivers.

2.13.7. Developing a general framework of rare plant population responses to habitat fragmentation

A. J. Franks[1], R. J. Hobbs[1], C. J. Yates[2];
[1]Murdoch University, Murdoch, Australia, [2]Department of Conservation and Land Management, Perth, Australia.

To effectively manage plant populations for conservation, there is a need to provide reliable information on the conditions required for maintaining viable populations. This is particularly true for rare taxa occurring in a fragmented landscape, such as that of south-west Western Australia. Resources do not exist to undertake comprehensive studies of population dynamics for every rare plant species of this region. By assigning rare plant taxa into functional groups, based on their floral architecture and putative pollinator, their fire life history and germination requirements, models will be developed for each functional group. Taxa were chosen from each functional group for detailed studies on how rates of pollination and seed production are affected by population size and landscape context. The results of these models will be extrapolated to other taxa within each functional group thereby providing guidelines for flora conservation, threatened ecological communities, and restoration programs. Here we present findings on our allocation of the rare plant taxa of WA into floral functional groups and how these groups respond to landscape fragmentation.

2.14.1. Microphytobenthos: a tool for monitoring, or a subject of ecological research?

W. Admiraal;
IBED, Amsterdam, The Netherlands.

Communities of diatoms and other microphytes are currently used for the routine monitoring of water quality. The EU-Water Framework Directive stipulates the use of microphytobenthos as a yard stick for ecological quality. It is questioned here whether the information on spatial distribution of species can be linked to specific biological attributes and to defined causes of environmental change. Microphytobenthic consortia develop structures embedding species, biofilms, and these provide a battleground for inter-specific competition. These properties of biofilms may confound one to one relationships of species attributes and distribution in environmental gradients. Environmental factors such as salinity or pH may not produce large discrepancies, yet experimental proof is lacking. Nutrients and essential metals are put forward as factors steering species composition via coupled effects on different levels of molecules up to biofilm communities. Research approaches will be discussed, using a number of case studies.

2.14.2. Probation of lifetime express-methods of control for functional state of Algae under water contamination

T. V. Parshikova, N. Musienko;
Kiev National University, Kiev, Ukraine.

The aim of investigations was selection of biophysical methods, making quick information possible on living algae cells. In experiments had been used natural and synthetic surfactants. From methods have been checked laser-doppler spectroscopy (LDS), extremely high frequency dielectrometry (EHF-dielectrometry), differential fluorimetry (DF) and luminescent-microscopic methods. As objects were investigated 17 species of algae from *Cyanobacteria*, *Chlorophyta*, *Rhodophyta*. LDS makes possible the estimation of speed of cells movement (µm/s) and its energy potential of moving (relative units). EHF-dielectrometry method makes possible the estimation of hydration level for intracellular structures of algae and state of water (free or bound) in it. For estimation of rates of biomass growth the exact results are obtained by DF method at the sacrifice of determining not only the ratio for different algae sections (by concentration of chlorophyll *a* and presence of other pigments) but also index φF (level of its potential photosynthetic activity). It was proved that one of these lifetime nondestructive methods may be used for express-control.

2.14.3. Using algal assessments and ecological thresholds to develop environmental criteria

R. J. Stevenson;
Michigan State University, East Lansing, MI, United States.

Numeric environmental criteria provide resource managers with specific targets for protecting or restoring valued ecological attributes. Non-linear relationships between valued attributes and pollution help justify specific concentrations of contaminants for criteria. Non-linear responses of ecological systems to environmental change should be common, but are seldom observed in large-scale studies. Temporal variability and scale of observation can be refined to detect thresholds in ecological response. Diatom indicators of total phosphorus concentrations of waters more precisely infer phosphorus conditions than one-time sampling and assay of total phosphorus in studies of both streams and wetlands, where nutrients have high temporal variability. Diatom indicators provided a temporally integrated assessment of phosphorus that increased the resolution in non-linear macroalgae-nutrient responses, suggesting that diatom indicators were more accurate measures of phosphorus availability than total phosphorus concentrations. Thresholds in algal-phosphorus relations provided candidates for numeric nutrient criteria.

2.14.4. An experimental approach to refining ecological optima and diatom species concepts

E. J. Cox;
The Natural History Museum, London, United Kingdom.

Whatever the organisms used, biomonitoring relies upon reliable identification of taxa that have well-defined ecological ranges and optima. However, for the majority of diatoms, ecological ranges and optima are based on relative abundances in field material correlated with physical and/or measurements, and a morphological species concept prevails, based on the interpretation of field collections. It is usually assumed that morphology is constant across environmental conditions, and that intra-specific variation is minimal. However, experimental studies and the occurrence of Janus cells have shown that diatom morphology is not constant across all conditions, but may vary in response to environmental variables. Similarly, there are inherent assumptions in the use of relative abundance data to calculate ecological optima that may falsify the results. The use of culture studies can address both issues. This paper will describe how species concepts and ecological optima can be refined using an experimental approach.

2.14.5. Recent developments in the use of benthic algae for ecological water quality analysis in rivers of Central Europe

E. Rott[1], P. Pfister[2], E. Pipp[1];
[1]Institut für Botanik, Innsbruck, Austria, [2]ARGE Limnologie, Innsbruck, Austria.

Extensive databases of benthic macro- and microalgae collected from a wide variety of lotic habitats and bioregions are used successfully for biology based water quality analysis in Central Europe. Especially for the mountain areas the bioregion and river type specific approaches (using data on species composition and dominance) allowed the clear identification of trophic status beside other environmental distortions (e.g. changes of hydraulic pattern). In these areas the identification of near-natural reference situations (as requested by the WFD) is still possible, whereas in most lowland areas reference situations are rare. For the latter cases reference situations can partly be reconstructed from historical data (herbaria, samples, documentations etc.). These data combined with biotests of species responses enables the biologist expert to establish a plausible system to identify degradation grades of natural communities: however it is a matter of politics to identify minimum requirements at which action must be taken to improve undesirable situations.

2.14.6. Floristical and seasonal distribution of epiphytic algae in Anzali Lagoon, Iran

M. Noroozi[1,2], T. Nejadsattari[3], M. Fallahi[4];
[1]Azzahra University, Tehran, Islamic Republic of Iran, [2]Agricultural Biotechnology Research Institue of Iran, Karaj, Islamic Republic of Iran, [3]Tehran University, Tehran, Islamic Republic of Iran, [4]Center of fishery research Anzali port, Anzali, Islamic Republic of Iran.

This study was carried on epiphytic algae in Anzali lagoon (Gilan province, Iran) from September 2000 through August 2001. Epiphytic algae were removed from natural and artificial substrates. Five macrophytes were used as natural substrate and dowel wooden rod as artificial substrate. In this study 150 algae were identified and enumerated by using Sedgwick-Rafter cell. Species belong to 6 classes and 64 genera. Species of Bacillariophyceae with 27 genera and 95 species were dominant and had the highest diversity. Chlorophyceae with 21 genera and 29 species was next. Cyanophyceae with 10 genera and 15 species. Euglenophyceae with 4 genera and 9 species and Dinophyceae and Crysophyceae represented with one species each. We used SIMI (Sanders Simillarity Index) and CC (Community Coefficient) to compere community structure and relative similarity of epiphytic algae between different substrates which revealed that epiphytic algal communities were not restricted to a specific substrate. Algal biomass on artificial substrate was higher than natural substrates. This might be due to inhibitory compounds secreted by plants such as allelopatic substances.

2.14.7. The biotesting of aquatic environment using test-systems - microalga and bioluminescent bacteria.

L. D. Gapochka, M. G. Gapochka, A. P. Zarubina, N. N. Kotcherghenko, L. A. Novosiolova;
Moscow State University, Moscow, Russian Federation.

Using three different biological test-systems: green microalga *Scenedesmus quadricauda* Breb., *Daphnia magna* Straus. and express-detection - bacteria bioluminescent test-system “Ecolum-08” (*Escherichia coli* K12 TG1 with cloned lux-operon of *Photorhabdus luminescens* ZM1) the influence of low-intensive electromagnetic field (EHF) on aquatic environment toxicity was studied. It is shown, that extremely high frequency irradiation can increase or diminish toxicity water solutions of phenol, pesticides, cadmium, cobalt, copper ions and their mixture. The effect observed depends on intensity, dose of EHF and on the type of substance and its concentration. To estimate toxicity we used microalga survival and express-detection (30 minutes) of bioluminescence intensity of bacteria. The possibility to diminish aquatic environment toxicity under EHF-irradiation seems to be very promising for practical use in ecology regulation.

2.15.1. Building a sustainable world

P. Raven;
Missouri Botanical Garden, St. Louis, MO, United States.

We live in a world of 6.4 billion people, half of them in poverty and malnourished, and at least 500 million literally starving. The global population might stabilize at 9 billion in a few decades if we continue to deal with it effectively. At present, however, we are estimated to be consuming global productivity at about 120% of the rate at which it occurs, up from an estimated 70% in 1970. We view with alarm the potential extinction of more than two-thirds of all species of eukaryotic organisms on earth by the end of the century, and must take steps to avoid this serious loss. The intensification of sustainable agriculture on productive lands is likely to be the most effective single strategy that we can undertake to accomplish this goal, using among other techniques biotechnology, integrated pest management, and the controlled use of water and chemicals to produce the desired results.

2.15.2. Development of transgenic temperate fruit trees and grapevines for virus resistance

M. Laimer, F. Maghuly, M. A. Khan, S. Leopold, H. Katinger;
Plant Biotechnology Unit, IAM, Vienna, Austria.

Different traits have been modified in transgenic fruit trees, comprising altered processing and storage qualities, modified nutritional properties, i.e. the influence of desirable/ undesirable components, modified growth habit and vigor, resistance to biotic and abiotic stresses, e.g. drought, low temperature. The breeding and cultivation of virus resistant plants is a major contribution to the control of viral diseases, since there do not exist chemical control strategies. However, beyond technical feasibility, efficiency of resistance, environmental safety and IPRs, also public acceptance needs to be considered. Also access to IP was defined as a major obstacle in the development of transgenic fruit and vegetable crops. Efforts are required to create public understanding and acceptance for these crop plants. To build public confidence the project ”Characterisation of transgenic fruit trees and analyses of direct and indirect biological interactions” was initiated to demonstrate the step-by-step principle with GMOs (http://www.boku.ac.at/sicherheitsforschung/open-e.htm), supported by the BMBWK and BMLFUW, Austria.

2.15.3. Government policies & public perception of biotechnology

G. T. Tzotzos;
Biodiversity Unit, Vienna, Austria.

In an increasingly global and knowledge-intensive economy, the ability to manage impacts of new technologies is an essential skill of governments and industry. New technologies introduce new uncertainties and potential risks related not only to human health and the environment but also to industrial competitiveness and trade. It is because of this that governments respond to the introduction of biotechnology in different ways. Governmental policies, in general, reflect the influence of a combination of factors the most prominent of which are: • socio-economic considerations • scientific evidence • the remit of regulatory institutions The fact that the priorities of, and therefore public acceptance of biotechnology in the industrialised world and least developing countries differ should be acknowledged. However, while such differences do exist, they have to be respected and ways be found that lead to greater convergence of mutual interests.

2.15.4. Environmental health aspects in modern food production

A. G. Haslberger[1,2];
[1]Department of Nutritional Sciences, University of Vienna, Vienna, Austria, [2]Department of Chemical Ecology and Ecosystem Research, Vienna, Austria.

Whereas farming has contributed to creating and maintaining a variety of valuable semi-natural habitats, consequences of food production have also contributed to pollution, resource depletion and loss of habitats, the main hazards for biodiversity according to the Convention of Biological Diversity (CBD). The results of the Millennium Ecosystem Assessment (MA) recently provided alarming evidences on the failures to achieve the UN- Millennium Development Goals and the severe loss of ecosystem diversity, where services of ecosystems are the basis for human health and well being. New developments in food production, such as technologies using modern methods of biotechnology as well as technologies educated more by ecological sciences including IPM or organic farming will ultimately need to avoid and correct dangerous developments. For GM food production international regulations, the CODEX Guidelines and the Cartagena Protocol on Biosafety have been implemented. Research and comprehensive reports such as the CEC- report on effects of transgenic maize in Mexico significantly increased knowledge and the quality of the risk assessment, but also specified areas of concern such as the need for better molecular characterisation and improved methods for profiling, gene flow and indirect consequences of changes in farming practices enabled by new methods. The values for protection in the environment are often debated differently, reflecting also regional different agro-ecological baselines and concepts of conservation biology. Coherent analysis suggests that local specific agro-ecological or even socio-economic characteristics often determine if a specific agricultural practice is beneficial in an area and models for a decision of the best possible practice in a specific area have been proposed. UN- organisations furthermore, demand improved forms of public private partnerships in developing, shaping, integrating and accessing to modern technologies to ensure equitable sharing of benefits, a central element of the CBD and sustainable development.

2.15.5. The unfinished agenda in agriculture

K. Ammann;
University of Bern, Bern, Switzerland.

We have an unfinished agenda. We also have an unfinished debate about what will be best for each country if it is to avoid hunger catastrophes in the future. This is the foremost task of this workshop, to find solutions. And the purpose of the session is to show you that actually there are many ways and many roads that give us solutions. 1. I am against eco- and corporate imperialism. More decisions should be made by countries and regions on theirown. 2 Organic farming and high-tech farming need to go together in the future. We simply have no time for ideological debates and battles over these issues. We should install a collaborative learning process instead. So, lets benefit from the advantages and avoid the disadvantages. And clearly we need to monitor new and old technologies and establish regulatory frameworks, which balance out risks and benefits. 4. In the near future we should focus on the UN Millenium Project, which will reduce dramatically famine for some 400 million people by 2015 - if only we find the political will to take some decisions and avoid unnecessary ideological fights in agriculture.

2.16.1. Metabolic engineering: a general background to the analysis of metabolic networks

M. Stitt;
Max Planck Institute of Molecular Plant Physiology, Golm Potsdam, Austria.

Metabolic engineering depends on knowledge abut the structure of metabolic pathways. This includes the structure of pathways themselves, information about sites where flux is controlled, and information about regulatory networks regulating the key enzymes. It has become increasingly clear that changes in the expression of single enzyme do not always generate the expected result. Sometimes this occurs because an inappropriate enzyme has been selected. I will consider strategies for identifying key regulatory enzymes. Frequently, changes in expression are compensated for by adjustments in the regulatory network. Thus it is sometimes more effective to alter the levels of regulatory metabolites or the regulatory properties of enzymes, rather than the level of expression of the enzymes themselves. However, control of flux is often shared between several enzymes in a pathway. It can then be useful to alter the regulatory networks in order to alter the expression of all or most of the enzymes in a pathway. I will consider how the distribution of control in metabolic pathways can be analysed, and give examples of the use of overexpressed transcription factors to alter metabolic fluxes. Often, unexpected interactions also lead to unexpected or undesired changes. To understand these responses, knowledge about the structure of the metabolic network is required. These can be analyzed using forward and reverse genetics, and more recently by the use of functional genomics. It will be discussed how multilevel genomics analysis using near whole-genome 22K ATH1 arrays for routine expression profiling, an in-house platform that allows sensitive and quantitative profiling over >1200 transcription factors by multiplexed real time RT-PCR, a robotised platform for the measurement of enzyme activities, and robotized enzymic assays and metabolite profiling can be used to understand complex metabolic responses.

2.16.2. Metabolic engineering of nitrogen assimilation with the Dof1 transcription factor in higher plants

S. Yanagisawa;
The University of Tokyo, Graduate School of Agricultural and Life Sciences, Tokyo, Japan.

Nitrogen assimilation is essential to the growth and development of plants. We investigated the utility of a plant-specific transcription factor, Dof1, in modifying nitrogen assimilation in higher plants, because Dof1 appeared to be an activator for multiple gene expressions associated with the organic acid pathway providing carbon skeletons for nitrogen assimilation. Expressing Dof1 induced up-regulation of genes encoding enzymes for carbon skeleton production, a marked increase of amino acid contents, and a reduction of the glucose level in transgenic Arabidopsis. In addition, elementary analysis revealed that the nitrogen content increased in the Dof1 transgenic plants. Most significantly, the Dof1 transgenic plants exhibited improved growth under low-nitrogen conditions, an agronomically important trait. An increase in the amount of free amino acids was also observed in the transgenic potato plants expressing Dof1. These results suggest that key transcription factors modulating regulons are powerful tools for metabolic engineering in higher plants.

2.16.3. Photosynthetic assimilation of formaldehyde in plants by genetic engineering

L. Chen[1,2], K. Li[1,2], I. Orida[3], H. Yurimoto[3], Y. Sakai[3], N. Kato[3], K. Izui[1];
[1]Graduate School of Biostudies, Kyoto University, Kyoto, Japan, [2]Biotechnology Research Center, Kun-ming University of Science and Technology, Kun-ming, China, [3]Graduate School of Agriculture, Kyoto University, Kyoto, Japan.

Most plants are photoautotrophic organisms mainly using CO_2 as a carbon source. Formaldehyde (HCHO) is a ubiquitous air pollutants and is also very toxic for plants. On the other hand, HCHO is a key intermediate for biological fixation of C1 compounds in methylotrophs. 3-hexulose-6-phosphate synthase (HPS) and 6-phospho-3-hexuloisomerase (PHI) are two important enzymes in HCHO fixation pathway in many methylotrophic bacteria. Our study shows that a functional photosynthetic assimilation pathway for HCHO can be installed by over-expression of HPS and PHI genes from a methylotrophic bacterium in the chroloplasts of *Arabidopsis thaliana* and tobacco. The expression of the two genes enhanced the tolerance of the transgenic plants to HCHO and augmented their ability to take up either gaseous or aqueous HCHO. Tracer experiments showed that $H^{14}CHO$ was assimilated into non-volatile metabolites and the TCA-insoluble fraction. This creates a novel strategy for phytoremediation of HCHO pollutant. This study might also open the way to confer plants an ability of photosynthetic assimilation of the other C1 compounds such as methanol and methane.

2.16.4. A biotechnological approach to improve the efficiency of CO_2 assimilation: re-cycling of glycolate in chloroplasts of *Arabidopsis thaliana*

H. Fahnenstich, R. E. Häusler, U. I. Flügge, **V. G. Maurino**;
Botanisches Institut, Univerisität zu Köln, Cologne, Germany.

In C3 plants the carbon gain by photosynthesis is tightly coupled to CO_2 loss by photorespiration starting with the oxygenation of RubP catalyzed by RubisCO. The prime function of this first reaction of the C2-photosynthetic carbon cycle is to salvage glycolate-2-P by conversion to glycerate-3-P, which re-enters the C3-reductive cycle. In C3-plants, competition of O2 with CO_2 at the active site of RubisCO results in a loss of at least 25% of the fixed carbon. Hence, diminished photorespiration might, in principle, contribute to an increased biomass production in C3-plants. It was therefore attempted to transfer the advantages of C4-photosynthesis to C3-plants. Häusler et al. have shown that the overexpression of C4-cycle genes in C3-plants leads to an attenuation of photorespiration, but also to pleiotropic changes in the pattern of endogenous enzymes. We have introduced two alternative and complete glycolate catabolic cycles into chloroplasts of the A. thaliana in order to release and re-fix CO_2 directly within the chloroplast. Analyses of single and double transformants and those with fully operational glycolate cycles will be presented.

2.16.5. Metabolic engineering of natural products for nutritional enhancement

R. A. Dixon;
Samuel Roberts Noble Foundation, Ardmore, OK, United States.

The impact of plant natural products on human health is increasingly recognized. However, only with the advent of genetic and genomic approaches has their biosynthesis been understood sufficiently to permit their engineering in crop plants. Proanthocyanidins (PAs) are oligomeric flavonoid antioxidants derived from (-)-epicatechin and/or (+)-catechin. Co-expression of the enzyme anthocyanidin reductase with flavonoid pathway transcription factors can introduce epicatechin into tissues that do not normally make it. Soy isoflavone phytoestrogens can be engineered in a number of species that naturally lack the pathway; the level of production depends on the activity of endogenous competing pathways, and can be increased by blocking these pathways. Engineered isoflavones accumulate as different sugar conjugates depending on the plant species. Saponins are components of a wide variety of herbal medicines. Genomics approaches are leading to the discovery of the genes encoding the enzymes for the biosynthesis of this complex family of glycosylated plant terpenoids, and metabolic engineering of the pathway is underway.

2.16.6. Turning blue - Commercializing metabolic diversions in flowers

J. G. Mason[1], Y. Tanaka[2];
[1]Florigene Ltd, Collingwood, Australia, [2]Suntory Ltd, Osaka, Japan.

Genetic Engineering is a tool of great potential for the ornamental plant industry with numerous examples of genetic manipulation reported in the literature. Typically these involve the use of model systems some of which have limited direct commercial value. However, when applied to commercial crops there arises the possibility of creating novel products - the driver of the ornamental industry. To date there is only one ornamental GM product, a carnation genetically engineered for novel flower colour, in the marketplace. These carnations were developed under a joint venture between Florigene Ltd and Suntory Ltd. The novel coloured flowers produced are on sale in the USA, Japan, Australia and some countries of Europe. Other species are now entering the commercialization pipeline. The research, development and commercialization of carnation and rose are summarized. As the long term prospects for ornamental GM products, like food crops, is determined by the regulatory environment the commercialisation of our flowers will be looked at with reference to the current regulations in market and production territories and the specific genetic modifications made.

2.16.7. How safe is the chloroplast?

C. Howe[1], D. Lister[1], J. Bateman[2], S. Purton[2];
[1]University of Cambridge, Cambridge, United Kingdom, [2]University College London, London, United Kingdom.

It is often suggested that placing transgenes in the chloroplast in genetically modified plants will offer significant protection in the field against transmission of the transgenes through the pollen, because chloroplasts are only very rarely transmitted (if at all) through the pollen of most crop plants. However, if chloroplast DNA were transferred to the nucleus at a significant frequency, this containment would be breached. It is clear that, on an evolutionary timescale, there has been major transfer of genes from the chloroplast to the nucleus. It has also been known for some time that movement from mitochondrion to the nucleus takes place at an unexpectedly high frequency in *Saccharomyces cerevisiae*. Recent studies have shown that transfer from chloroplast to nucleus also takes place at a significant frequency in tobacco. However, experiments using the green alga *Chlamydomonas reinhardtii* failed to detect transfer. This may provide information on the mechanism of transfer.

2.17.1. Europe's contribution to facilitating biodiversity data access for users

S. J. Owens[1], W. Los[2];
[1]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [2]University of Amsterdam, Zoological Museum of Amsterdam, Institute of Biodiversity and Ecosystem Dynamics, P.O. Box 94766, Mauritskade 61, 1092 GT Amsterdam, The Netherlands.

The European Network for Biodiversity Information, supported by the European Commission, has as its general objective the development of an open network of biodiversity information centres in Europe including national nodes of GBIF. The network is coordinated by the University of Amsterdam and has 60 members in 24 countries. The Network is opening up biodiversity information present in European institutes which hold the richest and most important biodiversity collections, literature and observation data and is concentrating on databases and activities that need co-operation at a European level, that bring together emerging initiatives in biodiversity informatics and analysis tools of connected databases, and is exploring the design of potential new research infrastructures that build upon the databases. The future organisation of such infrastructures at the national and international level is being discussed. Much of the initial information and opinion has come via the use of e conferencing and workshops. ENBI will focus on the market of end-users with special attention to developing specific products and services for professionals and policy makers.

2.17.2. From ink to electrons - Challenges and solutions in digitising herbaria

L. Speers;
GBIF, Copenhagen, Denmark.

Collectively, the plant and animal specimens in the world's museum collections combined with recent observational and monitoring data provide our most complete picture of the biological diversity of the planet. Unfortunately, the vast majority of this valuable legacy data is generally underutilized because it is not easily accessible in a digital format. The challenge is how do we cost effectively and efficiently digitally capture, interpret and make accessible this vast underutilized information resource? Due to the vast amount of legacy data residing in the world's herbaria, even small increases in efficiencies can make significant differences in overall costs. In January 2005, ENBI and GBIF co-hosted a workshop that brought together a group of international experts to discuss how recent advances in information technologies could be applied to increase the speed and efficiency of capturing the label data associated with the millions of specimens in the world's herbaria. The outcome of this meeting and its associated recommendations will be discussed.

2.17.3. Analysis of digital plant specimen data: the example of Gabon

M. S. M. Sosef, J. J. Wieringa;
Nationaal Herbarium Nederland - Wageningen branch, Wageningen, The Netherlands.

In a joint effort coordinated at Wageningen, data on 95% of all herbarium specimens of vascular plants ever collected in Gabon has been digitised (BRAHMS software). The over 60,000 records provide an extremely powerfull source of information to be used for research on and conservation and sustainable use of the vegetation in a country that harbours the richest lowland rain forest in Africa. An analysis of the data shows a.o. that, despite the intensified collecting efforts in the last 3 decades, only 16 ¼ degree squares are botanically fairly well know (>1 specimen per km^2). The total number of known species (native or escaped after introduction) is c. 5100 in 1342 genera and 192 families with the level of endemism being 10%. Numbers are still increasing every year, leading to an estimated true species richness of c. 6500. Using the correlation between number of specimens and species richness, an estimate of the total species richness per ¼ degree square can be made by extrapolation. Certain areas prove to be of particular importance for conservation. Methods to arrive at a biodiversity score for each square using a rarity-weighted species richness index are discussed.

2.17.4. Two decades of the ILDIS project and its World Database of Legumes

Y. R. Roskov[1], F. A. Bisby[1], J. L. Zarucchi[2], B. D. Schrire[3], R. J. White[4];
[1]The University of Reading, Reading, United Kingdom, [2]Missouri Botanical Garden, St. Louis, MO, United States, [3]Royal Botanic Gardens Kew, Richmond, United Kingdom, [4]Cardiff University, Cardiff, United Kingdom.

The International Legume Database & Information Service (ILDIS) is an international project started in 1985. Regional centres in 12 countries and a network of 48 taxonomic experts are participating to pool information in the ILDIS World Database of Legumes, which is used to provide a worldwide information service through electronic access, publications and enquiry services. The latest edition (2005) contains a near to complete World Species Checklist of the *Fabaceae* / *Leguminosae* family (c. 20,000 species). An on-line service is provided via LegumeWeb (www.ildis.org), Species 2000 & ITIS Catalogue of Life (www.sp2000.org) and GBIF Data Portal (www.gbif.org). Major ILDIS publications include 6 check-lists published at the Royal Botanic Gardens Kew: Legumes of Africa (1989), Legumes of West Asia (1991), Legumes of Indo-China (1994), Legumes of Northern Eurasia (1996), Legumes of South Asia (2003), Legumes of Malesia (2004); Phytochemical Dictionary of the Leguminosae (1994) and two CD-ROMs: Legumes of Northern Eurasia (1998) & ILDIS Legumes of the World, a draft checklist (2001). ILDIS has been supported by the GBIF ECAT programme in 2004/2005.

2.17.5. Flora Croatica database

T. Nikolí [1], K. Fertalj[2], B. Mila inoví [2];
[1]Department of Botany, Faculty of Science, University of Zagreb, Zagreb, Croatia, [2]Department for Applied Mathematics, Computer Science Group, Faculty of Electrical Engineering and Computing, University of Zagreb, Zagreb, Croatia.

Flora Croatica Database (FCD) is a multi-user database application for species-oriented and specimen-oriented systematic and taxonomic work on Croatian flora. It is designed for dealing with all kinds of data that are commonly used in systematic botany and floristic work. FCD comprises several main modules: (1) taxonomy, (2) herbarium, (3) literature, (4) horology (5) economic botany and (5) related data (ecology, multimedia). FCD was built over a relational database and relies on the normalised data model. Amongst other features, the client application provides the user with extended query by example (QBE) capabilities and with user-customised reports. The reports include taxon sheets, taxa checklists, herbarium labels, bibliography labels and other complex reports. The database is connected to a geographical information system (GIS) and FCD MapServer, which empowers easy production of distribution maps and other spatial analysis. Web interface enable searching, as well as data input, for several user types, together with geocoding facility and complex analysis of floral compositions.

2.17.6. Development of the database on economic plants of Flora of Armenia

A. G. Ghazanchyan[1], V. G. Sahakyan[1], A. A. Charchoghlyan[2];
[1]Institute for Informatics and Automation Problems of the National Academy of Sciences of Armenia, Yerevan, Armenia, [2]Institute of Botany of the National Academy of Sciences of Armenia, Yerevan, Armenia.

Flora of Armenia comprises about 3500 species of plants. Armenians have a long tradition of making good use of plant biodiversity for economic purposes. The analysis of botanic, enthomedical and other sources of information revealed that local population have used about 2000 species of 60% of flora in food, medicine, coloring, etc. In spite of rich diversity of plant species, botanic resources are limited. The development of database on economic plants is necessary for conservation biodiversity and sustainable use of botanic resources. Internet, the technology which gives an interface to data management via network capabilities, was selected as a technical solution for development such database. This method gives possibility to have public database, which could be connected without any additional installation software or hardware. Just an access to Internet. This web based software allows unlimited connections to database which is helpful for synchronous usage of the same data system. The database of economic plants contains detailed information about them, their arrangement in subject catalogue as well as their usage and geographic location.

3.1.1. Moving with the flow: What transport reveals about cell division and expansion

W. K. Silk;
University of California, Davis, CA, United States.

Recently there has been an explosion in the discovery of gene products associated with cell division. Several transport laws are useful to illuminate the physiological significance of the genes and proteins. Continuity equations reveal relationships among cell size and the rates of cell division and cell expansion and have been used with data on cell size and growth velocity to find cell division rates in three directions. Growth trajectories, functions showing the time course of the intra-organ position of cellular particles, can be used to find relationships among time, the appearance of gene products and the occurrence of cell division in control and genetically modified plants. Lagrangian specifications show correlations among cell division and later expansion rates. For these analyses, growth data in the meristem is needed. For root-soil interactions, a growth-diffusion equation can show the intra-rhizosphere pattern of metabolites produced or consumed during cell division.

3.1.2. The integration of cell proliferation and growth in leaf morphogenesis

A. J. Fleming;
University of Sheffield, Sheffield, United Kingdom.

Tremendous advances have been made in our understanding of the patterns of transcriptional regulators that control leaf formation. However, the mechanism by which these patterns are transduced into actual change of form remain obscure. Intuitively, patterns of cell division must play a key role in this process but various strands of evidence indicate that this is not the case.

To investigate the relative role of cell growth and division on plant morphogenesis, we have developed a novel method (microinduction) to locally and transiently manipulate these cellular parameters, both in the shoot apical meristem and within the developing leaf primordium. Our data show that local modulation of cell wall extensibility is sufficient to induce leaf formation and to modify leaf shape. Local promotion of cell proliferation has no impact on leaf initiation and, surprisingly, leads to an overall decrease in growth of the leaf lamina. These data support the primacy of cell wall characteristics in controlling plant morphogenesis and indicate that the influence of cell division on morphogenesis is context dependent and non-intuitive.

3.1.3. Establishing and maintaining axial growth: wall mechanical properties and the cytoskeleton

G. O. Wasteneys[1], D. A. Collings[2], M. Fujita[1], R. Himmelspach[2], E. Kawamura[1], M. C. Rashbrooke[2], T. Shoji[1];
[1]The University of British Columbia, Vancouver, BC, Canada, [2]The Australian National University, Canberra, Australia.

Organ morphology depends on cell placement and directional cell expansion. The microtubule cytoskeleton is implicated in both of these processes so genetic approaches to understand the role microtubules play in organ expansion are not straight forward. Our use of temperature-sensitive *mor1* mutants to disrupt cortical microtubule arrays in anisotropically expanding walls led to the surprising discovery that arabidopsis root cells can establish and maintain transverse cellulose microfibril texture without well organized microtubule arrays. One explanation for the altered mechanical properties of cell walls in these left-twisting and radially swelling mutants is that microtubule disruption affects the cell's ability to generate long cellulose microfibrils, which may be essential for perfect anisotropy. This new model opens up an attractive mechanism for the regulation of organ shape that depends not only on the orientation but also on the relative length of cellulose microfibrils to define the growth axis.

3.1.4. Crystal structure and evolution of expansins and their role in modifying the growing cell wall

D. J. Cosgrove, J. Sampedro Jimenez, L. Li, R. Cary, N. Yennawar;
Penn State University, University Park, PA, United States.

Expansins are proteins that loosen cell walls by dissociating wall polysaccharides, thereby allowing polymer creep and turgor-driven wall extension. They are important for plant cell growth and other processes where wall loosening occurs (see http://www.bio.psu.edu/expansins/). Expansins are encoded by four families, with 36 members in Arabidopsis and 58 in rice. By microsynteny analysis combined with sequence-based phylogenetic analysis, we estimate that 16-17 expansin genes were present in the ancestor of monocots and eudicots. We will present a hypothetical scheme to account for family evolution since this time. To investigate expansin's mechanism of wall loosening, we crystallized native Zea m 1, a beta-expansin from maize pollen, and determined its structure by X-ray crystallography. We will describe expansin structure and how it might interact with the cell wall to cause loosening.

3.1.5. The *Arabidopsis* leaf as a model system to investigate the link between cell cycle regulation and whole organ growth

G. T. S. Beemster;
Flanders Interuniversity Institute for Biotechnology (VIB), Ghent, Belgium.

Organ growth results from the progression of component cells through subsequent phases of proliferation and expansion before reaching maturity. We combined kinematic analysis, flowcytometry and microarray analysis to characterize cell cycle regulation during the growth process of leaves 1 and 2 of Arabidopsis thaliana. Kinematic analysis showed that the epidermis proliferates until day 12, thereafter cells expand until day 19 when leaves reach maturity. Flowcytometry revealed that endoreduplication occurs from the time cell division rates decline until the end of cell expansion. Genome-wide micro-array analysis allowed us to categorize known cell cycle genes into three major classes: Constitutively expressed, proliferative and inhibitory. Comparison with published expression data obtained from root zones corresponding to similar developmental stages and from synchronized cell cultures supported this categorization and enabled us to identify a high confidence set of 131 proliferation genes. Most of those were M-phase specific. Besides known cell cycle genes there were many unknowns or previously not associated with proliferation.

3.1.6. Establishing growth maps for *Antirrhinum* and *Arabidopsis* leaves

S. Bensmihen[1], J. Avondo[1], J. Everitt[1], A. I. Hanna[2], A. Bangham[2], E. Coen[1];
[1]John Innes Centre, Norwich, United Kingdom, [2]University of East Anglia, Norwich, United Kingdom.

In the past few years, many molecular biology studies have explored the role of genes in cell fate determination or regional patterning. However, understanding how these genes influence the dynamics of organ growth and shape change remains a major challenge. We want to bridge this gap by using a dynamic and integrative approach to model leaf growth in Antirrhinum and Arabidopsis. To do so, we have been using a combination of genetic, morphological, computational and imaging approaches. We have used tracking and clonal analysis of leaf cells, along with newly developed software, to analyse growth and obtain some growth parameters. This approach should provide clues to the primordial events triggering shape change and morphogen action. The talk will illustrate how integrating biological and computational methods may lead to a quantitative mechanistic framework for development and the possible implications for leaf mutant analysis.

3.1.7. Coordination of cell proliferation and cell expansion in the control of leaf size in *Arabidopsis thaliana*

G. Horiguchi, H. Tsukaya;
National Institute for Basic Biology/Okazaki Institute for Integrative Bioscience, Okazaki, Japan.

Leaf size is an important parameter characterizing leaf morphology. To understand the mechanisms controlling leaf size, we have isolated many mutants of Arabidopsis thaliana with altered leaf size. Since leaf morphogenesis depends on determinate cell proliferation, the size of a mature leaf is expressed by multiplication of cell size and cell number. Therefore, any leaf size mutants should be classified according to the specific effects of the mutation on the cell number and/or size. One of the classes suggests a mechanism that coordinates cell proliferation and cell expansion in developing leaves: when the leaf cell number decreases by a mutation such as angustifolia3 (an3) and aintegumenta, the leaf cell size increases, leading to the compensation of leaf area. As the first step to elucidate the mechanisms of compensation, we should understand the inductive step of compensation. To this end, cell number in the an3 leaves was manipulated by crossing known or newly isolated cell-number mutants and its effects on the compensation were evaluated. Our results provide a novel key concept that explains how leaf size is controlled at an organ level.

3.2.1. Evolution of floral organ identity: a primer

G. Theissen;
Genetics Department, University of Jena, Germany.

According to the ABCE and floral quartet models of flower development in higher eudicots, four classes of floral homeotic MADS-domain proteins interact in a combinatorial way to specify the identity of the four different types of floral organs, with class A+E proteins specifying sepals in the first whorl of the flower, A+B+E petals in the second whorl, B+C+E stamens in the third whorl, and C+E carpels in the fourth whorl. Flower development thus provides exciting opportunities to better understand the evolution of a morphogenetic system at the genetic and physico-chemical level. Comparative studies on orthologues of floral homeotic genes in phylogenetically informative seed plants, including all major groups of extant gymnosperms, basal angiosperms, diverse monocots as well as basal and higher eudicots, are currently providing detailed insights into the meaning, conservation and flexibility of floral organ identity. This again helps us to much better understand the origin and tremendous diversification of one of nature's most marvellous key innovations: the angiosperm flower.

3.2.2. Genomics of the lower eudicot *Aquilegia*: a new model for the study of floral evolution and ecology

S. A. Hodges[1], J. Borevitz[2], E. M. Kramer[3], M. Nordborg[4], J. Tomkins[5];
[1]University of California, Santa Barbara, CA, United States, [2]University of Chicago, Chicago, IL, United States, [3]Harvard University, Cambridge, MA, United States, [4]University of Southern California, Los Angeles, CA, United States, [5]Clemson University, Clemson, SC, United States.

The angiosperm genus Aquilegia presents a unique opportunity to investigate the molecular genetic changes underlying a recent adaptive radiation that involved floral and ecological diversification. In addition, Aquilegia has the benefit of representing a phylogenetic lineage that is intermediate between core eudicot model species like Arabidopsis and monocot models, such as rice. This combination of assets (and small ~350 Mb genome size) places Aquilegia in the singular position of facilitating studies of both recent and ancient evolutionary processes. By the application of innovative genomic techniques, we are developing a wide array of tools that will enable a whole community of researchers to study adaptation at the genomic level. These essential tools include the development of finely mapped RILs, a physical map, an EST database, and oligonucleotide arrays. Progress in this project and the application of these tools to questions relating to floral evolution will be discussed.

3.2.3. Floral gene expression in basal angiosperms: Alternatives to the ABC model

P. S. Soltis, D. E. Soltis;
University of Florida, Gainesville, FL, United States.

The ABC model of floral organ identity explains the regular, sequential development of sepals, petals, stamens, and carpels in eudicot flowers. This general model, based on studies of the derived eudicots *Arabidopsis* and *Antirrhinum*, may apply to nearly all eudicots, most of which are characterized by discrete whorls of floral organs. However, floral morphology of basal angiosperms is typically characterized by variable numbers of floral parts and gradual transitions among floral organs. We have investigated patterns of expression of A-, B-, C-, and E-function homologues in a sample of phylogenetically important basal angiosperms: *Amborella*, *Nuphar*, *Illicium*, *Magnolia*, *Eupomatia*, *Asimina*, and *Persea*. Homologues of floral genes from *Arabidopsis* and *Antirrhinum* are expressed more broadly across the floral meristem of basal angiosperms than in these models. These broader patterns of gene expression correspond to gradual intergradations among floral organs. Furthermore, broad patterns of expression are inferred to be the ancestral condition in angiosperms, followed by restricted localization of gene expression in core eudicots.

3.2.4. Evolution of floral homeotic genes in green plants

M. Hasebe[1], **M. Ito**[2];
[1]National Institute for Basic Biology, Okazaki, Japan, [2]University of Tokyo, Tokyo, Japan.

The flower is a reproductive organ in angiosperms, whose development is mainly managed by MADS-box genes and their positive regulator FLO/LFY genes. We characterized these genes in the basal angiosperms (Nymphaea, Magnolia, Houttuynia, and Amborella), the gymnosperm (Gnetum), the fern (Ceratopteris), the moss (Physcomitrella), and three charophycean green algae. These analyses suggest that (1) MADS-box genes were originally involved in haploid reproductive cell differentiation, (2) MADS-box genes were recruited in the diploid development early in land plant evolution, (3) the induction of FLO/LFY gene of MADS-box genes was established during vascular plant evolution after divergence from mosses, (4) Involvement of B-function MADS-box genes in petal development was established at the early stage of angiosperm evolution, (5) antagonistic expression of AP1 and AG orthologs was not established early in angiosperm evolution.

3.2.5. Floral organ identities and expression of MADS-box genes in Magnoliales

S. Kim, J. Koh, P. S. Soltis, D. E. Soltis;
University of Florida, Gainesville, FL, United States.

To investigate the floral organ identity programs in basal angiosperms with highly divergent floral morphologies, we examined expression patterns of floral MADS-box genes in representatives of Magnoliales. *Magnolia* flowers have an undifferentiated perianth of spirally arranged tepals. In contrast, *Asimina* has whorled, trimerous flowers with a perianth of distinct sepals and petals. *Eupomatia* flowers appear to lack a perianth but bear a calyptra, the homology of which is uncertain. Data from relative-quantitative-RT PCR, real-time PCR, and RNA *in situ* hybridization suggested that (1) broad expression of B-class homologs across the floral meristem in *Magnolia* correlates with the development of petaloid tepals; (2) organ identity in *Asimina* is controlled by a mechanism that is similar to, but independently derived from, that of *Arabidopsis*; and (3) the calyptra of *Eupomatia* exhibits gene expression patterns consistent with its interpretation as a modified bract. These results suggest that the ancestral floral developmental program was labile, with shifts in gene expression leading to profound differences in floral morphology, even in a single clade.

3.2.6. The evolution of carpel development.

C. P. Scutt, C. Fourquin, M. Vinauger-Douard, C. Finet, C. Dumas;
Ecole Normale Superieure de Lyon, Lyon cedex 07, France.

Molecular phylogenetic analyses have identified the ANITA grade species to very probably represent the earliest diverging lineages of flowering plants. Concurrently, excellent progress is being made in understanding the molecular control of flower development in a few highly-evolved model species. A comparison of basal and model angiosperms conducts us back in time to their (very early) common ancestors. By this method, it may be possible to formulate an anatomical and molecular picture of flower development in the common ancestor of the flowering plants. We are using comparative genomic techniques to identify genes from model plants whose roles in the development of the carpel, or female reproductive organ, have been conserved since the common ancestor of the angiosperms. Some of our recent studies have identified likely conserved functions in carpel development for the orthologues of *CRABS CLAW* and *TOUSLED* in the ANITA grade species *Amborella trichopoda* and *Cabomba aquatica*, respectively. We are also working to establish *C. aquatica* as a model angiosperm in which gene functional analyses will be possible.

3.2.7. Floral developmental genetics and genomics in *Gerbera* (Asteraceae)

T. H. Teeri, R. A. E. Laitinen, P. Elomaa;
University of Helsinki, Helsinki, Finland.

The development of inflorescences in the plant family Asteraceae has features that cannot be easily studied in the traditional model plants for flower development. In *Gerbera hybrida*, inflorescences are composed of morphologically different types of flowers tightly packed into a flower head (capitulum). The special features of Gerbera inflorescences have made the plant a rewarding target for comparative studies. We have shown that Gerbera MADS box genes grouping phylogenetically with B and C function genes of Arabidopsis and snapdragon function in organ determination very similarly than in the model plants. However, MADS box genes encoding proteins that interact with those of the ABC MADS box genes are different. For example, a Gerbera *SEPALLATA*-like gene controls not only organ identity, but also inflorescence architecture and reproductive meristem fate. A particularly intriguing question in Asteraceae relates to genes that regulate different development in marginal and central flowers. We are currently exploring differences in gene expression of Gerbera flower primordia using a cDNA microarray based on a collection of 16,994 Gerbera EST sequences.

3.3.1. In search of the primitive monocot flower: insights from comparative and developmental morphology

D. D. Sokoloff[1], P. J. Rudall[2], M. V. Remizowa[1];
[1]Moscow State University, Moscow, Russian Federation, [2]Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Recent molecular studies have clarified our understanding of higher-level monocot relationships, but evolution of morphological characters, including flower morphology, remains problematic. Parsimonious optimisation of floral characters onto existing molecular phylogenies suggests primitiveness of the "typical" monocot flower groundplan, i.e., six tepals in two whorls, six stamens in two whorls and three fused carpels in a superior ovary. This hypothesis involves reversals to non-monomerous apocarpy in some Alismatales, Pandanales and Arecaceae, which contradicts the traditional view that apocarpy is primitive. Monocot flowers with apocarpy also differ in other respects from the typical monocot flower groundplan, for example, in (functional) unisexuality and/or variation in merosity. This suggests that either (1) "typical" monocot floral structure evolved many times in parallel, or (2) in some monocot lineages a partial loss of integrity in regulation of flower development resulted in loss of the monocot floral groundplan.

3.3.2. Evolution of flowers and inflorescences in Monocotyledons

T. Stuetzel, T. Marx;
Ruhr University Bochum, Bochum, Germany.

The orientation of flowers is constant in many families, e.g. the median sepal of the outer whorl is always precisely adaxial in Eriocaulaceae and abaxial in Xyridaceae. In several families of the Liliales and Asparagales the position of the flower is highly variable. Classical phyllotactic patterns describe how the position of a leaf follows preceding leaves on the same axis and do not explain the position of the first leaf of a lateral axis. We found good evidence, that in species with variable orientation of the flowers, the flowers represent reduced lateral racems. The orientation of the flowers shifts from being influenced by the lateral axis to being defined by the main axis. The variability in floral orientation is a last remainder of a previously more complex inflorescence. The shift of the prophyll in many monocot inflorescences from an adorsed position to a more transversal position resembling the situation in dicotyledons may be the effect of very short internodes at initiation of the lateral branches. If the internode is still elongated when the axilar bud is formed, the prophyll is forced into an adorsed position by the pherophyll (subtending leaf).

3.3.3. Floral evolution in a highly derived monocot clade, Poales

P. J. Rudall;
RBG Kew, Richmond, United Kingdom.

Improved phylogenetic resolution among the 18 constituent families of Poales, including identification of *Ecdeiocolea* as a potential sister-group to grasses, allows new assessments of floral evolution in this economically important and species-rich order. Establishment of a developmental genetics programme in grasses has improved the potential for recognition of genes controlling specific floral traits. Despite these advances, the enigmatic homologies of grass reproductive structures remain poorly understood, partly because their highly derived morphology has resulted in a unique terminology. Two of the three families that form the basal grade of Poales, Bromeliaceae and Rapateaceae, have retained some of the characteristic aspects of the monocot floral groundplan such as showy tepals and septal nectaries, while the third, Typhaceae, displays anomalous and highly reduced floral morphology. The remaining four lineages (graminids, restiids, cyperids, xyrids), which all include abiotically-pollinated species, have undergone homoplastic evolution of traits such as perianth reduction and loss, and reductions in ovule and carpel number.

3.3.4. Some ontogeny and a little biology of floral diversification in the Commelinaceae

C. R. Hardy;
Biology Dept. and Herbarium, Millersville University, Millersville, PA, United States.

The Commelinaceae rival the orchids with respect to the diversity of floral forms and complexity. Floral diversification within the family has proceeded primarily via reduction, fusion, and various elaborations upon the plesiomorphic plan of six free stamens with longitudinally dehiscent anthers. Ontogenetic studies show this diversity to be underlain by a greater degree of ontogenetic diversity (i.e., similar flowers can be formed by different ontogenies). Examples include the occurrence of either centrifugal or centripetal patterns of stamen development to produce structurally similar androecia. Additionally, presumed homologous patterns of stamen reduction are achieved via either early abortion or absolute suppression of stamen primordia. Although my emphasis is on ontogeny, floral biology will be reviewed, and connections between the two will be highlighted with an example of the evolution of buzz-pollination in the family via very different morphogenetic pathways. This last case study also illustrates the process of reciprocal illumination between both ontogenetic and phylogenetic studies in regards to questions of structural homology.

3.3.5. Comparative floral structure and systematics of *Pelagodoxa* and *Sommieria* (Arecaceae)

F. W. Stauffer[1], W. J. Baker[2], J. Dransfield[2], P. K. Endress[3];
[1]Conservatoire et Jardin Botaniques de la Ville de Genève, Chambésy /Geneva, Switzerland, [2]Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom, [3]Institute of Systematic Botany, University of Zurich, Zurich, Switzerland.

Floral structure is compared in two genera of Arecoideae and discussed in a phylogenetic framework. Male flowers have three free, imbricate sepals, three basally congenitally united and apically valvate petals, and six stamens. Anthers are dorsifixed and introrse. The sterile gynoecium is tricarpellate. Female flowers have three free, imbricate sepals and three free, imbricate petals, which are fused with the sepals at the base. Four to six staminodes are congenitally united at the base and partially fused with the ovary. The gynoecium is syncarpous and pseudomonomerous. The three stigmatic branches are apical and sessile. The carpels are (syn-)ascidiate up to the level of the placenta and (sym-)plicate above. Each carpel has one ovule. The fertile ovule is erect up to anthesis and pendant afterwards. Pollen tube transmitting tracts encompass the secretory epidermis of the ventral slits. Floral structure in *Pelagodoxa* and *Sommieria* supports the sister group relationship between the two genera suggested in recent molecular phylogenies and reflects their close relationships to a major clade of arecoid palms from the Indo-Pacific region.

3.3.6. Pollination syndromes and diversification rates in the tropical *Gingers* (Zingiberales)

C. D. Specht, W. J. Kress;
Smithsonian Institution, Washington, DC, United States.

The development of novel structures is a major force in the diversification of plant lineages. Within angiosperms, floral structure presents a variety of traits upon which evolutionary forces act to create novel forms and functions. Many of these traits are associated with the specialization of pollination. In the Zingiberales, functional pollinators include mammals, birds and insects. Shifts between functional pollinator groups is linked with changes in the form of floral characters that reflect pollinator association. Using a phylogenetic framework and whole-tree methods for determining differential diversification, we demonstrate that shifts in major pollination syndromes are correlated with shifts in rates of diversification, indicating that floral syndrome acts as a key innovation in the evolution of diversity in tropical gingers. The main floral organ involved in pollination is the stamen, which develops a petal-like form in four of the eight major lineages. In two of those lineages (Costaceae, Zingiberaceae), 2 - 5 stamen fuse to form a novel structure, the labellum. The role of the labellum in the diversification of the Zingiberales is discussed.

3.3.7. Floral transitions among orchids: from the sublime to the ridiculous

R. M. Bateman[1], P. J. Rudall[2];
[1]Natural History Museum, London, United Kingdom, [2]Royal Botanic Gardens, Kew, United Kingdom.

Orchidaceae probably originated from an ancestor with radially symmetrical flowers. Two alternating whorls of three tepals occurred below two alternating whorls of three stamens, all closely spaced and connected to an inferior trilocular ovary. In contrast, strong bilateral symmetry characterises the majority of floral whorls of most extant orchid species. The evolutionary route leading to species-rich orchid groups required well-developed epigyny, progressive partial or complete suppression of the adaxial stamens, and fusion of the remaining stamen filaments to a syncarpous style; this generated a gynostemium. Subsequent evolutionary divergences relied more upon differentiation between (a) the two whorls of tepals and (b) the median (labellum) and lateral members of the inner tepal whorl. Exceptional variation is evident in tepal shape, colour and outgrowths such as spurs; these interact with the detailed morphology of the gynostemium to dictate pollination biology. We will review the limited data on the evolutionary-developmental genetic controls of such transitions, and explore evidence for their relative frequency, rapidity and profundity.

3.4.1. Biomimetics - taking a leaf from Nature's book

J. F. V. Vincent;
Dept of Mechanical Engineering, The University, Bath, United Kingdom.

Introductions inspire, preparing the listener by reviewing the topic, illustrating thoughts which lead to success, then challenging with ideas and conundrums to which those thoughts have not yet been applied. The listener is thus prepared for the rest of the presentations, receptive to the science and ready to ask searching questions. Look through this list, check the topics you know about, and think of ways of using them. Then work out what the other topics are going to be, and how the botanical examples can be turned from curiosities into technical marvels. Remember - one of the basic skills of creativity is making lists! Materials [Tough materials (wood analogues); Surface properties (Lotus, *Nepenthes*)] Structures [Attachment (Velcro, ivy, climbing *Galium*); Transpiration (textiles); Light-weight structures; Space and supportive structures (*Ficus*)] Mechanisms [Deployable structures (unfolding, growth, fungi); Energy storage (legume pods, cucurbita) ; Water sorption (sensing and actuation); Growth and Repair (*Pisum*)] Self- [Design and adaptation (cellular automata); Sensing (Venus fly trap)]

3.4.2. Purity of sacred Lotus: self-cleaning super-hydrophobic micro- and nano-structured biological surfaces and their biomimetic technical analogues

C. Neinhuis[1], Z. Cerman[2], W. Barthlott[2];
[1]Institut fÃ¼r Botanik, Dresden, Germany, [2]Nees Institut fÃ¼r Biodiver-sitÃ¤t der Pflanzen, Bonn, Germany.

Our discovery of self-cleaning properties of many plant surfaces in 1975 and their transfer into biomimetic technical surfaces since 1992 resulted in a paradigm shift in surface technologies. A short survey of the state of the art is presented. The remarkable physical effect is based on at least a hydrophobic surface layer and a complex geometry of combined micro- and nanostructures on different length scales. Such kind of roughness minimizes the contact area between water and surface. Water forms droplets that virtually show no adhesion and roll off at lowest inclinations. In addition droplets pick up particulate contaminations and consequently clean the surface. Super-hydrophobic and self-cleaning surfaces are of great interest for many applications. First products (facade paints) are available on the market under the trade mark Lotus-EffectÂ® since 1999, further products followed. This is one of the economically most successful results of biomimetics.

3.4.3. Anti-adhesive coatings: Why do elaborate insect attachment devices fail on some plant surfaces?

S. Gorb, E. Gorb;
MPI for Metals Research, Stuttgart, Germany.

Many aspects of insect-plant relationships deal with mechanical and chemical surface interactions. During the long period of co-evolution between flowering plants and insects, plants have developed not only structures attracting insects, but also a wide variety of surface attributes related to defence against herbivores. Various functions such as pollination, prevention of access to flowers, and insect trapping may involve similar general mechanisms related to surface structure and properties. Experimental data show that smooth, hairy, and felt-like substrates only slightly affect insect attachment. However, insects could not attach properly to surfaces covered with wax crystals. To explain anti-adhesive properties of substrata structured with crystalline waxes, four hypotheses are proposed: (1) Roughness-hypothesis; (2) Contamination-hypothesis; (3) Wax-dissolving-hypothesis; (4) Fluid-absorption-hypothesis. Our experiments on insect attachment to structured artificial substrates provide some evidences to the above hypotheses and inspirations for design of technological surfaces with anti-adhesive properties.

3.4.4. Biomimetics and water transport in plants: Putting negative pressures to work

A. Roth-Nebelsick[1], T. Stegmaier[2];
[1]Institute for Geosciences, Tübingen, Germany, [2]ITV Denkendorf, Denkendorf, Germany.

Water flow in the xylem is of technical interest due to the following properties: 1) An energy-consuming pumping mechanism is not required because water flow is generated by water loss at the transpiring sites, 2) water flow rates correspond to demand and 3) negative pressures can occur within the water column. Water transport in plants thus represents a unique biological transport system. There are currently no technical devices which make use of this principle. Devising technical systems using the principles of plant water transport have to be tightly coupled to the detailed analysis of the underlying biophysical mechanisms. There is, for example, evidence that fine structural adaptations of xylem conduits are involved in special interfacial effects which stabilize negative pressure states within the water column. In this contribution it will be demonstrated and discussed how technical applications for different uses can be realized by integrating the underlying biophysical processes of plant water transport.

3.4.5. The banana leaf as a teacher for lightweight design

R. Kappel[1], C. Mattheck[1], T. Speck[2];
[1]Forschungszentrum Karlsruhe GmbH, Eggenstein-Leopoldshafen, Germany, [2]Botanischer Garten der Universität Freiburg, Freiburg im Breisgau, Germany.

Biological structures consist of mechanical load carriers, which are highly optimized in terms of mechanical strength and minimum weight. A lot of parts of these structures act as tension ropes, even if this cannot always be identified immediately. The advantage of tension-loaded components is that they cannot fail by kinking or buckling like pressure-loaded ones, if their aspect ratio is too high. The non-woody banana leaf consists of non-stiff materials. However, by tricky arrangements of ropes and shell elements, structural stiffness of the stalk of the banana leaf results. Mechanical applications of the banana trick reveal a rope-dominated ultra-lightweight design, which is different from normal steel structures, because their unstable failure modes are avoided. Mechanical designs according to the banana leaf do not exhibit any instabilities and failures by predictable bending modes under overload. Although an absolute minimum of material is used, the structures were found to have an extreme high stiffness in prototypes.

3.4.6. Pressure, stabilisation, nature and Tensairity®

R. H. Luchsinger[1], M. Pedretti[2], A. Reinhard[1];
[1]prospective concepts ag, Glattbrugg, Switzerland, [2]Airlight Ltd, Biasca, Switzerland.

The green tissue of plants is supported by the cellular turgor pressure. This pressure induced stability is crucial for the adaptability of the young plant. Growing older, many plants change their structural integrity by lignification. The transformation is very energy expensive and thus only attractive for long living plants. In technology, load bearing structures are made of stiff materials as steel. Adaptability is hard to realize with these girders. It can be achieved with the light and deployable pneumatic structures. However, the load bearing capacity of these pressure stabilised structures is often too limited for e.g. temporary buildings. The technological gap between flexibility and strength, between transience and permanence was recently closed by the new structural concept Tensairity®, a development of Airlight Ltd in collaboration with prospective concepts ag. The synergetic combination of an airbeam with struts and cables leads to strong and adaptive Tensairity®-girders with minimal weight. Ideal applications range from temporary shelters and bridges to permanent wide span roof structures.

3.4.7. Self-repairing membranes for pneumatic structures: transferring nature's solutions into technical applications

T. Speck[1], M. Rüggeberg[1], T. Masselter[1], O. Speck[2], R. Luchsinger[3];
[1]Botanischer Garten der Universität, Plant Biomechanics Group, Competence Networks Biomimetik &BIOKON, Freiburg, Germany,
[2]Competence Networks Biomimetik &BIOKON, Freiburg, Germany,
[3]prospective concepts ag, Glattbrugg, Switzerland.

Over the last few years, plants have proved to be a real treasure trove as models for the construction of biomimetic technical structures and materials. One on-going project deals with the construction of technical membranes with rapid self-repair mechanisms inspired by plant structures. For analytically describing the (fast) self-repair characteristics of the parenchyma, lianas (e.g. *Aristolochia*) and herbaceous plants (e.g. *Phaseolus, Ricinus*) are used as model organisms. These plants react to fissures in their peripheral tissues with repair mechanisms on at least three hierarchical levels, which seal the lesion very effectively and secure the functional integrity of the plant structure. The mechanism on one level is based on fast strain-triggered deformation processes of pressurized parenchyma cells sealing the fissure. In cooperation with the Swiss company 'prospective concepts ag', biomimetically inspired self-repair functions are transferred into technical membranes of ultra-light pressurized beams based on the Tensairity® concept.

3.5.1. Mapping plant microtubules: the role of associated proteins in organizing MT arrays

C. Lloyd, J. Chan, G. Mao, A. Korolev, H. Buschmann, G. Calder;
John Innes Centre, Norwich, United Kingdom.

The spatial information for separating chromosomes and for the placement of cell walls is embodied in microtubule-based arrays that assemble and disassemble at different stages of the cell cycle. In higher plants there are four such assemblies and the way that such different structures can be organized from common building blocks depends largely on microtubule-associated proteins (MAPs) that regulate the dynamic and associative properties of microtubules. Many plant MAPs have been identified by homology with proteins whose functions are known in other eukaryotes but to target MAPs unique to plants we developed a proteomics approach for identifying proteins binding to Arabidopsis microtubules in vitro. We will describe progress in characterizing two novel MAPs, in particular MAP70, which is comprised of five isoforms. In addition, MAP65 is now recognized as the major cross-linking plant MAP and we will discuss recent work on how MAP65 unites microtubules in Arabidopsis cells and during secondary wall formation in the Zinnia model system.

3.5.2. Functional characterization of *Arabidopsis thaliana* gamma-tubulin complex components

E. Herzog, V. Seltzer, N. Janski, Z. Altanoury, J. Canaday, J. Evrard, A. Schmit;
Institut de Biologie Moléculaire des Plantes, Strasbourg, France.

Plant microtubule arrays are involved in specific intracellular trafficking. The variety of microtubule arrays is related to dispersed assembly sites, but the nucleation process seems conserved in eukaryotes, as orthologues of genes expressing Gamma-tubulin Complex Proteins (*At*GCP1 to 6) have been identified in the *A. thaliana* genome. Our aim is to functionally characterize *At*GCP1 to 6. We have shown that *At*GCP1, 2 and 3 interact with each other *in vitro* and are part of protein complexes *in vivo*. Using eGFP-tagging and immunolocalization in tobacco BY-2 cells, we have localized *At*GCP1, 2 and 3 at the nuclear envelope, a well-characterized plant microtubule organizing centre. *At*GCP2 and 3 domains which could be involved in targetting the entire proteins, and possibly nucleation complexes, to the nuclear surface have been identified. Recruitment and activation of gamma-tubulin nucleation complexes under cell cycle control could be instrumental in the regulation of microtubule nucleation in plant cells.

3.5.3. Ancient tubulin FtsZ in chloroplast and cell division

R. Reski, L. Gremillon, A. Martin, J. Kiessling, S. A. Rensing, E. L. Decker, E. Sarnighausen;
Plant Biotechnology, Freiburg, Germany.

Bacteria divide with the help of the filament-forming protein FtsZ. Based on biochemical as well as structural evidence this protein is regarded as the evolutionary ancestor of the eukaryotic tubulin. Nevertheless, plants harbour several ftsZ homologues in their nuclear genomes. Most of the encoded proteins are imported into plastids where they mediate chloroplast division. Additionally, FtsZ proteins can form filamentous networks in plastids for which we coined the term “plastoskeleton”, a dynamic structure which may help plastids to maintain and to change their shape. Moreover, some of these proteins are dual targeted to plastids and to the cytoplasm where they play, at least in the moss Physcomitrella patens, a role in cell division. Thus, they may serve as a molecular link between cell and organelle division. In vivo interactions of different FtsZ isoforms were demonstrated via FRET techniques. Isolation of FtsZ-interacting proteins in Physcomitrella is in progress. Financial support by DFG is gratefully acknowledged.

3.5.4. Cytokinesis in the view of the microtubule-associated protein PLE/MAP65-3

V. Wagner[1], J. A. Torres-Acosta[1], S. Müller[1], A. Smertenko[2], H. Nakagami[3], H. Hirt[3], P. Hussey[2], M. Hauser[1];
[1]Institute of Applied Genetics and Cell Biology, Vienna, Austria, [2]The Integrative Cell Biology Laboratory, Durham, United Kingdom, [3]Institute of Microbiology and Genetics, Vienna, Austria.

In plants proper execution of cytokinesis is guided by a plant specific cytoskeletal structure, called phragmoplast, consisting of microtubules (MT) and actin filaments. In the *Arabidopsis thaliana* cytokinesis defective mutant *pleiade (ple)* this structure is impaired. The spotty expression pattern in root meristems of *PLE/MAP65-3* (microtubule associated protein 65-3) and the localization of PLE/MAP65-3 to mitotic MTs, in particular to the phragmoplast midzone in *Arabidopsis thaliana* cell suspension cells is already an indication that *PLE/MAP65-3* is regulated in a cell cycle-dependent manner. One post-translational regulation might be governed by cyclin-dependent kinases (CDK) and / or mitogen-activated kinases (MAPK), since *in silico* analysis reveals several putative MAPK and CDK phosphorylation sites. The characterization of these sites will be presented.
This work is supported by the Austrian Science Fund (FWF P16410-B12)

3.5.5. TMV movement and the plant cytoskeleton

M. Heinlein;
Institut de Biologie Moléculaire des Plantes (IBMP-CNRS), Strasbourg, France.

Studies in higher plants have revealed the existence of RNA species that travel cell-to-cell and through the vasculature to serve as signaling molecules in plant development and gene silencing. RNA viruses encode movement proteins (MP) that may interact with the RNA transport machinery to spread the viral genome from cell-to-cell. The MP of Tobacco mosaic virus (TMV) is believed to form a ribonucleoprotein complex (RNP) with viral RNA (vRNA) and to represent the core of the infectious particle that spreads between cells. Previous studies indicated that the movement process is correlated with the ability of the MP to interact with microtubules. Here, it is reported that in cells at the spreading front of infection, the MP:GFP localizes to distinct mobile particles some of which move along filaments, presumably microtubules. Similar particles are also observed if viral RNA is labeled with GFP, suggesting that they may represent the proposed vRNPs.

3.5.6. KAT1 and KAT2 kinesin like genes are involved in the spatial control of cytokinesis in *Arabidopsis thaliana*

S. Müller, L. G. Smith;
UCSD - University of California, La Jolla, CA, United States.

Mitotic microtubule assemblies (preprophaseband, spindle, phragmoplast) are involved in the spatial and temporal establishment of the cross wall between daughter cells. The Tanled1 (Tan1) gene is required for the proper orientation of these microtubule (MT) arrays during mitosis in maize. Maize orthologs of Arabidopsis (At.h.) kinesins KAT1 and KAT2 were identified as interaction partners of TAN1 in a yeast two hybrid screen; KAT1 showed interaction with ATN (At.h. TAN1 like) in the yeast two hybrid experiment. Expression patterns of ATN, KAT1 and KAT2 are overlapping in immature flower buds and root tips, both of which are enriched in dividing cells. In a reverse genetic approach, we identified multiple kat1 and kat2 mutant plants, who do not exhibit obvious alterations from the wild type phenotype; the double mutant kat1;2 plant develops into a semi dwarf. In the kat1;2 double mutant, defects occur already early in embryogenesis giving rise to misplaced cell walls and consequently miss-shaped embryos and adult plants; in kat1;2 mitotic microtubule arrays are often tilted from the predicted orientation, as reflected in the oblique position of the new cell wall.

3.5.7. Shape and photosynthesis-dependent subcellular distribution of mitochondria in characean internodal cells depend on simultaneous interaction with actin filaments and microtubules

I. Foissner;
University of Salzburg, Dept. Cell Biology, Salzburg, Austria.

Shape, size, number and distribution of mitochondria in characean internodes varied according to the growth status and the metabolic activity within the cell. Vermiform or amoeba-like mitochondria were present in elongating internodes whereas younger and older cells contained short, rod-like organelles. Mitochondria were evenly distributed and passively transported in the streaming endoplasm. In the cortex, mitochondria were sandwiched between the plasma membrane and the stationary chloroplasts and distributed in relation to the pattern of pH banding. Highest mitochondrial densities were found at the acid, photosynthetically more active regions. In elongating cells, the shape and motility of mitochondria depended on the simultaneous interaction with both actin filaments and microtubules suggesting that the mitochondria possess the appropriate motor proteins which can be used either as tracks for migration or for immobilization. The cortical cytoskeleton probably controls the spatio-temporal distribution of mitochondria and promotes their association with chloroplasts, necessary for exchange of metabolites and detoxification.

3.5.8. Dynein-dependent microtubule motility polarizes the tubulin cytoskeleton in the plant pathogenic fungus *Ustilago maydis*

G. Steinberg, A. Straube, G. Finck;
Max-Planck Institute for terrestrial Microbiology, Marburg, Germany.

In the plant pathogen *Ustilago maydis* interphase microtubules (MTs) are nucleated at polar MTOC that send the plus-ends towards the cell poles. Interestingly, assembled MTs undergo rapid motility. Such motility participates in MT polarization in axons, but its role in *U. mayids* is unknown. Here we show that dynein mediates MT motility and that its activity is essential for organizing the interphase array. After disruption of MTs by benomyl and subsequent washout of the drug, MTs reappeared at numerous sites within the cytoplasm. Tagging the MT plus-ends with an fluorescent EB1-homologue revealed that these MTs had an anti-polar orientation. However, the MT array polarized within less that 2 minutes in a dynein-dependent fashion. Furthermore, no MT motility was seen in dynein mutants and MT polarization is rapidly lost at restrictive conditions. These data suggest that dynein-based MT transport participates in polarization of the tubulin array in interphase.

3.6.1. Ancient DNA and the history of maize in North and Middle America

V. Després;
Max Planck Institute for Evolutionary Anthropology, Leipzig, Austria.

Archaeology and genetics have to varying degrees independently shed light on the process of maize domestication. Archaeologists are limited to interpreting the phenotypic characteristics of archaeological cobs, while geneticists interpret the genetic consequences of human and natural selection by analyzing modern maize and its wild ancestor teosinte. Recent innovative approaches in the study of ancient plant genetics create the possibility of a more comprehensive understanding of the domestication process. Our research shows how ancient DNA can be used to address several different sets of questions concerning the domestication of maize. First, how the plant architecture or biochemical properties of starch, characteristics selected by maize farmers, but not directly observable in the archaeological cobs can be determined. Our analysis of three selected genes affecting maize architecture as well as starch and protein properties, show that all three characteristics were present in Mexican maize 4,400 years ago. For one of the genes we observe a closer relationship of the inbred maize Northern Flint from Northeastern North America to ancient and modern Southwest maize than to ancient and modern Mexican maize.

3.6.2. Desiccated plant remains and archaeogenetics

T. Brown;
University of Manchester, Manchester, United Kingdom.

Desiccated plant remains often display excellent preservation of biomolecules, enabling DNA sequences to be obtained with good success rates from material up to 2000 years in age. This means that, when such material is available, ancient DNA can answer questions relating to the biogeography of cultivated plants. For example, through use of cobs obtained from cave sites, it has been possible to study the origins of South American maize, without the complicating factors introduced by the movement of genotypes during the post-Columbian period. This work has led to a model in which the two Central American agricultural systems - highland and lowland -- generated separate expansions of maize cultivation into South America. One expansion centred on a highland culture that spread through the Panama highlands into the Andean regions on the east of South America, and the second expansion centred on a lowland culture which spread along the lowlands of the northeast coast of South America, entering the continent through the river systems. Comparison between ancient allele sequences also shows that maize has undergone a rapid rate of evolution since domestication.

3.6.3. The survival of DNA in charred seeds and its use in the study of plant population genetics

R. J. Giles[1], T. A. Brown[1], M. Charles[2], G. Jones[2];
[1]The University of Manchester, Manchester, United Kingdom, [2]The University of Sheffield, Sheffield, United Kingdom.

The presence of ancient DNA in charred plant remains has been reported by several groups although the validity of these results has been questioned. However recent research has confirmed the survival of DNA in wheat seeds charred for several hours. This study was aimed at improving the sensitivity of plant DNA detection methods by optimising DNA extraction and target amplification from artificially charred wheat seeds. Nuclear and cytoplasmic DNA amplification targets were assessed for their ability to survive the charring process. Charring regimes were chosen that result in the seed morphology that most closely resembles that found in archaeological material. The results have proven that DNA survival in charred seeds is remarkable and the new highly sensitive techniques will now be applied to genuine archaeological samples. The results will form part of a larger project aimed at using the genetic variation present in cereal landraces to help trace the trajectories by which agriculture spread into Europe.

3.6.4. Ancient olive DNA from pits: preservation, amplification, and sequence analysis

R. Elbaum[1], C. Melamed-Bessudo[1], E. Galili[2], S. Lev-Yadun[3], A. A. Levy[1], S. Weiner[1];
[1]Weizmann Institute of Science, Rehovot, Israel, [2]Israel Antiquities Authority, Atlit, Israel, [3]University of Haifa - Oranim, Tivon, Israel.

Olive (*Olea europea*) was domesticated by vegetative propagation of selected wild individuals with superior fruit. Later new cultivars were established repeatedly from feral trees or from crosses between wild and domesticated trees. Thus, the genetic background of modern domesticated lines is a mixture of ancient cultivars and local wild trees. Information coming from fossil DNA may illuminate the process of olive domestication because such DNA sequences provide data about genomes closer to the original wild population. To do this a reliable source for fossil DNA must be established, but the hot and humid regions of olive cultivation are not favorable to DNA preservation. In order to find well preserved and authentic fossil DNA, we defined chemical parameters of pits by IR spectroscopy that correlate with parameters of DNA quality such as template length in an olive-specific repeat array, and template quantity as determined by real time PCR amplification. Pits that past these tests contained high quality fossil DNA that we used for phylogenetic analysis. We present the first ancient olive DNA sequences and compare them to modern wild, feral and domesticated lines.

3.6.5. New approaches for obtaining plant DNA from museum collections

H. B. Cross, B. Gravendeel;
Nationaal Herbarium Nederland - Universiteit Leiden, Leiden, The Netherlands.

Herbaria contain vast quatities of plant material, and the ability to obtain usable DNA from these collections has the potential to augment many research projects. We report results from experiments on the efficacy of protocols modified for museum material, as well as attempts to obtain DNA from different plant organs, including seeds, stems, and flowers. One of the major modifications to our protocol was to proceed with the extraction without maceration of the tissue. With this non-destructive approach we have obtained DNA from plant tissue up to 200 years old. This approach has also worked on a variety of plant material preserved in different ways. For example, DNA was extracted from orchid pollinia that were attached to museum collections of bees. This was accomplished without destroying the pollinia or the bees, and allowed for further study of both organisms. As technical challenges are overcome, the utility of plant DNA from museum collections will continue to grow, and the applications of these results to ongoing research projects will be emphasized.

3.6.6. Ancient wine - tracing origins by microsatellite analysis of archaeological *Vitis vinifera* seeds

A. Schlumbaum;
Institute of Prehistory and Archaeological Science, Basel, Switzerland.

In three out of six archaeological samples of *Vitis vinifera* seeds from sites in France and Hungary with evidence of wine-making, microsatellite markers VV2S, ZAG21 and ZAG62 were successfully PCR amplified. Through comparison with databases of modern Vitis cultivars, the *Vitis vinifera* sample from the Roman site Aquincum Kaszásdülö (2nd -4th cent. AD) was assigned with high probability to Italian and Croatian populations based on three microsatellites. In the two samples from France two microsatellites were amplified, which were sufficient to narrow down the regional provenance: seeds from a Greek city at Marseille (5th cent. BC) were assigned to either Austria/Germany or France, seeds from an Iron Age site at Gailhan (5th cent AD) originated with higher probability from France than from either Austria/Germany or Italy. These preliminary data show that microsatellite sequences of archaeological *Vitis vinifera* seeds can be used to investigate the origin and history of ancient cultivars

3.6.7. Nuclear gene sequences and DNA variation of *Crypromeria japonica* samples from the postglacial period

N. Tani[1], Y. Tsumura[1], H. Sato[2];
[1]FFPRI, Tsukuba, Japan, [2]Shimane Prefecture, Matsue, Japan.

Genomic DNA was extracted from heartwood blocks of six Cryptomeria japonica individuals that had been buried for about

3600 years. Attempts were made to determine the sequences of five nuclear genes following PCR, using expressed sequence tag (EST) markers. We detected 15 nucleotide substitutions and four indels in a partial GapC gene sequence among 13 individuals of the buried and an extant population. For the entire haplotypes of the GapC region, pi and theta were 0.0063 and 0.0010, respectively. Estimates of DNA divergence statistics suggest that differentiation between the two populations was not great. However, permutation tests gave FST and KST values rejecting the null hypothesis (that populations were not differentiated). The significant level of haplotype diversity in the extant population compared to the buried population might be the result of gene flow from neighbouring artificial forests. Alternatively, it is possible that we failed to detect all the DNA variation in the buried population because of clonal growth and/or genetic structure in the buried population.

3.7.1. Are fungi living in lichens and plants the missing link to our understanding of fungal and plant evolution?

F. Lutzoni[1], A. E. Arnold[2], J. Miadlikowska[1], V. Reeb[1], F. Kauff[1];
[1]Department of Biology, Duke University, Durham, NC, United States, [2]Department of Plant Sciences, University of Arizona, Tucson, AZ, United States.

The discovery of an unexpectedly high diversity and abundance of cryptic fungi in healthy leaves of plants and thalli of lichens begs an explanation for their role as putative symbionts with regard to their respective hosts and ecosystems. Did the diversification of lichens and land plants lead to the diversification of endolichenic and endophytic fungi by providing new substrates in new environments for enhanced rates of fungal speciation? Or were beneficial interactions of these fungi with their hosts conducive to a higher rate of speciation among lichen-forming fungi and plant lineages? Do endophytes and endolichenic fungi serve as a reservoir for the evolution of fungal pathogens? Using a phylogenetic framework for the Ascomycota, the times of origin and diversification of fungal endophytes, endolichenic fungi, lichen-forming fungi, and of a selection of fungal pathogens will be estimated and compared to divergence times of main lineages of land plants.

3.7.2. Evolution, host specificity and ecology of sclerotial basidiomycetes that associate with lichens

J. D. Lawrey[1], P. Diederich[2];
[1]George Mason University, Fairfax, VA, United States, [2]Musée national d'histoire naturelle, 25 rue Munster, L-2160, Luxembourg.

The vast majority of described lichenicolous fungi are ascomycetes, but lichenicolous basidiomycetes are also known. The ones that have the widest host amplitude also produce conspicuous sclerotia or bulbils, structures thought to have a dormancy or dispersal function. The best known sclerotial lichenicolous fungus is the virulent pathogen, *Athelia arachnoidea*, the only member of the “athelioid” clade of basidiomycetes that is both lichenicolous and sclerotial. There is also a single described sclerotial lichenicolous species in the genus *Leucogyrophana*, a genetically heterogeneous group in the “bolete” clade. The bulbilliferous genus *Marchandiomyces* in the “corticioid” clade includes both lichenicolous and lignicolous species. Another group of bulbilliferous basidiomycetes that are at least facultatively lichenicolous is in the “cantharelloid” clade, and includes species in the genus *Burgoa*, all apparent anamorphs of *Sistotrema*. Phylogenetic analysis of rDNA sequences indicates that in all of these groups, the lichenicolous habit has evolved independently several times, probably from nonlichenicolous ancestors.

3.7.3. Lichens as a habitat for fungi - a molecular survey

D. Persoh;
Lehrstuhl für Pflanzensystematik / Mykologie, Bayreuth, Germany.

The presented study aims to assess the distribution and host/substrate selectivity of lichen-associated fungi, and to screen the habitat lichen for undiscovered species and new phylogenetic groups. 1086 fungal strains were isolated from lichens of the Lethariетum vulpinae. They were pre-sorted according to culture characteristics, and subsequently grouped by ITS/5.8S nrDNA sequence data. The 18S nrDNA was sequenced for representatives for each ITS genotype. The sequences were aligned with all publicly available high quality SSU nrDNA sequence data of Ascomycetes. Phylogenetic analyses of the alignment revealed the majority (91%) of the ITS genotypes to cluster the Dothideomycetes (35%), Chaetothyriomycetes (20%), Leotiomycetes (17%), Sordariomycetes (11%), and Lecanoromycetes (8%). Group specific oligonucleotide probes targeting the rRNA were designed for each of the 23 clades containing ITS genotypes of the isolated fungi, and immobilized on epoxy glass slides. These microarray chips were hybridized with fluorescent labelled RNA isolates of various lichens.

3.7.4. Endolichenic fungi: random inhabitants or symbiotic partners

J. Miadlikowska[1], A. E. Arnold[2], K. L. Higgins[1], S. D. Sarvate[3], P. Gugger[4], A. Way[1], V. Hofstetter[1], F. Lutzoni[1];
[1]Duke University, Durham, NC, United States, [2]University of Arizona, Tucson, AZ, United States, [3]University of Virginia Health System, Charlottesville, VA, United States, [4]University of Minnesota, St. Paul, MN, United States.

Studies of lichenicolous fungi (secondary fungi associated with lichen thalli) have been restricted, almost exclusively, to fungal species with visible reproductive structures on lichen surfaces. However, the potential for fungi to occur asymptomatically within thalli (e.g., as endolichenic fungi, analogous to endophytes of plants) remains mostly unexplored. We used a gradient of surface-sterilization to examine fungal communities associated with asymptomatic thalli of foliose lichens (Lobaria, Nephroma, Peltigera, and Umbilicaria) representing various habitats in neotropical, temperate, boreal, and arctic sites. Based on the sequences of the entire ITS region obtained from all cultivable fungal isolates, we explored diversity, taxon composition, geographic structure and host specificity of endolichenic fungi. Phylogenetic placement and affiliation of selected endolichenic fungi, endophytes isolated from different plant lineages, and representatives of major lineages of Ascomycota were explored using nuclear ribosomal genes, and used as the basis for a discussion of the evolution of the endophytic and endolichenic habits.

3.7.5. Inferring symbiont evolution across terrestrial plant lineages: Endophytic fungi from the tropics to the tundra

A. Arnold[1], S. D. Sarvate[2], L. Higgins[2], J. Miadlikowska[2], C. Davis[2], F. Lutzoni[2];
[1]University of Arizona, Tucson, AZ, United States, [2]Duke University, Durham, NC, United States.

Fungal endophytes are ubiquitous among green plants. Their potential to have coevolved with host plant lineages, to have descended from pathogenic or saprophytic fungi, and to inform our understanding of the fungal tree of life, have not been fully explored. We surveyed endophytes inhabiting photosynthetic tissues of all major plant lineages at sites from the neotropics to the Arctic. Over 6400 isolates were recovered from bryophytes, ferns and allies, conifers and angiosperms. NucITS data were obtained for 2030 isolates to assess endophyte diversity, host affinity, and spatial structure, and to select taxa for multilocus phylogenetic analyses. We recovered high upper-level diversity of endophytes at higher latitudes, whereas temperate and tropical sites were characterized by high species-level diversity. Many endophytes have wide distributions, but several clades showed strong host affinity and local distributions. Abundance of major fungal clades differed among host lineages within sites, and among related hosts at different sites. The impact of these cryptic fungi on hypotheses regarding the evolution of plant-fungal symbioses will be discussed.

3.7.6. Phylogeny of endophytic Xylariaceae from multiple photosynthetic hosts

E. C. Davis[1], A. E. Arnold[2], J. D. Rogers[3], J. Miadlikowska[1], K. Ryall[1], F. Lutzoni[1];
[1]Duke University, Durham, NC, United States, [2]University of Arizona, Tucson, AZ, United States, [3]Washington State University, Pullman, WA, United States.

The Xylariales are regularly identified as dominant components of the endophyte flora from phylogenetically and geographically disparate hosts. Using sequence similarity analyses of the internal transcribed spacer of nrDNA (ITS) from Xylarialean endophytes of liverworts, mosses, ferns, gymnosperms, angiosperms, and lichens, as well as non-endophytic Xylarialean species, we show that certain Xylarialean endophyte sequence groups are globally distributed, non host-specific, and show low sequence similarity to non-endophytic species. Our data further suggest that other endophyte groups have geographically local distributions and/or are more closely allied with non-endophyte taxa. Results of multi-locus phylogenetic analyses (nuclear ribosomal LSU, SSU, and 5.8S) place Xylarialean endophytes in the Amphisphaeriaceae and Xylariaceae, and further imply that the endophytic habit occurs in multiple lineages within the Xylariaceae. Well-supported clades are identified within the genus Xylaria, and there is low sequence divergence in LSU, SSU, and 5.8S among these groups.

3.7.7. Conflicting forces in asexual grass endophyte symbiosis

K. Saikkonen[1,2];
[1]Laboratory of Genetics, Department of Biology, University of Turku, Turku, Finland, [2]MTT Agrifood Research Finland, Plant Production Research, Plant Protection, Jokioinen, Finland.

Endophytic fungi are considered to be mutualists because they receive nutrition and protection from the host plant, and in grasses also asexual dispersion by growing into the host's seeds, while the host receives benefits through increased resistance to herbivores, pathogens and drought and flooding stress, and enhanced competitive abilities. However, benefits to the partners are only rarely symmetric and conflicting selection forces are likely to destabilize them. For example, (1) the asymmetry in dependence, (2) conflicts between host and fungal reproduction, (3) genetic mismatch between the partners, and (4) energetic costs of harboring the endophytic fungus might destabilize the symbioses. Because of these conflicts, life histories of grass endophytes are likely to be dynamic. The question is how ecology and genetics interact to shift fungal life history traits between the extremes of sexuality and asexuality and pathogeneity and mutualism.

3.8.1. Floras, the life-blood of plant taxonomy

R. K. Brummitt;
Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Consideration will be given to the importance of local, national, regional and global Floras in the modern age. At a time when taxonomy is taught less and less in universities and funding is directed increasingly to other branches of botany, we should not forget that the ability to correctly identify the plants on which we work is still of fundamental importance. In particular, conservation issues demand more and more knowledge of plants in the field, but it is known that our basic knowledge of the taxonomy of threatened plants is often very poor. Lip-service is often paid to the need for taxonomic work, but support for it is declining. The role of individuals, teaching establishments, botanical institutions and international bodies will be discussed. Floras have been the great stimulus for taxonomic work for two centuries, and offer the possibility for a focus of attention to attract the much-needed funding which will be essential if we are ever to complete the inventory of plant diversity. The main issue is not whether Floras should be produced in hard copy or in electronic form; the great need is to get the taxonomy done in the first place.

3.8.2. Different scales - different constraints (or not?)

A. E. Orchard[1], K. L. Wilson[2];
[1]Centre for Plant Biodiversity Research, CSIRO Plant Industry, Canberra, Australia, [2]Royal Botanic Gardens, Sydney, Australia.

Some people might think that the considerations and constraints encountered in producing a modern Flora treatment would be the same, whether the region being covered was big or small. Others would think that this would certainly not be true. What is the reality? We will explore this question by comparing current Floras covering various regions of different sizes, notably the recently completed 'Flora of New South Wales' (covering a medium-sized Australian State, with c. 6 000 vascular species), the continuing 'Flora of Australia' (for an island nation/continent with c. 20 000 species) and the continuing IOPI Species Plantarum Project's 'Flora of the World' (with 250 000-300 000+ species, depending on which estimate of global numbers one follows). All three are available in hard-copy and are currently being made available electronically. We will look at the features of both hard-copy and electronic versions.

3.8.3. Floras & informatics. A new age for floristic data

S. Castroviejo;
Real Jardín Botánico, Madrid, Spain.

Recently, some informatic applications have been developed to help producing morphological descriptions, etc. A demonstration of a new programme will be done. This programme has as characteristics: - it works over the Internet - can be feed from traditional descriptions, even already published - for any one of the species it displays a dot map made on-the-fly, a picture, a plate, a description, the list of synonyms, an updated list of localities, etc. - it shows geographic, cytological or graphical information taken from both sources: bibliography and herbarium specimens - it avoids the problem caused by the synonyms -the information related with a single species can be found under more than a single name- through a routine developed to understand the nomenclature and synonymy - it assist as well for specific identification without using dichotomical keys, but a interactive way of searching - it produces a list of any of the characters used for each taxon in a dichotomical identification key As summary, we can show a system to help providing taxonomic and floristic information not as a printed flora, but in a modern and interactive format through the Web.

3.8.4. California as a case study in the evolution of floristic modeling

B. Ertter;
University and Jepson Herbaria, University of California, Berkeley, CA, United States.

Although floristics is largely perceived as an exercise in information compilation and management, it is more accurately understand as a massive, on-going, internationally collaborative effort to model biodiversity. The taxonomic components (e.g., species) are not free-standing static entities, but rather dynamic hypotheses that derive their identities from the larger floristic framework in which they are nested. California provides an excellent case study of this concept and the various stages of floristic evolution. Initial cataloguing led to increasingly sophisticated (and competing) floras that incorporated the latest ecological, biogeographic, biosystematic, and phylogenetic developments, with significant pioneering efforts occurring in California. The electronic era now allows an improved expression of the dynamic nature of floras, as reflected by current developments in California floristics (i.e., the Jepson On-Line Interchange, ucjeps.berkeley.edu/interchange.html).

3.8.5. Diversity of approaches and layouts in regional “Floras” in Russia and neighboring countries

D. V. Geltman;
Komarov Botanical Institute of the Russian Academy of Sciences, St. Petersburg, Russian Federation.

“Flora of the USSR” (1934-1964) was followed by “Floras” of all former Soviet republics (except Russia) and several flora projects on the large regions of the former USSR, which have been accomplished (European part, Siberia, Far East, Middle Asia) or are near finishing (Caucasus). Regional and republican “Floras” generally followed the scheme of the “Flora of the USSR”, but there are several variations in approaches and layouts between “Floras” and even different treatment in the same “Flora”. V. L. Komarov species concept adopted in the “Flora of the USSR” can not be regarded as simply “extreme splitting” but reflects several natural features of the territory of study (vast lowland areas). A peculiar character of “Russian” Floras is a tradition to use schemes of more or less natural regions to describe geographical distribution; “Floras” of Siberia and the Far East have distribution maps for almost all species. At the same time there are no specimens lists in the majority of series. A concept of the new “Flora of Russia” is now in preparation. This “Flora” has a good chance to be a synthesis of advantages of both Russian and West European taxonomic schools.

3.8.6. Flora-writing exemplified by classical, conservational and unconventional models

K. Tan;
Institute of Biology, University of Copenhagen, Copenhagen, Denmark.

There are many ways to compile a Flora. The *Flora of Turkey* is a remarkable 10-volume work completed within a quarter-century of its inception. A review of the factors contributing to the Flora's success is provided. The *Flora of Turkey* is a classical Flora with an additional supplement recently produced by Turkish botanists. *Flora Hellenica* is another example of a classical Flora. Some aspects of its background and production are briefly mentioned.

Conservationists consider the endemic flora of a country needs protection for all time, and an opportunity arose to prepare a three-volume work on the endemic flora of Greece. The first volume, covering the Peloponnese, was published in 2001. Flora contributions and monographic work both have their uses. An unconventional model of Flora-writing is presented after the revision of a large family of plants. The Brassicaceae is a diverse group, several members of which have great economic importance. Biodiversity in the family is unquestionably demonstrated, together with comments on relationships. In summary, a good Flora survives long after the flora has gone.

3.8.7. Managing data for floristics

R. J. Pankhurst;
Royal Botanic Garden, Edinburgh, United Kingdom.

Databases can hold all the data required for the writing of a Flora, and can do so with much improved accuracy and precision, if data acquisition is managed carefully. Floristic data can then also readily be distributed and shared. All floristic data depends on the nomenclature. Data on literature and specimens (both with images), people, geography and distribution follow, and after that many other data types such as descriptive characters, keys, maps, uses and ecology. A draft of a Flora can be generated directly from the database, by selecting the data types and output formats. Standards are vital, as for authorities, citations and geography, and in standard data formats. Data retrieval is then more reliable, and data sharing easier. High quality can be achieved by various means. First, checks should be made when data is first entered. Later, special software can verify such as the dates for a certain person, and their publications and collections. Other checks can ensure that all relevant data is present, and at the planned level of detail. Examples will be given from the Flora of Turkey, the Euro+Med, the Species Plantarum Flora and the world Rosaceae databases.

3.9.1. Phylogeny of the Lamiales, with special reference to family Plantaginaceae, sensu APG

R. Olmstead[1], B. Oxelman[2];
[1]University of Washington, Seattle, WA, United States, [2]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden.

The clade Lamiales was first recognized on the basis of rbcL phylogenies of flowering plants and comprises the orders Lamiales, Scrophulariales, Plantaginales of previous authority-based classifications and taxa from related groups. The traditional family Scrophulariaceae was recognized to be a polyphyletic assemblage consisting of several clades now accepted as distinct families in the recent Angiosperm Phylogeny Group (APG) classification of angiosperms, including Scrophulariaceae s.s., Orobanchaceae, Calceolariaceae, Stilbaceae p.p., Phrymaceae, and Plantaginaceae. Perhaps the most widely distributed and biologically diverse segregate clade is the Veronicaceae (family Plantaginaceae) with close to 100 genera and 2000 species. Cosmopolitan in distribution, this group includes members that have been assigned to several distinct families on the basis of their diverse life histories and reproductive biology, including aquatic plants, wind and water pollinated plants, and plants with dramatically reduced floral structures. Plantaginaceae itself has strong support from plastid DNA data, but its position within Lamiales is unclear.

3.9.2. Phylogeny and biogeography of Cheloneae

A. D. Wolfe;
The Ohio State University, Columbus, OH, United States.

Cheloneae, as originally circumscribed, included 26 genera of Scrophulariaceae with cymose inflorescences. The number of genera included in the tribe, and the taxonomy of Scrophulariaceae has changed dramatically over the past decade as more sophisticated morphological and molecular analyses have been done. A phylogenetic study using ITS and *matK* sequence data was conducted on tribe Cheloneae to test for monophyly, examine biogeographic patterns, and assess relationships. The results of this study provide evidence that *Collinsia* and *Tonella* should be transferred from Collinsieae to Cheloneae and that Russelieae should be expanded to include *Tetranema*. Our results also indicate a New World origin for Cheloneae with dispersal of the Asian component over Beringia. North American Cheloneae may have originated in the Klamath Region of the western United States with expansion to the Rocky Mountain/Columbia Plateau region followed by diversification of several genera. We propose a post-Tertiary evolutionary radiation of the large North American genus *Penstemon*.

3.9.3. Phylogenetic investigations of the Antirrhineae: Implications for taxonomy, biogeography, and character evolution

W. J. Elisens, R. K. Hoggard;
University of Oklahoma, Norman, OK, United States.

The monophyly of the Antirrhineae lineage is supported consistently in molecular phylogenetic analyses, which is concordant with unique morphological (e.g., poricidal capsule dehiscence) and iridoid (e.g., antirrhinoside) characters, and its near uniform delimitation as a tribe or subfamily within the historical ‘Scrophulariaceae’. The primary unresolved systematic hypotheses involve sister group and infra-lineage relationships, generic boundaries, and patterns of character evolution. Analyses of plastid and nuclear molecular markers have identified several clades within the Antirrhineae such as ‘Maurandyinae’ + *Asarina* + *Cymbalaria*, *Anarrhinum* + *Kickxia*, and *Antirrhinum* s. l. + *Mohavea* + *Chaenorrhinum*. Our investigations focus on resolving phylogenetic and biogeographic relationships among the Old World/New World ‘*Maurandya’* clade, North American/South American taxa *Gambelia* + *Galvezia*, and Old World/New World species of *Linaria* + *Nuttallanthus*. Biogeographic patterns and the evolution of morphological and phytochemical characters, chromosome numbers, and cross incompatibility are examined within several lineages.

3.9.4. Searching for morphological synapomorphies for the clades in the Veroniceae

M. M. Martínez-Ortega[1], L. M. Muñoz-Centeno[1], D. C. Albach[2];
[1]Departamento de Botánica, Universidad de Salamanca, Salamanca, Spain, [2]Institute of Botany, Vienna, Austria.

Veroniceae have arisen as a surprising sister group to *Plantago* (plus *Aragoa*) in DNA sequence analyses. A new infratribal and infrageneric rearrangement for the *Veroniceae* and for *Veronica* has been proposed based on the most recent evidence from DNA sequence data (three DNA regions, both nuclear and plastid), morphological evidence, and biogeographical considerations. Looking for morphological synapomorphies is apparently misleading, especially for each subgenus in *Veronica* s. l. (including *Hebe, Pseudolysimachion, Synthyris*) due to difficulties arising from widespread homoplasy (mainly parallel evolution). In an attempt to overcome these difficulties, several previously under-explored morphological characters have been studied. A combined analysis of some of them (e. g. base chromosome number, seed coat) shows that, although this is not an easy task, it is also not a misconceived plan at least for some clades. Information on character evolution in Veroniceae is important to determine possible synapomorphies for the *Veroniceae-Plantago-Aragoa* clade.

3.9.5. Biogeography of Plantaginaceae: Family-level trends and intriguing generic patterns

H. M. Meudt[1], D. C. Albach[2];
[1]Massey University, Palmerston North, New Zealand, [2]University of Vienna, Wien, Austria.

Recent molecular phylogenetic work on Plantaginaceae *s.l.* has revealed new insights into the evolution and biogeography of the family as a whole, as well as some of its tribes and genera. Plantaginaceae consists of two main sister lineages: 1) a mostly New World clade (*Angelonia* and relatives plus some members of Gratioleae), and 2) a mostly Old World clade (*Veronica, Antirrhinum,* etc.) plus its sister clade of New World Cheloneae, *Russelia* and *Tetranema.* An overview of different biogeographic hypotheses will be discussed for Plantaginaceae, with an emphasis on shifts between the Old and New Worlds. In addition, we will focus on the biogeography of *Ourisia, Digitalis* (including *Isoplexis*), *Globularia,* and other genera with existing phylogenies. Finally, a synopsis of some of the remaining genera in the mostly New World clade will be provided, highlighting potentially interesting biogeographic distributions and underscoring the need for more phylogenetic research on these groups.

3.9.6. Phytochemistry of Plantaginaceae

S. R. Jensen;
DTU - Denmark, Lyngby, Denmark.

Plantaginaceae have been much investigated with regard to its chemical constituents. Iridoids and phenylethanoid glycosides are widespread in the family and show a suitable variation to be useful as taxonomic markers. The iridoid glucosides aucubin and catalpol as well as their esters are, together with the phenylethanoid glycoside verbascoside, perhaps the ancestral constituents in the family. With some variations, these are present in most Plantagineae, Veroniceae, Globularieae and Cheloneae. On the other hand, Gratioleae and Antirrhineae mostly lack these compounds and the former instead contain triterpene glycosides, while the latter is characterized by the iridoid antirrhinoside. The specialized aquatics Callitriche and Hippuris both contain the expected compounds, while the creepers Ellisiophyllum and Sibthorpia are almost completely depauperated in iridoids. Within Veroniceae, the genera Lagotis, Wulfenia and Veronicastrum are clearly different from Picrorhiza and Veronica. A preliminary investigation of the former genus Hebe shows that this taxon chemically fits well within Veronica.

3.9.7. Phylogenetic relationships within the genus *Linaria* Mill. (Plantaginaceae): the case of sect. *Supinae*

A. Juan[1], M. B. Crespo[1], M. F. Fay[2];
[1]Instituto Universitario de Investigación-CIBIO, Alicante, Spain, [2]Royal Botanic Gardens, Kew, United Kingdom.

Linaria is the largest genus in the tribe *Antirrhineae*, and it is distributed throughout the northern hemisphere. Its main centre of distribution is located in the Mediterranean basin. According to Sutton (1988), the genus is divided in five sections: *Linaria*, *Supinae*, *Pelisserianae*, *Versicolores* and *Diffusae*. Phylogenetic relationships among the sections were investigated using nuclear DNA (ITS: internal transcribed region) and plastid DNA (*trn*L-F: the *trnL* intron and the *trnL-trnF* intergenic spacer). Section *Supinae* includes many closely related taxa, many of them endemic or restricted to small areas. Both regions (ITS and *trnL-F*) showed a low level of nucleotide variability and were not informative at the specific level. Most of the taxa in the section formed a polytomy in the strict consensus tree. To resolve this problem, we also analysed many of the *Supinae* taxa using AFLP (amplified fragment lenght polymorphisms).

3.10.1. Ecological genetics of homoploid hybrid speciation

L. H. Rieseberg[1], B. Gross[1], C. Lexer[2];
[1]Indiana University, Bloomington, IN, United States, [2]Royal Botanic Gardens, Kew, United Kingdom.

New species may arise via hybridization and without a change in ploidy. This process, termed homoploid hybrid speciation, is theoretically difficult because it requires the development of reproductive barriers in sympatry or parapatry. Theory suggests that isolation may arise through rapid karyotypic change and/or ecological divergence of hybrid neospecies. Here, we evaluate ecology's role in hybrid speciation, with an emphasis on the underlying genetics. We review theoretical developments related to the ecology of hybrid speciation, propose a set of explicit questions that must be answered to verify the role of ecological selection, discuss published work with reference to these questions, and report new data supporting the importance of ecological selection in the origin of hybrid sunflower species. We show that that homoploid hybrid species are most likely to arise under conditions of strong ecological selection and that ecological divergence is critical for their persistence.

3.10.2. Mixing genomes: changes to genome structure and gene expression during diploid hybrid speciation in *Senecio*

R. J. Abbott[1], **G. Liu**[1], M. J. Hegarty[2], K. J. Edwards[2], S. J. Hiscock[2];
[1]St Andrews University, St Andrews, United Kingdom, [2]Bristol University, Bristol, United Kingdom.

The detection of recently originated plant species provides significant opportunities for examining structural and functional genomic changes that occur during and immediately following plant speciation. The Oxford ragwort, *Senecio squalidus*, is a new diploid hybrid species that originated in the British Isles within the past 300 years from material introduced from a hybrid zone between two species, *S aethnensis* and *S. chrysanthemifolius,* that occur on Mt Etna, Sicily. We have generated linkage maps of all three taxa using AFLP, SSR and allozyme markers to determine the genomic contributions of the two parent species to *S. squalidus,* and to examine possible alterations to the genome structure of the hybrid during or shortly following its origin. In addition, we shall report the results of a gene expression assay that has employed a recently developed anonymous cDNA microarray resource to examine changes to floral transcriptome during the origin of *S. squalidus*.

3.10.3. Swamping the swamp gum: Habitat fragmentation increases hybridization in a woodland eucalypt

D. Field[1,2], A. Young[1], R. Whelan[2], D. Ayre[2];
[1]Centre for Plant Biodiversity Research, CSIRO Plant Industry, Canberra, Australia, [2]Institute for Conservation Biology, Department of Biological Sciences, University of Wollongong, Wollongong, Australia.

Habitat fragmentation can result in changes to population parameters that may promote interspecific hybridization. We examined the influence of absolute and relative population size on hybrid production in 16 populations of *Eucalyptus aggregata,* a tree species occupying woodland remnants in south eastern Australia. Proportion of hybrid offspring in open-pollinated families increased with declining absolute and relative population sizes, such that hybrid seed were 45% of seed crops in populations <40 trees. Growth data show hybrids to be vigorous, but chemical analysis of leaves indicate significant changes in the quantity and identity of insect defence chemicals. In terms of *in-situ* conservation, these results suggest that hybridisation may result in genetic assimilation (swamping) of *E. aggregata* by its common relatives in fragmented landscapes. For *ex-situ* conservation, seed crops from such sites should not be used for revegetation as they contain many hybrid genotypes.

3.10.4. Pollination strategies and natural hybridization in orchids

S. Cozzolino;
Dep. Plant Biology,University of Naples Federico II, Naples, Italy.

Natural hybridization often occurs upon secondary contact between species that are not fully reproductively isolated. The evolutionary consequences depend on the strength of pre-zygotic and post-zygotic barriers among the parental taxa. Although orchids are typically thought to attract highly specific pollinators, hybridization has been widely reported in this group. In Mediterranean orchids, different levels of pollinator specificity exist. Food-deceptive *Orchis* and *Anacamptis* species show weak pollinator specificity, whereas the sexually deceptive *Ophrys* species display a highly specialized pollination strategy. Experimental evidence indicates that groups with high pollinator specificity largely rely on pre-mating reproductive barriers, whereas groups with weak pollinator specificity show strong evidence for intrinsic post-mating reproductive barriers. Molecular analyses of orchid hybrid zones support these results and indicate that the types and strength of reproductive barriers directly affect the rate and the evolutionary consequences of hybridization.

3.10.5. Hybrid zones as bridges to gene flow across species boundaries in *Silene latifolia* and *S. dioica*

A. Widmer, C. Rothenbühler, A. Minder;
Geobotanical Institute, Zürich, Switzerland.

Silene latifolia and S. dioica (Caryophyllaceae) are closely related species that differ in habitat preferences and floral traits. Silene latifolia grows in relatively sunny and dry habitats and has white flowers that are pollinated predominantly by nocturnal moths, whereas S. dioica grows in nutrient-rich and moist habitats and has red flowers that are pollinated during the day by bees and butterflies. Where the habitats of both species meet, hybrid populations are formed. Hybrids are viable and fertile and may thus serve as bridges to gene-flow across species boundaries. Using molecular markers we characterize the genetic composition of two large hybrid zones in the Swiss Alps and investigate the extent of introgression from S. latifolia into S. dioica and vice versa using autosomal and sex-linked markers. The results provide new insights into the porosity of Silene genomes and form the basis for the study of adaptive trait introgression.

3.10.6. Towards the molecular genetic analysis of the barrier to gene flow between *Populus alba* and *P. tremula*, two ecologically divergent European forest trees

C. Lexer[1], J. A. Joseph[1], M. F. Fay[1], A. Buerkle[2], M. Nica[3], B. Heinze[3];
[1]Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom,
[2]University of Wyoming, Laramie, WY, United States, [3]Federal Office for Research and Forests, Vienna, Austria.

Barriers to gene flow between ecologically divergent species are of special interest to students of adaptation because the genes conferring ecological differences are expected to segregate in hybrids. Hence, hybrid populations offer a powerful tool for the genetic analysis of adaptively important traits. Perhaps the biggest impediment to unlocking the potential of interspecific populations lies in the difficulty of generating multi-generation crosses in long-lived species, e.g., forest trees. Natural hybrid zones offer an attractive alternative: the increased genetic variability and admixture linkage disequilibrium (admixture LD) present in hybrid populations can be utilized for association studies. We have launched a research program to study the potential of admixture LD - based studies in hybrid zones of *Populus alba* and *P. tremula*, two ecologically divergent forest trees, and first results of this ongoing work will be presented.

3.10.7. Hybridization and polyploidy:crossing the ecological divide

D. A. Levin;
University of Texas, Austin, TX, United States.

Speciation often is accompanied by the shifts in the ecological and temporal niches (new adaptations) of populations. The genetic resources required to adapt to new environments are best afforded by mixing disparate gene pools. Yet a rich genetic milieu is not a sufficient substrate for speciation, because recombination and gene flow from the progenitor may prevent the stabilization of novel genotypes (adaptations). Polyploidy coupled with hybridization is key to ecological divergence with its attendant new adaptations, because it congeals new genotypes and erects genetic barriers around them, and magnifies ecological disparities between hybrid derivatives and progenitors. Polyploidy coupled with hybridity also may enhance lineage persistence by elevating immediate fitness and evolutionary flexibility through genome-specific gene silencing, intergenomic recombination, genome reorganization, and increased genetic robustness.

3.11.1. Forests in a CO_2-rich world: Old questions, new challenges

R. J. Norby;
Oak Ridge National Laboratory, Oak Ridge, TN, United States.

The increasing amount of CO_2 in the atmosphere is a global change that will influence forests for many decades into the future. Photosynthetic assimilation of CO_2 increases as the atmospheric concentration rises, but will this result in more tree growth or faster cycling of C through the forest? The question is critical because forests are prominent in the global C cycle and could provide an important negative feedback that slows the pace of climate change. Building on decades of research with seedlings and young trees, the current generation of experiments in forest stands confirms that net primary productivity, the total annual production of organic matter, should be higher in future forests. In the deciduous forest in the Oak Ridge free-air CO_2 enrichment experiment, productivity is enhanced by elevated CO_2 but the additional C is not recovered in tree biomass. Instead, it is allocated to fine roots that turn over rapidly and do not contribute to a removal of CO_2 from the atmosphere. Our challenge is to predict if other forests will allocate C similarly and how forest responses to elevated CO_2 will be modified by other resources and climatic change factors.

3.11.2. Ecosystem responses to increased atmospheric CO_2 concentration: Interactions with spatial and temporal variation in nitrogen and water

R. Oren, H. McCarthy, S. Palmroth;
Duke University, Durham, NC, United States.

In a *Pinus taeda* (L.) dominated ecosystem at the Duke Forest, spatial variation in leaf area index (*L*) corresponds to small topographic relief at the site (~20 m). In plots positioned at the higher portion of the landscape where site nitrogen (N) availability is low, *L* of the planted pine had expanded slowly, reaching a lower maximum than plots positioned marginally lower at the site, and permitting higher proportion of canopy *L* from naturally regenerating broadleaf species. Nevertheless, absolute *L* of broadleaf species also increases with site N, but this increase is small due to heightened competition with the pine. In this setting, increasing atmospheric CO_2 (using Free Air CO_2 Enrichment, FACE) where N availability is low has no effect on *L* and growth; where N availability is high CO_2 enrichment enhances *L* and growth of the pine only. Inter-annual variation in water availability did not affect the above responses in four years of progressive water limitation, although drought reduces the absolute differences in leaf area among plots and treatments. However, the recovery from drought differs among species and depends on nitrogen availability and CO_2 treatment.

3.11.3. Plant-Microbe interactions in soil regulate ecosystem response to atmospheric CO_2

K. S. Pregitzer[1], D. R. Zak[2];
[1]Michigan Technological University, Houghton, MI, United States,
[2]University of Michigan, Ann Arbor, MI, United States.

A major uncertainty in predicting ecosystem response to a changing environment is the extent to which increases in plant and ecosystem productivity will be sustained as CO_2 continues to accumulate in the Earth's atmosphere. Here we present results from a major FACE experiment in Wisconsin that demonstrate how microbe interactions in soil mediate key feedback mechanisms controlling ecosystem response to elevated $CO_{2.}$ Results demonstrate that increases in plant growth under elevated CO_2, and its diminishment by elevated O_3, have altered net primary productivity, fine root production and biochemistry, substrate availability for microbial metabolism, the composition of soil fungal communities and the formation of soil organic matter. We demonstrate how altered plant growth and tissue biochemistry under elevated CO_2 cascade through soil microbial communities to influence the ecosystem-level cycling of C and N in ecologically and economically important forests in the Upper Great Lakes region, USA.

3.11.4. Nutrients, rising CO_2 and carbon sequestration by the world's forests: a reality check

B. A. Hungate;
Northern Arizona University, Flagstaff, AZ, United States.

Will carbon uptake by the world's forests partly counteract human CO_2 emissions over the next century, and thereby help mitigate climate change? Some suggest that it might, though often such predictions overestimate the biogeochemical flexibility of forest ecosystems. For example, increased nitrogen (N) fixation in response to rising atmospheric CO_2 has been invoked as a means to match potential carbon with N requirements of growing vegetation, yet in long-term field experiments, without additions of non-N fertilizers, CO_2 has no effect on N fixation. Similarly, in a woodland ecosystem, elevated CO_2 enhanced immobilization of N in plant biomass and soil organic matter, causing N availability to plants to decline. Based on specific examples from field experiments in woodland ecosystems, metaanalyses of published data, and biogeochemical theory, I argue that the expectation that forests will sequester large quantities of carbon is probably exaggerated.

3.11.5. Does exposure to elevated CO_2 delay the onset of senescence: Evidence from leaf, canopy and remote measurements in the POPFACE/EUROFACE Experiment.

G. Taylor[1], M. J. Tallis[1], F. Miglietta[2];
[1]University of Southampton, Southampton, United Kingdom, [2]CNR, Firenze, Italy.

It has been suggested that the extended seasonality and delayed senescence observed in temperate forests, since the 1970s, is a consequence of increased ambient temperatures. Here, we present evidence to suggest a direct effect of elevated atmospheric CO_2 in mediating this effect in *Populus.* Using open-top chambers, we have shown that senescence is delayed in elevated CO_2 and have identified quantitative trait loci (QTL, areas of the *Populus* genome), responsible for this effect. In an ecosystem (FACE) experiment, we report evidence from leaf, canopy and remote measurements in *P x euramericana* and *P. nigra* that senescence is also delayed in elevated CO_2. These include assessments of canopy and leaf reflectance spectroscopy, (NDVI), Leaf area index (LAI) and leaf chlorophyll content suggesting that canopy longevity may be increased following exposure to elevated CO_2. The consequences of this for productivity and adaptation to future CO_2 will be considered, as will results from microarray analysis, where gene expression profiling has been completed as senescence progressed in both ambient and elevated CO_2.

3.11.6. CO_2 effects on juvenile tree stands, studied in 'mini-ecosystems'

D. Overdieck;
Oekologie der Gehoelze, Berlin, Germany.

There is a strong need to conduct CO_2 enrichment experiments on plants at the community level under soil and microclimatic conditions as close to nature as possible. Therefore, several long-term experiments were conducted with juvenile Fagus sylvatica and Quercus robur stands in field enclosures ('mini-ecosystems') connected to soil containers of which the inner climate was regulated according to continuously working sensors outside. These systems not only allowed to measure total net CO_2/H2O gas exchange of small stands together with rooted soil but also leaf and stem gas exchange and soil respiration. Selected results from several studies are compared in order to connect net photosynthesis and transpiration rates of leaves at elevated CO_2 with the total 'mini-ecosystem' gas exchange, with the aim to contribute to the answer on the question: Can woody plant systems serve as sinks for the additional troposheric CO_2 and is there any interaction with their water use?

3.11.7. Effect of rising CO_2 on rainforest trees: Trends in ŭ^{13}C and water use efficiency of tropical *Cedrela* and *Swietenia* from Brazil

P. Hietz[1], W. Wanek[2], O. Dünisch[3];
[1]Institute of Botany, BOKU, Vienna, Austria, [2]Institute of Ecology and Conservation Biology, University of Vienna, Austria, [3]Biozentrum Klein Flottbek, University of Hamburg, Germany.

Tropical forests are important sources (due to forest loss) and as sinks (through absorption by intact or re-growing forests) in the global carbon cycle. Without FACE experiments in any tropical forest, the effect of rising [CO_2] on an entire forest can only be studied through historical trends, such as those preserved in tree rings. While most rainforest trees do not produce annual rings, some do, and we present the first detailed analysis of long-term trends in C isotopes from two species from Brazil. Cellulose ŭ^{13}C from 37 *Cedrela odorata* (11 to 151 yr old) and 16 *Swietenia macrophylla* trees (48 - 126 yr) decreased substantially, with the strongest changes during the past 50 years. A comparison of cellulose from different decades and from trees of different cambial age showed that the trend observed is largely related to the decade the wood was produced in, and not to tree age. Internal CO_2 increased from about 220 to 260 ppm and intrinsic water use efficiency increased by 34% in *Cedrela* and by 52% in *Swietenia*. This may have implications for the water cycle and can also help to explain a trend towards increased tree growth and turnover observed in some tropical forests.

3.12.1. Phytoremediation technology for the management of trace element contaminated environment

M. N. V. Prasad;
University of Hyderabad, Department of Plant Sciences, Hyderabad, India.

Phytoremediation technology for the management of trace element contaminated environment
Anthropogenic and natural flux of toxic trace elements are increasing in the environment deteriorating the quality of living. Phytoremediation technology includes a range of plant-operated processes that lead to the amelioration, removal, and containment of the toxic trace elements and operate on the principles of biogeochemical cycling. Various categories of plants viz, ornamentals, tree crops, aquatic macrophytes, algae, cell cultures, weeds, industrial crops are being applied in this strategy. This presentation would focus on the relevance of natural accumulators, molecular and genetic manipulation of plants, soil amendments with cheaters, interactions of soil organisms with higher plants, rhizosphere exudates for enhanced accumulation or exclusion of trace elements. Phytoremediation processes are in general slow and therefore is the general disbelief for its field applications on large scale. However, the contemporary knowledge disproved this disbelief and phytoremediation technology is being transferred successfully for field applications.

3.12.2. Heavy metal uptake strategies of plant species growing on calamine (Pb/Zn) soil

B. Aigner[1], H. M. Sieghardt[1], W. Körner[2], W. F. Punz[1], M. Weidinger[3];
[1]Department of Plant Ecophysiology and functional Anatomy of Plants, Vienna, Austria, [2]Department of Geological Sciences, Vienna, Austria, [3]Institution of Cell Imaging and Ultrastructure Research, Vienna, Austria.

Some plant species on heavy metal enriched soils are able to influence uptake and distribution of heavy metals. Four species from lead-zinc enriched mine spoil on the Hochobir (Carinthia/Austria) were investigated. Plant heavy metal (Pb, Zn) content was determined using DCP-OES, distribution in different leaf tissues by means of EDXA. Leaf anatomy was examined by means of LM and SEM. Sequential extraction of the soil yields information on the mobility of the heavy metal fractions and the concentrations were measured with ICP-OES. In all plants lead concentration was highest in the roots. Regarding zinc distribution different strategies were observed: while *Linaria alpina* is an excluder type - most of the Zn is located in the roots. *Arabidopsis halleri, Thlaspi minimum* and *Alyssum ovirense* are accumulators. The results show that in all analysed accumulator plants zinc is translocated in the aboveground organs; there are great differences, however, in distribution within several aerial parts (shoot, different leaf types) and tissues (epidermis vs parenchyma).

3.12.3. Plant-fungal interactions in hyperaccumulating plants

K. Turnau[1], **P. Ryszka**[1], E. Orlowska[1], J. Mesjasz-Przybylowicz[2];
[1]Institute of Botany of the Jagiellonian University, Krakow, Poland, [2]Materials Research Group, iThemba LABS, Faure, South Africa.

Recently, the presence of arbuscular mycorrhizal symbiosis (including abundant formation of arbuscules) was demonstrated in Ni and As hyperaccumulating plants, which are being used in phytoextraction. In addition, in the case of *Berkheya coddii*, originating from Ni enriched ultramafic soils in South Africa, increased metal uptake was observed, which was due to the presence of a AM fungus. The most effective in stimulation of plant growth were strains originating from Ni-rich soils. The positive effect of a fungus was correlated with the richness of the developed arbuscules. This strongly suggests the importance of the appropriate selection of the strains. Both, in hyperaccumulating and nonaccumulating plants, AM fungi can either decrease or increase metal uptake. Diverse strains originating from several sites were used to estimate their influence on heavy metal uptake by plants. Under natural conditions, the fungi are not expected to increase strongly heavy metal uptake of these plants, due to the presence of both types of fungi, inhibiting and stimulating metal uptake. New technologies have to be developed to optimize the phytoextraction technique.

3.12.4. Cadmium induced changes in antioxidant enzymes in tobacco and coffee cell suspension cultures

R. A. Azevedo[1], P. L. Gratão[1], P. J. Lea[2], R. A. Gomes-Junior[1], V. A. Vitorello[3], P. Mazzafera[4];
[1]ESALQ, Universidade de São Paulo, Piracicaba, Brazil, [2]Lancaster University, Lancaster, United Kingdom, [3]CENA, Universidade de São Paulo, Piracicaba, Brazil, [4]Universidade Estadual de Campinas, Campinas, Brazil.

The contamination of the environment by heavy metal pollution is a serious problem. Oxidative damage often occurs due to the generation of oxygen reactive species induced by heavy metals. A class of antioxidant enzymes has been reported for the scavenging of the oxygen reactive species. We have studied the antioxidative responses of in vitro suspension cultures of tobacco and coffee to cadmium. It was observed alterations in CAT and peroxidases activities in BY-2 tobacco cells and an significant increase in GR activity. The results suggest that in BY-2 cells the main defence system to Cd stress is variable during the heavy metal exposure time. The synthesis of GSH is evident during the onset of the stress with CAT and peroxidases taking over the antioxidative responses once the stress becomes severe. For coffee cells, Cd exposure also induced an enzymatic oxidative response. The main response appears to be via the induction of SOD and CAT activities for the removal of ROS, or by the induction of GR to ensure the availability of reduced glutathione for the synthesis of

Cd-binding proteins (PCs). Financial support by FAPESP and CNPq.

3.12.5. Nutrients and heavy metal transfer from soil to the host-hemiparastic plant association *Cistus-Odontites luteus* growing on mine spoils

C. Poschenrieder[1], A. Lombini[1], M. Llugany[1], E. Dinelli[2], **J. Barcelo**[1];
[1]Universidad Autonoma de Barcelona, Bellaterra, Spain, [2]Università di Bologna, Bologna, Italy.

Odontites luteus (former Scrophulareaceae) a hemiparasitic plant was found associated with Cistus species at mine sites in Italy (Cu mine) and Catalonia (Pb, Ba mine). Soil, root and shoot concentrations of selected mineral nutrients (Ca, Mg, K, Fe, S, Mn, Zn, and Cu) and of non-essential elements (Al, Cd, Pb, Ba, and Sr) were analysed in order to get a first picture on how the hemiparasitic nutrient adquisition strategy may influence the mobility of these elements. *Cistus sp.* restricted the root to shoot transport of Cu, Zn, Al and Pb. In *O. luteus* similar root and shoot concentrations of Cu and Zn suggest that in this hemiparasitic plant the transport was less hampered, probably due to a direct uptake of mobile metal species from either or both xylem and symplastic sites of the host. In contrast, mobility of Pb was restricted also in the hemiparasite. The host-hemiparasitic plant association may serve as a model system for future investigations on metal mobility as a function of metal speciation in plants. *Acknowledgement: Supported by DGICYT (BFU2004-02237CO$_2$-01) and Plà Recerca Catalunya 2001 (SGR00200).*

3.12.6. Toward the determination of the genetic basis of heavy metal accumulation in six wild metallicolous and non-metallicolous *Salix caprea* populations

M. Türktas[1], M. Puschenreiter[2], P. Sommer[2], W. Wenzel[2], J. Strauss[1], M. Hauser[1];
[1]Applied Genetics and Cell Biology, Vienna, Austria, [2]Institute of Soil Science, Vienna, Austria.

Due to fast growth and biomass production and the ability to accumulate high amount of cadmium (Cd) and zinc (Zn), Salix caprea is well studied for the clean up of metal-contaminated soils by phytoextraction. However only limited information on the population structure of S. caprea is available. Thus, analyses of the genetic structure of six metallicolous and non-metallicolous S. caprea populations was initiated. Genotyping 11 microsatellite markers, we found no evidence for clonal propagation. Low, but significant differentiation was observed between some S. caprea populations. By correlating the amount of heavy metal accumulation with the genotypes we anticipate to determine a genetic basis of this trait. To associate genes responsible for heavy metal accumulation, expression of candidate genes was quantified by real-time PCR during the vegetation period in leaves of S. caprea cultivated on contaminated and uncontaminated soil. The relationship between seasonal changes of gene expression as well as associations between the capacity of heavy metal accumulation and the genotypes will be discussed.

3.13.1. The roles of plant terpenoids in the environment and in the plant

T. D. Sharkey, A. E. Wiberley, T. G. Falbel, A. R. Linskey;
University of Wisconsin-Madison, Madison, WI, United States.

The smaller terpenes, isoprene, monoterpenes, and sesquiterpenes, play important roles in helping plants cope with stress. These compounds are made by related enzymes that are coded for by a rapidly-evolving family of genes. This has allowed these compounds to fill a variety of roles within plants including tolerance of, or resistance to, heat stress, oxidative stress, herbivory, and microbial attack. This talk will focus on the smallest isoprenoid, isoprene, and its role in protecting against thermal and oxidative stress. Isoprene does not protect against very high or sustained temperature and isoprene emission is uncommon in hot desert plants. However, plants that suffer frequent moderately high temperatures, such as tree leaves exposed to full sunlight on a still day, tend to emit substantial quantities of isoprene. Many trees routinely emit 2% of the carbon they take in for photosynthesis as isoprene, but this can range to over 50% of carbon lost as isoprene. Leaves at the tops of trees emit four times more than leaves at the bottom of the same tree. The evolution of the capacity for isoprene emission, and the atmospheric consequences will be addressed.

3.13.2. The biology and molecular genetics of terpene metabolism in plants

J. Chappell, S. Wu, S. Takahashi, S. Lee;
University of Kentucky, Lexington, KY, United States.

Terpenes are a structurally diverse class of compounds that play important biological roles ranging from antimicrobial defense compounds to hormones controlling development programs in plants. Interestingly, terpene biosynthesis has only been observed in plants, microbes and insects, but not in animal species. In plants, terpenes are synthesized by 2 complex biosynthetic pathways compartmentalized to the cytoplasm and the plastids. Recent progress in understanding the structure and function of the terpene biosynthetic genes contributing to the cytosolic pathway has advanced our appreciation for the biological significance of these compounds in plants, as well as suggested mechanisms for how these genes may have evolved and been adapted for specific functions. Understanding the biochemistry and molecular biology of terpene metabolism has also provided insights into how these pathways may be engineered for practical applications in agriculture and medicine.

3.13.3. Regulative aspects of isoprene formation in grey poplar (*Populus x canescens*) leaves

J. Schnitzler;
Institut für Meteorologie und Klimaforschung (IMK-IFU), Garmisch-Partenkirchen, Germany.

Trees produce a wide spectrum of volatile organic compounds (VOCs) such as isoprene. Recently much progress was made to elucidate the metabolic pathway leading to isoprene. Two possible committing steps in the plastidic pathway are the deoxyxululose 5-phosphate (DOXP) reductoisomerase (DXR) catalysing the first specific reaction of the methylerythritol phosphate (MEP)-pathway and isoprene synthase (ISPS), the final enzyme releasing isoprene from dimethylallyl diphosphate (DMADP). The presentation summarizes actual work on molecular, biochemical and physiological aspects of isoprene formation in order to understand its biological function. Seasonal and daily variations of gene expression rates of *dxr* and *ispS* in relation to enzyme activity, DMADP pools and isoprene emission rates from poplar will be shown demonstrating the high variability of isoprene formation. Furthermore immunological and immunohistochemical data on the tissue-specific localisation of ISPS will be presented.

3.13.4. Plant terpenoids in information webs: the ecology of 'crying' for help

M. Dicke, I. F. Kappers, L. L. F. Luckerhoff, H. J. Bouwmeester, R. Mumm;
Wageningen University and Research Centre, Wageningen, The Netherlands.

In response to herbivory plants produce volatiles that attract the enemies of the herbivores as a kind of ‘bodyguards’. Terpenoids are a major class of herbivore-induced plant volatiles that have been recorded from a large number of plant species in response to herbivory by e.g. caterpillars, mites, beetles or bugs. The volatiles that a plant releases can be exploited by all organisms in the environment, including herbivores and neighbouring plants. Therefore, the emission of herbivore-induced plant volatiles may alter various interactions in the food web and in the information web. In this presentation a link will be made between chemical ecology, molecular biology and community ecology. More and more terpene synthase genes are being cloned and characterized and these genes allow exciting new options to investigate the role of terpenoids in multitrophic interactions. Novel tools that allow major progress include combining metabolomics and genomics with ecology. This will be illustrated with research on cucumber and Arabidopsis.

3.13.5. Modeling the emission of stored and "non-stored" monoterpenes from *Pinus pinea*

S. M. Noe[1], P. Ciccioli[2], Ü. Niinemets[1];
[1]Department of Plant Physiology, University of Tartu, Tartu, Estonia, [2]Istituto sull'Inquinamento Atmosferico del C.N.R.,, Rom, Italy.

We developed a dynamic model to describe time-dependent chanegs in VOC emissions from the foliage of Mediterranean conifer *Pinus pinea*. The model consist of a storage pool in resin ducts and two nonspecific monoterpene storage pools in leaf liquid and lipid phases. The monoterpene emission is further controlled by stomatal conductance, that is reflected in a dynamic stomatal control term. The model was parameterized using laboratory monoterpene ^{13}C labeling- and delabeling data. The model is capable to map the dynamics given by the measured ^{13}C labeling data, and demonstrates that the emissions from the non-specific storage pools dominate the monoterpene emission in light. The model further demonstrates that the composition of emitted monoterpenes is dependent on monoterpene physico-chemical characteristics. We conclude that non-specific monoterpene storage pools should be included in monoterpene emission models in both the species possessing and lacking specific foliar monoterpene storage structures.

3.13.6. Isoprene and other terpenoids in the marine environment

S. L. Shaw;
University of California, Berkeley, Berkeley, CA, United States.

Isoprene and other terpenoids are produced in the oceans by photosynthetic algae. While differences exist between marine and terrestrial terpene biosynthesis, isoprene production appears to occur through similar mechanisms in both locales. Environmental and physiological parameters such as light, temperature, and chlorophyll content affect isoprene production from phytoplankton and seaweeds. Bacteria and grazers do not directly produce or consume isoprene, but virally-infected phytoplankton have reduced production rates. Possible functions of isoprene to phytoplankton and seaweeds will be discussed. Air-sea isoprene fluxes can affect tropospheric oxidant chemistry and aerosol formation. New satellite-based global marine flux estimates will be compared with the limited in situ measurements available. Recent field campaigns show that iron fertilization can significantly increase marine isoprene fluxes above background values.

3.13.7. Seasonal terpene emission variation investigated for monoterpene emissions from European beech (*Fagus sylvatica* L.)

C. Holzke, R. Koppmann;
Inst. of Chemistry and Dynamics of the Geosphere (ICG), Research Center Juelich, Juelich, Germany.

In our study we investigated the terpene emissions from European beech (*Fagus sylvatica* L.) in a deciduous forest. Applying the branch enclosure technique changes in the emission pattern and the variation of emission rates over the year were investigated for two following vegetation periods. Our results show that European beech emits significant amounts of monoterpenes, especially sabinene. Monoterpenes have strong impact on the processes in atmospheric chemistry and in inter- and intra-specific signal transmission of plants. The over all emission pattern of beech differed only slightly while emission rates changed up to two orders of magnitude as a function of temperature and light over the day. Highest emission rates were observed in summer and lowest in fall. However, no emissions were found in early spring although leaves were fully developed and temperature and light conditions were comparable to the conditions in fall. Moreover, a temperature independent decline of emissions in late summer characterizing a seasonality of terpene emissions was found resulting in changes of the standard emission rate on the order of one magnitude.

3.14.1. Quantifying the role of dispersal, ecological drift, and species sorting in determining the diveristy of local communities

V. Vandvik;
University of Bergen, Bergen, Norway.

Metacommunity theory shows that regional dynamics can have considerable consequences for the diversity and composition of local communities. However, whereas the theory explores the role of dispersal in *maintaining* diversity within communities, empirical ecologists have largely focused on the role of dispersal in *limiting* local diversity. I argue that there is no necessary relationship between the two; hence we actually do not have the empirical data needed to test and quantify how regional and local processes interact to determine local diversity. Here I present an empirical approach that can be used to explore these questions. It is based on a quantitative partitioning of the natural regeneration within intact communities onto different sources of recruits (e.g., local vs. dispersed). Recruits from these different sources are then followed over time to asses the relative importance of local processes (e.g., species sorting vs. ecological drift) in determining diversity of the adult vegetation. Finally, species traits can be used to determine whether species sorting results from life-history trade-offs or habitat niche differences among species.

3.14.2. Invasibility, propagule availability and diversity of an alpine plant community under simulated climate change

K. Klanderud, Ø. Totland;
Norwegian University of Life Sciences, NO-1432 Ås, Norway.

Which factors control alpine plant community invasibility and diversity under natural conditions, and how will climate warming affect colonization processes and diversity? We examine the relative role of propagule availability and community-level interactions for the invasibility and diversity of a high-diversity plant community in alpine Norway, under natural and elevated temperature conditions. Adding propagules from 27 regional species into heath vegetation increased community diversity significantly. High resident species richness and cover of the highly abundant *Dryas* reduced invasibility. Propagule limitation and competitive exclusion from established species controlled community invasibility and diversity more than the availability of safe sites and the experimental warming. The establishment success of the ‘invaders’ increased under elevated temperature, but intensified competition from established species on emerging seedlings under experimental warming suggest that climate change effects on biotic interactions may affect long-term colonization processes and diversity of alpine plant communities.

3.14.3. Competition-colonization trade-offs and seed limitation in tropical forests

H. C. Muller-Landau[1], S. Wright[2];
[1]University of Minnesota, Saint Paul, MN, United States, [2]Smithsonian Tropical Research Institute, Panama City, Panama.

Competition-colonization trade-offs between species’ ability to arrive at sites and to win sites at which they arrive may contribute to diversity maintenance in stabilizing (niche-y) or merely equalizing (neutral) ways, depending on the specifics of the trade-off and the degree of competitive asymmetry in the community. Alpha and beta diversity patterns are also affected by species dispersal distances in general, even absent any interspecific differences or trade-offs. We use 18 years of seed rain data within a diverse tropical forest to quantify seed production, seed dispersal distance, and seed limitation for 80 tree species, and 11 years of seedling dynamics data to evaluate species’ competitive abilities and competitive structure. Seed limitation is very strong for most species, and varies widely among species due to large differences in seed production and lesser differences in dispersal distances and clumping of seed rain. Seed size mediates a trade-off between seed production and competitive ability among species. We investigate the potential of the observed competition-colonization trade-off and seed limitation to contribute to diversity.

3.14.4. Competition, colonization, or herbivory: which explains patterns of dominance in herbaceous communities

W. P. Carson, A. Baumert;
University of Pittsburgh, Pittsburgh, PA, United States.

We seek to offer a unified and mechanistic explanation for the dominance of goldenrods (Solidago) in herbaceous communities across vast regions of the US. Goldenrods coexist with numerous other long-lived herbaceous species, yet these other species rarely become dominant. We are conducting one of the first ever field tests of the predictions of mechanistic resource competition theory while simultaneously evaluating alternative explanations for dominance, specifically, colonization ability and herbivore tolerance. We ask the simple question: Are species abundant because they are superior competitors, superior colonizers, or resistant to herbivores? Our goal is to determine whether species’ traits (e.g., colonization ability) are capable of explaining the mechanism underlying patterns of relative abundance. Alternatively, traits may not provide a viable explanation if species share many of the same plant traits. Our findings to date suggest that goldenrods dominate herbaceous communities because relative to the species they coexist with, they are simultaneously the best resource competitors, the best colonizers and are unpalatable to browsers.

3.14.5. Roles of chance and adaptation in the assembly of fern communities

M. J. Lechowicz[1], B. Gilbert[2], J. Karst[2];
[1]McGill University, Montreal, PQ, Canada, [2]University of British Columbia, Vancouver, BC, Canada.

We evaluated correlations among fern distributions, the underlying abiotic environment, and the spatial proximity of sampling points at meso- and fine-scales (135-3515 m and 4-134 m, respectively) within an old-growth, deciduous forest. Moisture availability contributed significantly to fern distribution at both spatial scales, and species kept the same positions along the moisture gradient across scales. Dispersal had no significant role in determining meso-scale distributions of fern species. At the fine-scale, however, the environment was strongly spatially structured, and species distributions along moisture gradients might just as well have arisen in neutral dispersal processes as through any niche requirements. Such spatially structured local environments may foster the persistence of dispersal-limited plants. While neutral or random models of species coexistence cannot explain the patterns we have observed, any deterministic models that rely on strict niche requirements without accounting for local dispersal and the inherent spatial structure of the environment neglect the important interaction of these factors.

3.14.6. Plant community assembly and the unimodal productivity-diversity relationship

M. Pärtel, L. Laanisto, M. Zobel;
University of Tartu, Tartu, Estonia.

The unimodal (hump-backed) productivity-diversity relationship was first described by J. P. Grime for British herbaceous vegetation. The original explanation claimed that smaller diversity at low productivity is due to abiotic stress, while at high productivity, competition (niche limitation) is decreasing diversity. Alternatively, evolutionary-historical mechanisms (the species pool size may be small for low or high productivity habitats) and dispersal limitation (diaspores of proper species do not arrive the community) may limit local diversity. Seed addition experiments in grasslands have increased diversity mainly in unproductive habitats, indicating that both dispersal and niche assembly may limit local diversity, but in different parts of productivity gradient. We studied published evidences on productivity-diversity relationships and found that unimodal relationship was restricted to herbaceous vegetation and cold climate. Thus, besides the productivity gradient, life-form specific ecological mechanisms, and regional evolutionary history may determine the balance between dispersal and niche limitation in plant communities.

3.14.7. Quantitative partitioning of regional and local processes shaping diversity productivity-diversity relationships

T. K. Rajaniemi[1], D. E. Goldberg[2], R. Turkington[3], A. R. Dyer[4];
[1]University of Massachusetts Dartmouth, North Dartmouth, MA, United States, [2]University of Michigan, Ann Arbor, MI, United States, [3]University of British Columbia, Vancouver, BC, Canada, [4]University of South Carolina-Aiken, Aiken, SC, United States.

Much recent research in explaining plant community diversity has focused on quantifying the relative impacts of regional and local processes. These analyses have been used successfully within communities, but the power to generalize must come from investigations of patterns of diversity across communities. We employed a novel analysis to integrate multiple regional and local processes to explain patterns in species richness across two plant communities that differ in productivity. While abiotic stress and competition appeared to limit richness within both communities, only differences in species pools resulting from long-distance dispersal and climate fluctuations explained the higher richness in the less productive community. By identifying both the factors that impact diversity within communities and those that vary systematically across communities, our integrated approach provides a better understanding of regional diversity patterns and a stronger basis for predicting community responses to environmental change.

3.15.1. Ozone in Europe: Distribution and effects on plants in the Carpathian mountain and Southern Alpine regions

M. Schaub[1], A. Bytnerowicz[2], W. J. Manning[3], K. Grodzinska[4];
[1]Swiss Federal Research Institute for Forest, Snow and Landscape Research WSL, Birmensdorf, Switzerland, [2]USDA Forest Service, Pacific Southwest Research Station, Riverside, CA, United States, [3]University of Massachusetts, Amherst, MA, United States, [4]Polish Academy of Sciences, Institute of Botany, Krakow, Poland.

Ozone has become the major phytotoxic air pollutant in Europe. Researchers from the USA and Europe have determined the distribution and effects of ozone in forested and natural areas in the Czech Republic, Poland, Romania, Slovakia and Ukraine, in the Carpathian Mountain region and in Italy, Spain and Switzerland in the Southern Alpine region. There is evidence that ambient ozone concentrations as they are monitored in Central and Eastern Europe can cause a variety of effects to vegetation such as visible foliar injury, growth and yield reductions, and altered sensitivity to biotic and abiotic stresses. Ozone may cause shifts in species composition and loss of biodiversity in forest and grassland ecosystems. It is often difficult to assess the sensitivity of natural ecosystems to ozone, especially when considering the diversity of sites as they are found across the Carpathian and Southern Alpine regions. The current international efforts for the establishment of a biologically more meaningful ozone standard demonstrate that more data for dose-response relationships are needed in order to enable ozone risk assessment for natural plant ecosystems.

3.15.2. Ozone in Europe: distribution and temporal trends in the Carpathian region

A. Bytnerowicz[1], R. Musselman[2], P. Fleischer[3], B. Godzik[4], O. Badea[5], F. Popescu[6];
[1]USDA Forest Service, Riverside, CA, United States, [2]USDA Forest Service, Fort Collins, CO, United States, [3]Research Station of Tatra National Park, Tatranska Lomnica, Slovakia, [4]Institute of Botany, Polish Academy of Sciences, Cracow, Poland, [5]Forest Research and Management Institute, Bucharest, Romania, [6]Forest Research and Management Institute, Simeria, Romania.

Ambient ozone (O_3) concentrations are highly variable in the Carpathian Region. Some areas of the Carpathian Mountains in Romania and Poland, as well as the Sumava and Brdy Mountains in the Czech Republic are characterized by low concentrations of the pollutant (seasonal mean concentrations ~30 ppb). Other parts of the Carpathians, especially western part of the range (Slovakia, Czech Republic and Poland), portions of the Eastern Carpathians (Ukraine) and Southern Carpathians (Romania), and the Jizerske Mountains in the Czech Republic have high O_3 levels (peak values >100 ppb and seasonal means ~50 ppb). Large portions of the central European mountain forests experience O_3 exposures above those recommended for protection of forest and natural vegetation (AOT40 values of 10,000 ppb x h and 3,000 ppb x h, respectively). The most endangered forests are in the Slovak parts of the Carpathian Mountains and in the Jizerske Hory of the Czech Republic. There is need for continuation of ambient O_3 monitoring efforts with a combination of active monitors and passive samplers for understanding risk from ambient O_3 in forests and other ecosystems of the Carpathian Region.

3.15.3. Plants and plant ecosystems at risk in the Carpathian mountain region

K. Grodzinska[1], J. Oszlanyi[2], F. Popescue[3];
[1]Institute of Botany PASci, Krakow, Poland, [2]Institute of Landscape Ecology SAV, Bratislava, Slovakia, [3]Institute of Forest Research and Management, Simeria, Romania.

The Carpathian Mountains represent one of the most significant natural regions in Europe. They are characterized by high richness of plant species (30% of the total European flora) and unique natural and seminatural ecosystems. The Carpathians are recognized as a biosphere core areas of an European significance, providing important ecological corridors for the pan-European migration routes. More than 50% of the Carpathian territory is forested, arable lands, pastures and meadows occupy 29%, alpine meadows and rocks 15%. The Carpathians have been under direct (management) and indirect (pollution) human impact for a long time. SO_2, NO_X and dust emissions have been affected the Carpathian ecosystems since the last 50-60 years, recently they are affected by increasing concentrations of ozone (O_3). Consequences of human activity for the biodiversity and health of the Carpathian ecosystems as well as preservation policy and protection of the Carpathian landscape will be presented.

3.15.4. Plant response to ozone in the Carpathian mountain region

W. J. Manning[1,2], B. Godzik[1];
[1]University of Massachusetts, Amherst, MA, United States, [2]Polish Academy of Science, Krakow, Poland.

Ozone has become an all-pervasive phytotoxic air pollutant in the Carpathian Mountain regions of the Czech Republic, Poland, Romania, Slovakia and Ukraine in Central and Eastern Europe. In warm months, increases in combustion, mainly from more cars and trucks, accelerates the photochemical oxidant cycle to produce ozone. Long-range transport from Western Europe also contributes to higher ozone levels in the region. In areas where ozone is known to exceed natural background levels, sensitive native plants may be injured by ozone. We found twenty-nine species of plants in natural areas that exhibited ozone-like injury. By exposing plants to ozone under controlled conditions, we were able to verify 8 forbs (Alchemilla spp., Astrantia major, Centaurea nigra, Centaurea scabiosa, Impatiens parviflora, Lapsana communis, Rumex acetosa, and Scenecio subalpinus), 3 shrubs (Coryllus avellana, Cornus sanguinea, and Sambucus racemosa), 3 trees (Alnus incana, Pinus cembra, and Sorbus aucuparia) and two vines (Humulus lupulus and Parthenocissus quinqefolia) as detector bioindicator plants that can be used to indicate relative air quality for ambient ozone

3.15.5. Ozone in Europe: Distribution, temporal trends and physiological effects on plants in the Southern Alpine region

K. Novak[1], J. M. Skelly[2], J. Innes[3], M. Schaub[1], N. Kraeuchi[1], F. Bussotti[4], G. Gerosa[5], A. Ballarin-Denti[5];
[1]Swiss Federal Institute for Forest, Snow and Landscape Research, WSL, Birmensdorf, Switzerland, [2]The Pennsylvania State University, University Park, PA, United States, [3]University of British Columbia, Vancouver, BC, Canada, [4]University of Florence, Florence, Italy, [5]Department of Mathematics and Physics, Catholic University, Brescia, Italy.

Numerous studies have shown that tropospheric ozone can have negative effects on forest plant species in many parts of Europe including the southern Alpine region, where ozone exposure frequently exceed the critical levels set to protect forest vegetation. These high ozone exposures occur throughout southern Switzerland and northern Italy and are not limited to urban and industrial centers, but often occur in rural areas many kilometers from the source of the precursor pollutants. A variety of studies have been conducted in open-top chamber facilities, in controlled laboratory conditions, and under open field conditions and both morphological and physiological effects have been observed on a variety of ozone-sensitive plants species native to this region as well as much of Europe. As ozone exposures continue to annually exceed the set critical levels, ongoing research focuses on addressing the question as to how ozone affects forests on a regional scale. This paper aims to provide an overview of more than a decade of ozone research as well as the ongoing research conducted in the southern Alpine region.

3.15.6. Ozone sensitivity of temperate grasslands

S. Bassin, M. Volk, J. Fuhrer;
Agroscope FAL Reckenholz, Federal Research Station for Agroecology and Agriculture, Zürich, Switzerland.

Grasslands cover a major part of European landscapes, and they are important for both agricultural utilization and the conservation of biodiversity. With their long growing season, their exposure to air pollutants, mainly tropospheric ozone, is high. The resulting long-term effects may include species-specific reductions in productivity or reproduction, which may lead to a change in species dominance or even a loss of genetic or species diversity. Recent studies using single plants, mesocosms, or intact communities confirmed that ozone affects individual species, and their interactions. This review indicates that the magnitude of ozone effects observed in experiments and obtained by modelling varies according to the degree of system complexity and the duration of the exposure. Effects tend to decrease over time, and complex communities tend to react less than individual plants or simple mixtures. However, further work with established grassland communities will be necessary to fully assess the risks of exposure to ozone.

3.15.7. Validation of the 'unifying theory' on O_3 sensitivity in adult forest trees of Central Europe (*Fagus sylvatica* versus *Picea abies)*

R. Matyssek[1], A. Nunn[1], I. Reiter[1], R. Grote[2], M. Löw[1], K. Häberle[1], W. M. Havranek[3], G. Wieser[3];
[1]Chair of Ecophysiology of Plants, 85354 Freising, Germany, [2]Inst. f. Meteorologie u. Klimaforschung IMK-IFU, Karlsruhe, Garmisch-Partenkirchen, Germany, [3]Federal Office and Research Centre for Forests, Alpine Timberline Ecophysiology, A - 6020 Innsbruck, Austria.

Reich (1987, Plant Physiology 3: 63-91) claimed plant responses to chronic O_3 stress to be explained through a “unifying theory” based on leaf diffusive conductance. Convergence was suggested per equivalent total O_3 uptake or uptake per leaf life span, although validation for adult forest trees has been lacking so far. Here, experimental validation is exemplified for beech versus spruce under ambient air or enhanced O_3 impact through free-air fumigation. Given actual growing seasons and leaf longevities as well as age and O_3 effects, spruce required, per leaf surface area, 5 years for the O_3 uptake of beech during one growing season. The “unifying theory” was supported as both species displayed similar proportional decline in photosynthesis in relation to cumulative O_3 exposure and uptake per “leaf lifespan day”. Non-linearity relative to O_3 flux rather than AOT40 extends the scope towards O_3 detoxification and repair. Overall, spruce was not inherently less O_3-sensitive than beech.

3.16.1. Save it, use it, share it - biodiversity as boundary object

U. E. Eser[1,2];
[1]Koordinationsstelle Umwelt, Nuertingen, Germany, [2]Interdepartmental Center for Ethics in the Sciences and Humanities, Tuebingen, Germany.

In this paper I analyse the concept of biodiversity from the perspective of science studies. Its invention and establishment are interpreted as particular interests to professionalize environmental concern. As the concept and politics of biodiversity transcend traditional boundaries between science and society and between facts and values, its invention is interpreted as boundary work, as an effort to redefine the legitimate boundaries of science in ways that include evaluative statements and political practices. After analysing the interests of the involved scientists the focus of the paper shifts towards the political context. In reconstructing the different interests that were involved and finally addressed in the Convention on Biodiversity I show that biodiversity can meaningfully be regarded as a boundary object, i.e. an object that is able to co-ordinate different groups without a consensus about their aims and interests.

3.16.2. Biodiversity governance between sustainable use and biopiracy

C. Goerg;
UFZ-Centre for Environmental Research, Leipzig; Germany, Leipzig, Germany.

The term Biodiversity is constituted in two distinct ways. At the one hand its meaning is directed towards a comprehensive understanding of one of the most important global environmental problems. At the other hand its recent career is connected with the economic value of genetic resources, being the raw material of new biotechnology companies. Over the last years an international regulation system was build up to create the political-institutional framework for the sustainable use of Biodiversity. But this governance systeme is neither an efficient framework for Biodiversity conservation nor an effective political framework to regulate the functional prerequisites of global markets of genetic resources. At the contrary, it is a highly contradictionary and contested network established by a number of international institutions and organisations. In the contribution, based on a research project on the global management of genetic resources, this governance structure is analysed towards the question whether it allows a fair and equitable sharing of benefits arising from its use - or whether it favour Biopiracy, as some activist group argue.

3.16.3. A new international regime - practical issues for botanists

K. Davis, S. Kemp;
Royal Botanic Gardens, Kew, Surrey, United Kingdom.

A new International Regime (IR) on access to genetic resources and benefit-sharing is now being negotiated under the Convention on Biological Diversity. Proposals include mandatory disclosure of the country of origin in applications for intellectual property rights and a system of certificates of origin/legal provenance/source for genetic material. What will the practical implications of the IR be for researchers and institutions, and how can we help shape the outcome?
If any new system is to sustain rather than hinder biodiversity research and conservation, the research community to be proactive and involved in its development. Biologists need to communicate with peers, partners and government negotiators, and also to demonstrate that our work is worthy of support not suspicion. We need to re-examine how we: collect plants with appropriate consent; collaborate; ensure permit terms stay linked to material we curate, use and exchange; share benefits; disseminate information; and raise awareness. We will provide an update on the start of IR negotiations (February 2005) and give examples of practical measures at the Royal Botanic Gardens, Kew.

3.16.4. Images of nature: Connecting scientific knowledge and the valuation of biodiversity - a case study from southern Chile

K. Jax[1], U. Berghöfer[1], E. Schüttler[1], S. Fistric[1], R. Rozzi[2];
[1]UFZ Environmental Research Centre Leipzig-Halle, Leipzig, Germany,
[2]Universidad de Magallanes, Punta Arenas, Chile.

Images of nature are expressions of people's perception of nature in which facts and values, experiences and cognitive knowledge are still closely connected. For this reason they can form an interface for interdisciplinary and participatory work on the evaluation of biodiversity. Since July 2003, these issues are investigated in the course of a German-Chilean research project in the very south of Chile (BIOKONCHIL). The region is one of the few not fragmented temperate forests of the world and is characterized by high biological diversity and naturalness. On the other hand time economic pressures, such as salmon farming or intensive tourism are recently threatening biodiversity in the region. The paper will present the methodological approach and first results of the project. The project uses ecological theory and the analysis of images of nature to connect scientific knowledge and people's perception of biodiversity. The aim is to provide insights into the valuation of biodiversity from different perspectives (ecological, ethical, economic). Ultimately this serves to provide supportive information for the decision process of the region's development.

3.16.5. Monitoring biodiversity, the quadrature of the circle for biologists. a workshop report from Austria

W. Holzner;
University of Natural Resources and Applied Life Sciences, Centre for Environmental Studies and Nature Conservation, Vienna, Austria.

An indicator set for monitoring biodiversity has to meet very diverse demands: - comply to international commitments, not only the CBD but also the different tasks burdened by the EU on its member states and - match already existing international examples, particularly EU guidelines (which are in statu nascendi), - be specially designed for Austrian conditions and necessities; - directly connected to pressures threatenig biodiversity or measures that have an influence on biodiversity; - based on sound science and statistically valid data, - but also fostering a system oriented, transdisciplinary approach with results that are comprehensible and convincing to everybody, - alltogether an approach that is conservative but also selfreflexive and innovative as well, - and will last but not least not only look fine on paper but will be really useful for the promotion of all forms of BD on all levels, - and is of course inexpensive, because the money should be used for action rather than mere monitoring. A bold team of experts has tackled the task to design such a miraculous indicator set. As their project will be already in an advanced stage in July, let us see how they succeeded.

3.16.6. World bank and forest conservation in India

A. Mukherjee;
Gujarat Institute of Development Research, Ahmedabad, India.

The conservation of the forest by the 'State Forest Department' of the Government of India is a bound duty. The same become either strengthened or weakened due to the involvement of foreign monetary aids. During the last couple of years the involvement of some World Bank aided projects in a few states of India reveals an unprecedented outcome in this matter. The present paper represents a case study undertaken in the western state of India with the aim to evaluate the impact of such punctual monetary funding towards local forest conservation. This study does indicate that the concept of conservation is being well appreciated and supported by the regional population, however there remains a big feeling of insecurity among the local people leading to the unsaid conflict between the forest and its dwellers.

3.17.1. Biologically active plant compounds in food

G. T. Kroyer;
Institute of Chemical Engineering, Vienna, Austria.

Phytonutrients and phytochemicals are commonly referred by nutritionists to biologically active compounds naturally occurring in plants that have physiological effects in human and might prevent or delay chronic degenerative diseases and enhance human health. Numerous phytochemicals have been identified as components of edible plant food with special focus on polyphenols, flavonoids, anthocyanins, carotenoids, isoflavones and lignans. Most that have been studied have in common an ability to act as antioxidants and free radical scavengers to prevent cell damage and are associated with reduced risk of cancer, cardiovascular disease and help prevent and/or treat other medical ailments. They are found in a number of foods, e.g. soy, legumes, fruits, berries, vegetables, seeds, tea, grapes and wine, representing an important factor to consider in the formulation of functional foods and in the choice of a healthy diet. Future food trends will be aimed at modification and fortification of food to enhance naturally phytochemical concentrations for incorporation in the diet for the benefit of the consumer.

3.17.2. Functional food - relevance and trenbds in nutrition

W. Pfannhauser;
Institute of Food Chemistry and Technology, Graz, Austria.

A change in paradigm has occurred : food is now seen also as a tool for better health rather than only to cover energy needs. Definitions are given, differences are pointed out. The legal situation in the EU is stressed. Functional Food Science offers new insights to the interrelationship between food and health. The proof lies in the discovery of beneficial effects of food(components). The scientific background of the claims and trends in Europe are outlined. The tendency to use functional ingredients as food supplements is stressed. Health claims play an important role on the market. Examples are given and the dose - response relationship and potential overdosing is discussed. In any instance food quality - which also comprises the health or beneficial effect - is a dynamic concept, subjected to sociological changes and perception of new scientific knowledge, which is defined according to a personal ranking order of values

3.17.3. Purple wheat - a raw material with high content of phytonutrients

E. Berghofer, I. Kreilmayr, **S. Siebenhandl**, V. Zahlner;
University of Natural Resources and Applied Life Sciences, Vienna, Austria.

Current interest in the health benefits provided by grain consumption has led to an increased focus on the phytochemical content of different grain varieties. Among these, special attention is paid to purple or blue varieties which contain additionally anthocyanins. The objectives of this study were to determine the phytochemical content and reducing power of purple wheat (various milling fractions) and purple wheat products (bread, wafers and pasta) from two diverse varieties in comparison to one normal quality wheat variety. The phytochemical content was characterised by total phenolic content, total anthocyanin content and yellow pigment content. Results demonstrated that purple wheat contained more secondary plant metabolites which resulted in a higher reducing power compared to conventional wheat. Thus, purple wheat is an interesting potential source for innovative cereal products within the health food market.

3.17.4. Anthocyanes from edible berries - pigments with physiological effects

M. Murkovic;
Graz University of Technology, Graz, Austria.

Anthocyanins are water soluble substances from plants, mainly from fruits, that are responsible for the cyanic colors of the fruits. Due to the phenolic structure the anthocyanins are strong antioxidants having the potential to reduce the risk of degenerating diseases where oxidative reactions are involved. On basis of these preliminary results a double blind placebo controlled study was conducted to show the effect of the elderberry juice on the cholesterol level. The results showed a small effect on the serum cholesterol. Other blood parameters were not affected. The effect on the cholesterol concentration was not significant. The antioxidant effect of anthocyanins was not confirmed in serum after oral uptake of the elderberry juice. The pharmacokinetics of the anthocyanins from elderberry were analysed in serum. It could be shown that the maximum concentration of the anthocyanins in the serum after ingestion of the powder was reached after 30 min. After 7 h the anthocyanins were cleared from the serum. Using a lipid rich meal prior to the uptake of the elderberry juice the level in the serum was much slower.

3.17.5. Antioxidant properties of ethanolic extracts from holy basil and galangal and its application to inhibit lipid oxidation in cooked minced meat

T. Juntachote[1], E. Berghofer[1], F. Bauer[2];
[1]University of Natural Resources and Applied Life Sciences, Vienna, Austria, [2]University of Veterinary Medicine, Vienna, Austria.

Ethanolic extracts from Holy basil and Galangal were prepared and evaluated for their antioxidant properties and their effects on lipid oxidation in cooked minced meat during storage at 5 °C. The ethanolic extracts of Holy basil and Galangal had good thermal (80°C, 1 h) and pH stability. The DPPH radical scavenging activities of both extracts were high and showed antioxidant activity, superoxide anion scavening activity and reducing power in a concentration-dependent manner. Therefore, this extracts possibly worked as primary antioxidants that reacted with free radical and oxygen radical. Holy basil and Galangal extracts function as Fe^{2+} chelator and also inhibited lipoxygenase activity. Furthermore, ethanolic extracts from Holy basil and Galangal inhibited the lipid oxidation in cooked minced meat during storage at 5 °C by reducing both peroxide value (POV) and 2-thiobarbituric acid-reactive substances (TBARS). Thus, this extracts may be a possible natural antioxidant source for meat and meat products.

3.17.6. Increases of human plasma antioxidant capacity after consumption of controlled diets high in the content of anthocyanins, flavonoids and other phenolics

E. Sofic[1], A. Rustembegovic[2], A. Imamovic[3], Z. Rimpapa[4], J. Toromanovic[4], S. Redzic[4], N. Denisova[5], G. Kroyer[6];
[1]University of Sarajevo, Sarajevo, Bosnia&Herzegovina, Bosnia and Herzegovina, [2]Anton Proksch Institute, Vienna, Austria, [3]Faculty of Pharmacy, University of Sarajevo, Sarajevo,, Bosnia and Herzegovina, [4]Faculty of Science, University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [5]HNRC, Tufts University, Boston, MA, United States, [6]University of Technology, Vienna, Austria.

Objectives: The objective of this study was to investigate whether a diet of fruits and vegetables would affect the antioxidant capacity of human plasma. Design: Twenty healthy persons consumed two sets of conrolled diets. Diet A contained eleven servings of fruits and vegetables each day for seventeen days. Diet B was the same as Diet A, except Diet B provided three servings of kale and blueberries for days six through eleven. There was a free-living period of seven weeks between the two experiments using either Diet A or Diet B. Fasting plasma antioxidant capacity, measured as ORAC, alpha-tocopherol and ascorbic acid were determined with HPLC-ECD on days 1, 6, 12 and 18. Hippuric acid in the urine was measured by a photometric method. Results: Plasma ORAC, alpha-tocopherol, ascorbic acid and urine hippuric acid of these persons were significantly increased by diet A, but more by diet B. Conclusion: Increased consumption of fruits and vegetables with high contents of phenolics, flavonoids, anthocyanins and vitamins can increase the plasma antioxidant capacity and the excretions of hippuric acid in the urine of humans

3.17.7. Evaluation of in vitro estrogenic activity of some Fabaceae species.

E. Agradi, E. Vegeto, S. Regondi, G. Fico, E. Incurato, **F. Tomè**;
University, Milan, Italy.

The estrogenic activity of plants is related to the presence of compounds referred to as phytoestrogens, mainly isoflavonoids, lignans and cumestans; however other substances have been found to bind to the human estrogen receptors. Based on recent literature, foods rich in such substances, beside having effects on the reproductive system, seem to play an important role in chronic degenerative disease prevention. Thus the evaluation of the estrogenic activity of foods belonging to the traditional nutritional habits of populations with a low incidence of cardiovascular and hormone-dependent cancer, may contribute to new strategies for better population health. In this work we have analysed the *in vitro* estrogenic activity of crude extracts of many *Fabaceae* species largely used as food in Mediterrenean and Oriental tradition, using an assay based on engineered human cells expressing the estrogen receptors and a reporter gene. Results indicate that many *Fabaceae* show estrogenic activity, mainly present in the more polar extracts; however consistent differences were observed in related species and among varieties of the same species.

4.1.1. D-type cyclins: Dual roles in G1/S control and development in *Arabidopsis*

J. A. Murray;
Institute of Biotechnology, Cambridge, United Kingdom.

In plants, control of the cell cycle is of key importance in the activity of meristems, developmental processes and the overall control of growth. Arabidopsis has ten D-type cyclin genes (CYCD), and the use of synchronised cell suspension cultures shows that these are expressed with distinct timing during cell cycle re-entry and during the cell cycle. We have focussed on CYCD3 as a key regulator both of the G1/S transition, and of differentiation and endoreduplication. CYCD3 is an unstable protein, rapidly turned over in a proteasome-dependant manner, and overexpression in suspension cells shows that it drives cell through the G1/S boundary but this causes an extension of G2 phase before the point at which B-type cyclin expression is activated. CYCD3;1 is highly expressed in developing primordia, and we propose that the primary role of CYCD3;1 is to maintain cells in a mitotic cycling state and to block endoreduplication until sufficient cells have been produced in a developing organ.

4.1.2. Complexities of the E2F-regulated gene expression networks during the cell cycle and differentiation

E. Ramírez-Parra, B. Desvoyes, J. C. del Pozo, M. P. Sanchez, E. Caro, S. Diaz-Triviño, P. Castillejo, **C. Gutierrez**;
Centro de Biologia Molecular, Madrid, Spain.

The balance between cell proliferation and differentiation is crucial in multicellular organisms but particularly relevant in plants where organogenesis is a postembryonic process. Maintenance of this balance requires a complex and finely tuned transcriptional regulation, both temporally and spatially. The E2F/DP family of transcription factors was originally considered to be involved exclusively in regulating G1/S genes. Recent evidence has revealed that, surprisingly, this is not the case, since they actually regulate genes that belong to many different functional categories. We are interested in identifying set of genes that are preferentially regulated by different E2F in a cell type- and developmental stage-specific manner. Among them, those involved in controlling the initiation of DNA replication and macromolecular biosynthesis play important roles in the maintenance of proliferative potential, the switch to the endocycle program, the acquisition of a differentiated state and, ultimately, the correct morphogenetic patterns.

4.1.3. Recombination-replication-repair connection of geminviruses

H. Jeske;
Institute of Biology, Stuttgart, Germany.

Geminiviruses are single-stranded (ss) DNA-containing plant pathogens. One major driving force of their evolution is recombination. Using an optimized two-dimensional gel electrophoresis in combination with hybridization and electron microscopy, we have discovered that the recombinational flexibility is reasoned by a recombination-dependent replication mode (RDR). Compared to complementary strand synthesis (CSR) and rolling circle replication (RCR), which both accompany RDR, the latter mechanism allows the virus to repair every broken or unfinished DNA intermediate as far as homologous templates are available. Surveying different combinations of geminiviral and satellite DNAs, two strategies can be discriminated between Old World and New World begomoviruses. The first is rather promicous and transreplicates other DNAs without a cognate DNA-binding sequence for the viral replication-associated protein (Rep), whereas the latter needs the interaction of Rep and Rep-binding sequences.

4.1.4. Regulation of the transition from G2 to mitosis in higher plants

D. Francis[1], H. J. Rogers[1], J. Dickinson[1], I. Siciliano[1], C. B. Orchard[1], R. J. Herbert[2];
[1]Cardiff University, Cardiff, United Kingdom, [2]University College,, Worcester, United Kingdom.

The classic eukaryote cell cycle comprises mitosis (M) and DNA replication which are separated in time by G1 and G2. In effect, it is the conduit through which proliferative cells travel from one mitosis to the next. We study the transition from G2 to mitosis and in this paper I will describe what we know about this transition at the molecular level. In plants, the key regulators of this transition are A-type cyclin dependent kinases (CDKs), A-type cyclins, B-type CDKs /cyclin Bs. CDKAs are expressed from S-phase to G2 whilst, only in G2 are plant-specific B-type CDKs expressed. A-type CDKs but not B-types can complement budding and fission yeast mutants *cdc28*$^-$ and *cdc2*$^-$*,* respectively. B-type CDKs also differ in that a conserved sequence PSTAIRE (A-types) in the helix Ŭ1 reads as PPTLARE / PPTTLRE in B-types. At G2/M, in fission yeast the Cdc2-cyclin complex is phosphoregulated by WEE1 kinase competing with CDC25 phosphatase at an ATP binding domain of Cdc2. In higher plants only recently, have putative phosphoregulators of CDKs emerged. We have cloned a full length *Arath;WEE1* and a small *Arath;CDC25* and are now testing the efficacy of these genes as cell cycle regulators.

4.1.5. DNA endo-reduplication - bypassing checkpoints and control points

J. A. Bryant[1], A. H. Quelo[2], J. P. Verbelen[2], G. Dambrauskas[3], S. Aves[1], D. Francis[4], H. J. Rogers[4];
[1]University of Exeter, Exeter, United Kingdom, [2]University of Antwerp, Antwerp, Belgium, [3]State University of North Carolina, Raleigh, NC, United States, [4]University of Cardiff, Cardiff, United Kingdom.

DNA endo-reduplication, the repeated replication of DNA in the absence of mitosis, is common in plants, so common in fact that it should be regarded as a normal cell cycle variant. Endo-reduplication can only happen if the checkpoints that link M to the subsequent S-phase are suppressed and if the mitotic control point is completely by-passed. In tobacco BY2 cells, mitotic cell division is inhibited by withdrawing auxin. However, after a lag of about three days, the cells start to elongate and then initiate DNA endo-reduplication. This implies that the molecular events required for DNA replication are induced in this auxin-minus growth pattern. Analysis of mRNA populations by RT-PCR indicates that the expression of the gene encoding CDC6, a protein required for initiation of DNA replication, is induced under these conditions. This may be compared with the 'normal' cell cycle that occurs in the presence of auxin, in which the expression of this gene is almost entirely confined to late G1 and to S-phase. Exactly what the role of auxin is in that pattern of expression is not clear, because the endo-reduplication data show that *CDC6* expression may be auxin-independent.

4.1.6. DNA endoreduplication during caryopsis development in sorghum (*Sorghum bicolor*).

A. Kladnik[1], P. Chourey[2,3], D. Pring[3], **M. Dermastia**[1];
[1]Department of Biology, Biotechnical Faculty, University of Ljubljana, Ljubljana, Slovenia, [2]Department of Plant Pathology and Agronomy, University of Florida, Gainesville, FL, United States, [3]United States Department of Agriculture, Agricultural Research Service, Gainesville, FL, United States.

We report here temporal and spatial occurrence of endoreduplication (ERD, a form of polyploidization in somatic cells of many eukaryotes) in developing caryopsis of sorghum. After a short phase of intense mitotic activity and cellularization, endosperm cells showed ERD as early as 5 days after pollination (DAP), that peaked at 11 DAP in nuclei in the central region of endosperm. The highest measured C-values in those cells were 96 C (1 C represents the nuclear DNA content of a non-replicated haploid genome). A positive correlation was seen between the nuclear volume and the nuclear C-values. Positive correlation was also observed among the nuclear DNA content, volume of endosperm cells and the starch content. In the later stages of development, approximately 70% of variance of endosperm cell volume could be explained by ERD. Nuclei with non-ERD DNA were observed exclusively in the peripheral layers of the endosperm. ERD was also prominent in the maternal pericarp nuclei, with DNA content up 16 C.

4.2.1. Control of chloroplast gene expression in *Chlamydomonas*

M. Goldschmidt-Clermont, L. Merendino, K. Perron, C. Rivier, S. Depp, V. Fiechter, M. Rahire, I. Howald, J. D. Rochaix;
Departments of Molecular Biology and Plant Biology, University of Geneva, Geneva, Switzerland.

Chloroplast biogenesis requires the concerted action of two genomes, in the plastid and in the nucleus. Genetic analysis in the green alga *Chlamydomonas reinhardtii* has revealed a large number of factors that are encoded in the nucleus and are required for the expression of chloroplast genes. These factors are involved in post-transcriptional steps of gene expression such as RNA processing, splicing, translation or assembly of protein complexes. They show a surprising specificity for single chloroplast genes or gene clusters. A striking example comes from the chloroplast *psaA* gene of *Chlamydomons* which contains two split group II introns. The three exons are widely scattered in the plastid genome and are transcribed as separate precursors that are then spliced *in trans*. The maturation of *psaA* mRNA depends on the products of at least fourteen nuclear genes, including *Raa1, Raa2* and *Raa3*, which we have isolated and characterized*.* These factors are part of large ribonucleoprotein complexes in the chloroplast.

4.2.2. Small genomes in plastids from primary and secondary endosymbioses

U. Maier;
Cell Biology, Marburg, Germany.

Primary plastids, which are found in green algae, land plants, red algae and glaucocystophytes, are surrounded by a double membrane and evolved by the incorporation of a cyanobacterium-like cell and its reduction to a plastid. Other plastids, the complex plastids, originated from secondary endosymbiosis. Here, a eukaryotic phototroph with primary plastids was engulfed and reduced to a plastid surrounded by three or four membranes. Some secondary evolved algae show highly reduced genomes. I will present new findings on dinoflagellates and cryptomonads, and how these organisms compartmentalize the genetic information. Neither in primary nor in secondary endosymbiosis, organisms are known, which are related to the phototrophic symbiont. This situation complicates the reconstruction of genomic evolution in early steps of intracellular co-evolution. However, several intracellular cyanobacteria are known, which can be used as model systems for the transition of free-living organisms to permanent intracellular symbionts. One of these transitions will be presented in the case of a cyanobacterium/diatom interaction.

4.2.3. Co-evolution of nucleus and plastid - the model *Oenothera*

R. G. Herrmann, S. Greiner, J. Meurer;
Department Biologie I, Bereich Botanik, München, Germany.

The evolution of eukaryotic genomes, which in plants traces back to endosymbiotic conglomerates of three cells, was coined by three basic processes that changed the genetic potentials of the symbiotic cells into a single integrated compartmentalised genetic system. *Compartmental co-evolution*, one of these processes, becomes apparent after organelle exchanges between species which can lead to serious developmental disturbances in the resulting genome-plastome hybrids. - The genus *Oenothera* represents a unique resource to study the impact of nucleo-organelle interaction in plant development and evolution, due to a favourable combination of genetic features and the existence of a highly developed cytogenetics and taxonomy of genome, plastome, and chondriome. This allows to exchange plastids and nuclei, also to substitute individual chromosome pairs between species. - We have characterised in natural and artificial combination the five basic plastid chromosomes and six basic genomes of subsection *Euoenothera* to study the interspecific plastid/nuclear network in developmental and speciation processes that is possible in a continental dimension.

4.2.4. Transcription in plastids: ontogenetic and phylogenetic aspects

T. Börner, C. Emanuel, K. Liere, T. Preuten, M. Swiatecka, A. Weihe;
Institut für Biologie (Genetik), Humboldt-Universität, Berlin, Germany.

The highly complex transcriptional machinery of plastids provides fascinating insights into the ways leading to the integration of an organelle into the genetic system of a eukaryotic cell. Plastid genes are transcribed by a plastid-gene encoded RNA polymerase (PEP) and, at least in land plants, by one or more nuclear-gene encoded RNA polymerase(s) (NEP). PEP is a bacterial-type RNA polymerase such as already used by the cyanobacterial ancestors of plastids. Several data indicate that NEP is represented by one or more phage-type RNA polymerases. The nuclear gene for NEP originated by duplication from the gene coding for the mitochondrial RNA polymerase in nearly all eukaryotes. PEP promoters are found upstream of genes for proteins needed in photosynthesis and of many genes with house-keeping function. The nucleus controls PEP activity by supplying various sigma factors and by NEP needed to transcribe the genes for PEP subunits. NEP gene transcripts and transcripts of NEP-transcribed genes show eminently different levels in dependence on age and type of tissue indicating an individual and spatial developmental role.

4.2.5. Sequences affecting translation of plastid mRNAs

M. Sugiura, M. Yukawa, M. Nakamura, H. Kuroda;
Nagoya City University, Nagoya, Japan.

The plastid translation system includes bacterial-like ribosomes and tRNAs. However, about two-thirds of tobacco plastid mRNAs contain no Shine-Dalgarno-like sequence (typically GGAGG) at a proper position in the 5’ UTR. To study plastid translation, we previously developed an *in vitro* translation system from tobacco chloroplasts. Here, we improved it by using a gene coding for green fluorescent protein and by modifying extraction and reaction conditions. The improved method is ca. 100-fold more active than the original system, extremely lower in background and requires no facility for radioactive materials. Using this system, we identified *cis*-sequences and repressing sequences of several plastid mRNAs, and analyzed effects of codon usages and of codons immediately downstream of AUG.

4.2.6. Assembly-controlled regulation of chloroplast gene translation

Y. Choquet, C. Loiselay, L. Minai, K. Wostrikoff, B. Rimbaud, J. Girard-Bascou, D. Drapier, R. Kuras, F. Wollman;
UMR7141 CNRS/UPMC, Paris, France.

Studies of the biogenesis of the photosynthetic protein complexes in the green algae Chlamydomonas reinhardtii have stressed the importance of the concerted expression of nuclear and chloroplast genomes. The accumulation of chloroplast and nuclear encoded subunits from photosynthetic complexes is a concerted process. Many unassembled subunits are rapidly degraded but others show an assembly-dependant regulation of their rates of synthesis, known as a ‘Control by Epistasy of Synthesis’ or CES process. For example, the rate of synthesis of cytochrome f, a major subunit of the cyt. b6f complex encoded by the chloroplast petA gene, is decreased 10 fold in the absence of its assembly partner SUIV. This results from an autoregulation of petA mRNA translation that involves negative feedback from the C-terminal domain of the unassembled polypeptide. Our results show that assembly-dependent autoregulation of translation initiation are widely spread in the chloroplast of C. reinhardtii, since all major photosynthetic complexes contain at least one CES subunit. These regulations would involve nucleus-encoded gene specific translation activators.

4.2.7. Assembly of membrane integral quantum traps

L. A. Eichacker;
LMU, Munich, Germany.

Through evolution, membrane integral protein complexes are used to trap light quanta for photosynthesis. Protein complexes of the photosynthetic machinery have been crystallized; however, the position of several subunits within the complexes is not clear and assembly of the subunits is a just emerging field of interest. Here, we show that Synechocystis PCC6803, Chlamydomonas reinhardtii and higher plant chloroplasts provide excellent model systems to study the assembly process. In this direction we adress the regulation of the assembly process and present components that participate in the molecular regulation of the assembly process. Technically, we present that assembly of membrane protein subunits into functional complexes can be well studied by using 2 BN-/SDS-PAGE and demonstrate the detection of protein complexes by fluorescence and the identification of membrane integral alpha-helices by mass spectrometry.

4.3.1. The control of apical cell growth and morphogenesis by ion dynamics

J. A. Feijó[1,2];
[1]Universidade de Lisboa, Faculdade de Ciências, Dep. Biologia Vegetal, Lisboa, Portugal, [2]Centro de Biologia do Desenvolvimento, Instituto Gulbenkian Ciência, Oeiras, Portugal.

Despite copious amounts of detailed info at the physiological and, more recently, on the molecular side, regulation of growth in pollen tubes still lacks an integrative model. In the past we have propose that "ion dynamics" maybe a common denominator in the regulation of living cells. In pollen tubes, fluxes are polarized, implied that carriers for protons, calcium, chloride and potassium shows non-linear patterns in space (polarized distribution of carriers) and also in time (oscillatory and chaotic behaviors). In accordance, P-ATPases are excluded from the apex membrane by a mechanism that involves polarized translation, actin cytoskeleton and membrane recycling. We are exploring transcriptomic information out of Arabidopsis genechip to boost these kinds of correlations and develop functional tests for specific molecular entities. Yet, data emanating from the different fields must be integrated in a coherent theoretical way. A simple computer model balance the intracellular turgor with differential rigidity of the cell permits the exact simulation of most of the basic cellular features of pollen tubes.

4.3.2. Cell wall architecture and anisotropic growth in pollen tubes

A. Geitmann;
Institut de recherche en biologie végétale, Montréal, PQ, Canada.

The cell wall is one of the structural key players regulating pollen tube growth, since plant cell expansion depends on an interplay between intracellular driving forces and the controlled yielding of the cell wall. Since pollen tubes show extreme anisotropic growth behavior, the physical properties of the cell wall should be expected to differ between growing and non-growing regions. We evidenced these differences using local deformation performed by micro-indentation. This approach revealed a strong gradient in rigidity along the longitudinal axis of the cell, that cannot be explained by geometrical features as demonstrated with finite element modeling. To identify the roles of individual cell wall components for cellular architecture we used enzymes that specifically digest or change the configuration of cell wall polymers such as callose, cellulose or pectins. We related the mechanical data with the distribution of these polymers assessed with fluorescence labeling techniques. This revealed that in particular the distribution of methyl-esterified and acidic pectins seems to be a fundamental structural feature of anisotropic cellular growth.

4.3.3. Wall structure and oscillating growth of Nicotiana tabacum pollen tubes

J. Derksen[1], M. M. Wolters-Arts[1], E. S. Pierson[1], F. Liners[2], P. van Cutsem[2], I. Lichtscheidl[3], V. Zarsky[4], **J. Derksen**[1];
[1]Faculty of Science, Inst IWWR, Nijmegen, The Netherlands,
[2]University of Namur, Inst. of Biotechnology, Namur, Belgium,
[3]University of Vienna, Inst of Ecol and Conservation Biol., Vienna, Austria, [4]Charles University, Inst. of Experimental Botany, Prague, Czech Republic.

Using cryo-FESEM, we assessed porosity and 3-D construction of pollen tube walls. Below phreatic point-sublimation of water from broken pollen tube walls revealed a network of continuous fibers interconnected by short rods with 50nm spacing. Such a structure cannot form a mechanical barrier even for larger molecules, such as proteins. Using the JIM 5 antibody or the basic dye Toluidine blue, a clear, banded pattern was seen in the wall. Using the 2F4 antibody for egg-box pectin, similar patterns were detected. Remarkably, the same pattern was found in the much later deposited secondary wall after Aniline blue staining for callose. Progressive removal of water soluble wall components with EDTA showed the tube cell to be tiled with scales that probably represent the bands seen after Toluidine blue staining. In contrast to the secondary wall, the primary wall almost completely dissolves with EDTA-extraction, indicating its coherence to depend on pectin. Banding patterns of pollen tubes grown *in vitro* appeared to depend on the media used, on growth conditions, but also on culture time. *In vivo*, banded patterns occur less frequent, but may appear regularly after stress.

4.3.4. Pollen tube growth and guidance: $[Ca^{2+}]_c$ is a key element in the crosstalk of signaling pathways which modulate apical secretion

R. Malhó;
Dept Plant Biology, University of Lisbon, ICAT, Campo Grande, Lisboa, Portugal.

Pollen tube growth relies on an extremely fast delivery of new membrane and wall material to the apical region where growth takes place. Despite the obvious meaning of this fact, the mechanisms that control this process remain very much unknown. A tip-focused $[Ca^{2+}]_c$ gradient is known to play a central role in the regulation of pollen tube growth and modulation of the $[Ca^{2+}]_c$ concentration results in changes in the rate and direction of growth. One of the targets of this Ca^{2+} signalling pathway was therefore claimed to be the secretory pathway and we have been studying this process. We found that different signaling pathways (from phospholipids to calmodulin, from cAMP to phosphoinositides) converge in the modulation of apical secretion. Interestingly, the common link among the different signaling pathways is their ability to modify Ca^{2+} levels thus pointing to the key role of this ion in the crosstalk. A working model of how this can be achieved is discussed.

4.3.5. Variability of the actin staining pattern in pollen tubes

K. Hörmannseder[1], G. Obermeyer[1], I. Lichtscheidl[2], I. Foissner[3];
[1]University of Salzburg, Dept. Molecular Biology, Salzburg, Austria, [2]University of Vienna, Dept. Cell Imaging and Fine Structure Research, Vienna, Austria, [3]University of Salzburg, Dept. Cell Biology, Salzburg, Austria.

We investigated the cytoskeleton of pollen tubes using an improved method for actin visualization, the simultaneous fixation and staining with fluorescent phalloidin. In all pollen tubes, longitudinal actin filament bundles were present in the shank and the subapex contained more randomly oriented bundles. The actin cytoskeleton of the tip consisted either of a meshwork of randomly oriented actin strands or of longitudinally aligned actin bundles. The longitudinal bundles had a length of about 10 µm and formed a dome-like structure immediately behind the tip. In pollen tubes with apical actin meshworks mitochondria moved up to the subapex before joining the grainwards directed cytoplasmic streaming. The mitochondria of pollen tubes containing apical actin bundles migrated up to the tip. These observations and data obtained by video-enhanced contrast microscopy indicate that fine-meshed actin networks form a barrier for the movement of large organelles (but not vesicles) towards the tip. Growth rates were similar for all pollen tubes suggesting that the orientation of apical actin filaments has no significant effect on the deposition of cell wall material.

4.3.6. Making and steering the cell polarity engine in pollen

V. Zarsky[1], M. Potocky[2], F. Cvrckova[1], L. Synek[1], M. Quentin[2], D. Pickova[1], D. Ziak[2];
[1]Charles University, Prague, Czech Republic, [2]Institute of Experimental Botany ASCR, Prague, Czech Republic.

Male gametophytes of Spermatophytes are tiny organisms specialised in dry conditions survival and sexual reproduction. Siphonogamy evolved from a weeks-consuming process in some Gymnosperms to the fertilization race taking just a few hours in Angiosperms. Directionality and speed of growth are crucial parameters. Using systems of *in vitro* pollen tube cultures we are characterizing selected aspects of pollen development, especially in respect to processes potentially regulated by small GTPases of Rab and Rho families. In particular, we focus on the final steps of exocytosis, involving the exocyst complex, phospholipases D activities, and the function of formins. We have observed specific synthetic/preparatory phase before tobacco pollen tube emergence which results in the establishment of self-perpetuating tip-focused secretory machinery. We will report on data providing evidence that there are positive-feed back processes operating at the tip which are responsible for the sustained directional growth resulting eventually in a successful fertilization. Supported by GAAV CR A6038410, GACR 204/05/0268 and EU-HPRN-CT-2002-00265 TIPNET grants.

4.3.7. Pollen tube growth mutations in *Arabidopsis*

S. Bonhomme, H. Guermonprez, A. Guyon, E. Lobstein, K. Böhme, F. Nogué, P. Guerche;
INRA, Versailles, France.

Pollen tube growth inside the pistil is a key step of sexual plant reproduction, allowing the traveling male gametes to reach the waiting female oosphere and central cell. Upon hydration on the stigma, the pollen grain containing both the sperm cells germinates and elongates a tube through tip growth in the female tissues, that will target an ovule where to deliver its content. Cell biology of pollen tube polar growth is well described for a number of species, and many of the key actors have been characterized. However, the genetic control for this tip growth process remains unravelled. The development of Arabidopsis model and the increasing number of available mutant lines of this specie offer the possibility to screen for mutations leading to pollen tube growth defect, and potentially identify genes determinant for this process. We isolated two novel genes, *KINKY POLLEN* and *POKY POLLEN TUBE*, encoding proteins that are essential for normal pollen tube tip growth. The detailed study of both genes suggests that their roles might not be restricted to pollen tube elongation, but would also concern other polar growth processes.

4.4.1. The Early Evolution of Water-Conducting Cells in Vascular Plants: Integration of Paleobotanical and Neobotanical Data

W. E. Friedman;
University of Colorado, Boulder, CO, United States.

Although there is clear evidence for the establishment of terrestrial plant life by the end of the Ordovician, the fossil record indicates that land plants remained extremely small and structurally simple until the Late Silurian. Among the potential key innovations associated with this first major radiation of land plants is the evolution of tracheids, water-conducting cells defined by the presence of lignified secondary cell wall thickenings. Comparative studies of key basal (and potentially plesiomorphic) extant vascular plants, along with structural and chemical analyses of early fossil tracheophytes, are slowly beginning to yield formal hypotheses for the developmental evolution associated with establishment and early diversification of tracheids. Finally, the issue of the potential homology (or lack thereof) of tracheids with the hydroids of *Aglaophyton* and bryophyte grade plants will be discussed.

4.4.2. Diversification of the secondary xylem structure in early lignophytes

J. Galtier, **B. Meyer-Berthaud**;
UMR Botanique-AMAP- CIRAD, Montpellier, France.

The middle Devonian aneurophytalean progymnosperms are generally accepted candidates as ancestors of the earliest seed plants. Their wood is composed of rather broad tracheids with crowded bordered pits on all walls and homocellular, tall and narrow rays. Suggested evolutionary trends include: 1) a decrease in diameter of tracheids (in both arborescent archaeopteridaleans progymnosperms and pityans seed plants), 2) inversely an increase in diameter of tracheids in the other early seed plants; 3) a decrease in pit seriation in archaeopteridalean, protopityans and some early seed plants; 4) a restriction of pitting to the radial wall of tracheids in early seed plants; 5) an increase in mean width of rays in archaeopterialeans and seed plants. Some characters are rare (ray tracheids, xylem parenchyma) or so variable in the ancestral group (ray height) that their polarity is difficult to establish. To summarize, the early lignophytes, known from the Mid Devonian to the Early Carboniferous exhibit successive, apparently independent, trends in their wood structure representing as many developmental adaptations to different habits and environments.

4.4.3. Morphospaces and exploration of evolutionary phenomena in stems

M. E. Olson, J. A. Rosell;
Instituto de Biologia, Mexico, DF, Mexico.

We construct hypothetical two-parameter graphs as simple depictions of the “big picture” of the evolutionary biology of stems.

We use these "morphospaces" to direct searches for undocumented anatomical and biomechanical phenomena, and provide examples from our recent research. The axes of these morphospaces reflect common parameters such as stem construction and mechanical or conductive behavior. E.g. flexural stiffness (EI) of early ontogenetic stages on Y axis, EI of late stages on X axis. We discuss the allometry, anatomy, and biomechanical behavior of the western Mexican dry tropical forest endemic *Bursera instabilis*, an apparent example from the upper left corner of this morphospace (self-supporting when young, branches non self-supporting with age), along with comparisons of the other members of the *simaruba* clade of *Bursera* (Burseraceae). We also discuss the role of the mechanisms that permit "movement" from one area of morphospace to another (with an example of heterochrony in Moringaceae), and the forces that might be favoring such changes.

4.4.4. Homoplasy in the major trends of xylem evolution

S. J. L. Jansen[1], P. Gasson[1], P. Baas[2], F. Lens[3], P. Rudall[1];
[1]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [2]Nationaal Herbarium Nederland, Universiteit Leiden branch, The Netherlands, [3]Laboratory of Plant Systematics, K.U.Leuven, Belgium.

Once the major "Baileyan" trends in xylem evolution were established early in the last century, the apparently irreversible nature of character state transitions made systematic wood anatomy highly respected as a way of confirming or contradicting the phylogenetic position of woody plant groups. Recent insights in plant phylogeny combined with progress in understanding water transport processes in wood, have led to a more homoplasious and dynamic view of xylem evolution. There is a clear need to re-evaluate long established concepts of phylogenetic wood anatomy, which remain hampered by problems of typology and ambiguous evolutionary frameworks. More correlation between functional and comparative studies would open new ways to amplify observations of xylem physiologists by comparative inference. Future research should emphasise investigation of the genes involved in the control of key xylem characters, especially the development of perforation plates and bordered pits.

4.4.5. Inter-and intraspecific variations in the structure of intervascular and interfiber pit membranes, as observed by field-emission scanning electron microscopy

Y. Sano;
Graduate School of Agriculture, Hokkaido University, Sapporo, Japan.

Information about structural variations in the pits of angiosperm remains limited and fragmentary for a large number of species and types of pit. Thus, we have studied the structure of intervascular and interfiber pit membranes in some dicotyledonous wood by field-emission scanning electron microscopy. The intervascular pit membranes of some species consisted of thin surface layers and a dense middle layer, while no similar middle layer was detectable in the other species. In the latter type, microfibrils of some of the pit membranes were sparsely interwoven in small areas of the pit membranes and openings of up to several hundred nanometers in diameter were present in such regions. Interfiber pit membranes tended to be porous with the specialization of fiber. Pit membranes between fibers with distinctly bordered larger pits were dense, and consisted of a few layers. By contrast, pit membranes between fibers with minutely bordered smaller pits were usually porous, and layered structure was not apparent. Our observations suggest that the structure of intervascular and interfiber pit membranes is more complicated than has previously been acknowledged.

4.4.6. Efficiency *vs* safety trade-offs underlying xylem structure and function

U. G. Hacke, J. S. Sperry, J. K. Wheeler;
University of Utah, Salt Lake City, UT, United States.

Air-seeding probably occurs when air is pulled through the largest pore of pit membranes into a water-filled xylem conduit. It leads to embolized conduits and thereby reduces hydraulic and stomatal conductance. The fact that xylem is usually not more resistant than required in a specific habitat suggests that there are costs involved in developing cavitation-resistant xylem. Cohesion-driven transport requires an adequate reinforcement of conduit walls. The more negative the pressure can become in a conduit, the greater are the potential forces acting on its walls. Besides this mechanical cost of developing safe xylem, there is a hydraulic cost. We found that resistant vessels have less pit membrane area than vulnerable ones. This suggests that cavitation is caused by the rare largest membrane pore, whose average size increases with total pit area per vessel. Total pit area was correlated with vessel surface area. As a result, we observed a trade-off between vessel resistivity and cavitation resistance. The constraint on pit area and vessel surface area explains why vessels are not longer, and why pits account for c. 50% of the total xylem resistivity.

4.4.7. Embolism repair: a functional perspective

M. A. Zwieniecki, N. M. Holbrook;
Harvard University, Cambridge, MA, United States.

Stems are complex structures charged with the task of transporting water under substantial negative pressure that often leads to cavitation. The mechanism by which some plants are able to reverse cavitation and restore water flow through embolized vessels remains poorly understood. Although the process requires energy input and thus the involvement of living cells, it remains unknown how plants are able to increase the hydrostatic pressure within cavitated conduits without raising the pressure of the entire vascular system. Based on studies of *Gossypium sp.* (cotton) and *Acer rubrum* (red maple), we present data relevant to the driving force for water flow into cavitated conduits and address the time scale for such repair using in-vivo MRI observations of stems in transpiring plants. How these data help to distinguish between proposed mechanisms for embolism repair will be discussed in relation to xylem structure and function.

4.5.1. Modern evidence in regard of the S distyly supergene linkage group in *Primula*.

J. A. Richards;
University of Newcastle, Newcastle, United Kingdom.

Of 430 *Primula* species, 91% are distylous with reciprocally positioned anthers. Long-styled ('pin') individuals (*ss*) have smaller, more numerous pollen and longer stigma papillae than short-styled ('thrum') plants (*Ss*) and distyly is linked to a diallelic sporophytic incompatibility. True-breeding thrums are unknown, suggesting a thrum-linked recessive lethal. Most homostyles have a recombinational origin allowing earlier workers to propose a distyly supergene linkage group with three recombinable elements. It is now known that female recognition is independent of style and papilla length, and male recognition is independent of, and can be recombined with, the locus controlling pollen size.Dominance control for male mating type is independent of that for pollen size. Incompatibility recognition is located in at least two sites in the gynoecium, and differs between pin and thrum selfs. Male and female expressed recognition factors can be recombined, suggesting that the gene is duplicated in association with different operators. Eight recombinable elements may occur in the supergene, which may have evolved more than once within the genus.

4.5.2. Reconstructing the history of heterostyly in *Primula* and embedded genera with a 250-taxa cpDNA phylogeny

A. R. Mast[1], E. Conti[2], J. Richards[3], S. Kelso[4];
[1]Florida State University, Tallahassee, FL, United States, [2]University of Zurich, Zurich, Switzerland, [3]University of Newcastle, Newcastle, United Kingdom, [4]Colorado College, Colorado Springs, CO, United States.

Since Charles Darwin's work on distyly in *Primula* (ca. 430 spp.), the genus has played a central role in our understanding of distly's function and genetic control. In distylous species, populations maintain a genetic polymorphism that produces two flower morphs, each differing reciprocally in the position of their anthers and stigmas. We generated a 250-taxa cpDNA phylogeny with data from the matK gene, rpl16 intron, trnL/F spacer, and trnL intron for *Primula* and embedded genera (*Dodecatheon*, *Cortusa*, *Dionysia*, and *Sredinskya*) and reconstructed the history of the dimorphism and the correlated self-/intra-morph physiological incompatibility. We offer evidence that distyly arose prior to the most recent common ancestor of all extant taxa of *Primula* and that none of the 35 monomorphic taxa of *Primula* diverged prior to the origin of distyly. We consider the ramifications of this for models of the evolution of distyly that rely upon the existence of primitively monomorphic species of *Primula* (i.e., the existence of "primary homostyles").

4.5.3. Phylogenetic relationships of the heterostylous *Vitaliana primulifera* (Primulaceae)

C. J. Dixon, P. Schönswetter, G. M. Schneeweiss;
Institute of Botany, Vienna, Austria.

Although Primulaceae are a textbook example for heterostyly, its occurrence outside the largest genus *Primula* is rare. One such case is the monotypic European endemic genus *Vitaliana*, which has been separated from the homostylous genus *Androsace* mainly because of the presence of heterostyly. Previous molecular studies using nuclear ITS and plastid trnLF sequences, however, show that *Vitaliana* nests within the European *Androsace* sect. *Aretia*. A close relationship of these two groups has already been suggested by certain morphological traits and karyological data. We extended the sampling to include both more sequence data (matK, rpl16) and more accessions of *Vitaliana* to (i) pinpoint the closest relative of *Vitaliana* among the homostylous species of *Androsace* sect. *Aretia*, and (ii) to address the phylogenetic relationships of the mostly allopatric intraspecific taxa within *Vitaliana*, traditionally recognized on the subspecific level.

4.5.4. Molecular genetic analysis of the *S* locus in *Primula vulgaris*

P. M. Gilmartin, J. Li, B. Dudas, I. Manfield, M. Webster, H. Cook;
University of Leeds, Leeds, United Kingdom.

Despite intense and historical interest in the ecology, evolutionary biology and classical genetics of floral heteromorphy in *Primula vulgaris*, almost nothing is known about the molecular basis of heteromorphic flower development. In order to investigate the biological processes underpinning this classical breeding system, we have applied molecular genetic approaches to identify genes and DNA sequences located at the *Primula S* locus. These studies have identified several sequences that are tightly linked to the *S* locus and as such provide the first molecular markers for this complex locus. We have also used classical and molecular genetic analyses to study mutant phenotypes that show linkage to the *S* locus. In combination, the analysis of available mutant phenotypes, *S* locus-linked DNA sequences and recombinants has enabled us to generate a map encompassing the *S* locus. This map includes genes that flank the locus. These sequences define the boundaries of the locus and will facilitate the identification and ordering of BAC clones across this region. Recent progress towards the molecular characterisation of the *S* locus and associated genes will be presented.

4.5.5. Genetics and evolution of breeding systems in *Turnera* (Turneraceae): Using the Primulaceae as a paradigm

J. S. Shore[1], M. M. Arbo[2], A. Fernandez[2];
[1]Department of Biology, York University, Toronto, ON, Canada,
[2]Instituto de Botanica del Nordeste (UNNE-CONICET), Corrientes, Argentina.

Primula provides a valuable model for investigations of distyly. We use this model as a basis for comparison of the genetics and evolution of breeding systems in *Turnera*. Distyly is widespread in the Turneraceae and polyploidy and karyotype evolution have played significant roles in speciation in this genus. Distyly tends to breakdown to self-compatible homostyly in high polyploids, but this pattern is not absolute and may be restricted to few clades. Distyly is determined by a single Mendelian locus with two alleles. Short-styled plants are *Ss* while long-styled plants are *ss*. Homostylous species and mutants appear to be determined by an allele, S^H, at the distyly locus with the dominance relationship $S > S^H > s$. The inheritance and compatibility relationships among long-styled, short-styled, and homostylous plants, are consistent with the possibility that a linked gene complex determines distyly. Studies of the molecular basis of distyly in *Turnera* have revealed two proteins that localize to the transmitting tissue of short styles. Genetic mapping to localize distyly has revealed two genes that co-segregate with the distyly locus.

4.5.6. Ecological contexts for reproductive shifts in Primula to secondary homostyly

S. Kelso;
Colorado College, Colorado Springs, CO, United States.

The complex genetic, morphological and biochemical foundations of heterostyly have been studied with a particular focus on Primula. In secondary homostyly, a crossover within the genetic linkage enables self and intra-morph fertilization, in contrast to the obligate outcrossing enforced in the heterostylous condition. Homostyles can be rare mutants in normally heterostylous species or separate taxa with distinctive morphologies and distributions. Three models for homostyle success are presented: the diploid reproductive assurance model, the hybrid opportunist model, and the allopolyploid secondary contact model. They share ecological contexts enhanced by climatic and anthropogenic perturbation such as unreliable pollination, population fragmentation, and proximity of novel habitats or migration routes. Although successful establishment of homostyles is supported by selfing potential, some taxa show herkogamous traits that may enhance or maintain outcrossing opportunities.

4.5.7. Evolution of breeding systems and ploidy levels in *Primula* sect. *Aleuritia*, a paradigm of the secondary contact model

A. Guggisberg[1], S. Kelso[2], E. Conti[1];
[1]Institut für Systematische Botanik, Universität Zürich, Zürich, Switzerland, [2]Biology Department, Colorado College, Colorado Springs, CO, United States.

Primula sect. *Aleuritia* displays a fascinating array of breeding systems, ploidy levels, and biogeographic patterns. The observed correlation between polyploidy, homostyly, and arctic distribution has been explained by the secondary contact model. Glacial advancement during the Pleistocene caused fragmentation of diploid, heterostylous populations. As glaciers retreated, the differentiated diploid populations came into contact again and hybridized, giving origin to polyploid, homostylous taxa. To investigate this proposed model and test specific hypotheses on the origins of polyploids, we generated detailed phylogenies of *Primula* sect. *Aleuritia*, using one nuclear and five chloroplast DNA regions. In the resulting trees, the polyploid taxa did not form a monophyletic group, but originated independently from within different diploid clades, in agreement with the secondary contact model. Furthermore, our results supported conflicting relationships of most polyploids in the nuclear and chloroplast trees, as expected under the hypothesis of hybrid origins.

4.6.1. Adaptive structures of fungi as a key to the interpretation of their evolution and mechanisms of ecological and geographical distribution

M. A. Bondartseva;
V.L. Komarov Botanical Institute of RAS, Saint Petersburg, Russian Federation.

An approach is suggested according to which all systematic criteria are regarded as ecologically inert or ecologically active. The first ones are accepted as sure markers of belonging to any phylogenetic line. Ecologically active characters are determined by pattern genes and were shaped under the influence of fungus adaptation to the environment, substrate and a strict ecological niche. Winning of the space, assimilation of the new substrates, increase of competitive ability and the achievement of the best conditions for the formation and distribution of spores are the main stimuli in evolution of the adaptive structures. Phenomenon of parallel lines of development and convergence must be taken into consideration when regarding the problem. Nutritional functions of mycelium and morphological structures for spore distribution are regarded. Types of adaptive evolution in the different groups of fungi are discussed.

4.6.2. Agaricales (Basidiomycota - Fungi) species in Brazil

J. Putzke, M. T. L. Putzke;
Universidade de Santa Cruz do Sul, Santa Cruz do Sul, Brazil.

The Agaricales (Basidiomycota - Fungi) are poorly known from Brazil, despite this country as been called as having one of the greatest biodiversity in the world. The first works where carried out by European botanists but the most important work, as been that of Johannes Rick, who studied Agaricales (among other fungi) from Southern Brazil, providing description of almost 700 species and being called now as the fther of Brazilian mycology. Studying collections done in several Brazilian states since 1986 and reviewing the bibliographical data and herbaria collections, a list of the species known up to now is provided together with descriptions and illustrations to be employed in the first book on Agaricales for this country (in preparation). The data collected indicates that there are 1230 species and 137 genera known to the area. The description of 12 species new to science is provided and the new occurrence of other 16 species of Agaricales is indicated. Tricholomataceae is the family with greater number of species, followed by Agaricaceae and Cortinariaceae. The agaricobiota from neighboring countries is compared and the relationships are discussed.

4.6.3. The nordic saproxylic network

J. N. Stokland[1], **D. S. Schigel**[2];
[1]Norwegian Istitute of Land Inventory, Aas, Norway, [2]Botanical Museum, Finnish Museum of Natural History, Helsinki, Finland.

The Nordic saproxylic database has the ambitious aim to organize species-specific ecological information for all wood-inhabiting species in the Nordic region (i.e. Denmark, Finland, Norway and Sweden). One major organism group is fungi of which both Ascomycetes and Basidiomycetes are included. The other major groups are invertebrates, vertebrates, mosses and lichens. By the end of 2004, the number of species in the database is about 4000. We expect the number to approach about 7000 species during the coming years. The species-specific ecological information categorizes the association of a species to different wood qualities (decay, diameter, microhabitat, etc.). Each species is ranked according to their preferences for such host characters. The species associated to dead wood form a food web where many species have ecological relationships at higher trophical levels (through predation, parasitism, symbiosis, etc). Such species are also included in the database. The database includes information about which species that is recorded in each country and from which country the ecological data origins.

4.6.4. Molecular diversity of ectomycorrhizal and associated fungi in pine forest on serpentine soil

A. Urban[1], M. Puschenreiter[2], W. Wenzel[2], J. Strauß[3], M. Gorfer[3];
[1]Department of Systematic and Evolutionary Botany, University of Vienna, Vienna, Austria, [2]Department of Forest- and Soil Sciences, University of Natural Resources and Applied Life Sciences, Vienna, Austria, [3]Department of Applied Plant Sciences and Plant Biotechnology, University of Natural Resources and Applied Life Sciences, Vienna, Austria.

The diversity and phylogenetic composition of ectomycorrhizal and ectomycorrhiza-associated fungi in a natural forest on serpentine was explored. 14 Ectomycorrhizal fungi associated with Pinus sylvestris growing on serpentine outcops were identified, aphyllophoralean fungi and Russulaceae being dominant. Ectomycorrhiza associated fungi were assessed by cultivation and by molecular cloning, RFLP typing and sequence analysis. Species spectra of ectomycorrhiza-associated fungi assessed by cultivation and by molecular cloning were almost entirely different, the only fungus found by both methods being Phialocephala fortinii. Among the fungal clones, ascomycetes with helotialean, dothideomycetalean chaetothyromycetalean and with hypocrealean affinities were present. One clone belongs to a new fungal lineage with closest affinities to Taphrinomycetes and Orbiliomycetes (Ascomycota). The results of a screening of ectomycorrhizal samples with newly designed specific primers for mycorrhiza-associated fungi suggest that the fungal community in the ectomycorrhizosphere is structured by taxon-specific interfungal interactions.

4.6.5. Micro-fungi on rock and man-made materials - conquerors of an extreme environment

K. Sterflinger;
ACBR, Vienna, Austria.

Micro-fungi are commonly regarded as inhabitants of soil and decomposers of organic materials in nutrient rich environments. However, fungi are also found on inorganic substrata and live under oligotrophic and poikilotrophic conditions. Material surfaces including natural and man-made materials represent an ecological niche characterized by low aw, high UV-radiation and high temperatures. In temperate climatic regions the fungal community on rock and material surfaces is dominated by fungi belonging to the common soil flora, in semi arid and arid regions those fungi are unable to survive and the rock fungal community is shifting towards darkly pigmented microcolonial fungi. In soil, however, these slow-growing fungi are out-competed by rapidly rowing moulds. Due to a very similar in-situ morphology and a lack of differentiation the species diversity of microcolonial fungi was believed to be relatively low. Molecular data, however, show that there is high diversity and the number of newly described species is constantly growing.

4.6.6. Occurrence of filamentous microfungi and effects of nutrient, pH, temperature and salinity on growth of selected antarctic soil fungi from Windmill Islands

S. A. Alias;
University of Malaya, Kuala Lumpur, Malaysia.

A mycological survey was conducted during summer of 2002, 2003 and 2004 on soil samples at Windmill Island, Antarctic continent. Soil plated method was used in this study and were incubated at 4ºC. A total of 220 of soil samples were collected and these comprised of 245 strains of fungi representing 10 species of soil microfungi. These include *Antarctomyces* sp., *Aureobasidium*-like sp., *Cadophora malorum*, *Geomyces c.f. cretaceous*, *Mucor* sp., *Thelebolus* sp., *Trichosporiella* c.f. *cerebriformis*, 1 unidentified Ascomycete sp. and 2 unidentified species. Studies on the effects of nutrient, pH, temperature and salt concentration on fungal growth were carried out on selected Antarctic soil fungi. *Phoma* sp., *Aureobasidium* sp., *Thelebolus* sp. and *Antarctomyces* sp. were cultured and growth rates were compared on two media, Potato Dextrose Agar and Corn Meal Agar with different salinity, pH and temperature. The plates were incubated at 4 and 25 ºC and measurements of the colony diameter were recorded. Ultrastructure studies were carried out and occurrence of the microfungi were compared with other part of the Antarctic to discuss their mycogeographic distribution.

4.7.1. Size, distribution and phytogeographical position of the Balkan endemic flora

V. Stevanovic[1], K. Tan[2], A. Petrova[3];
[1]Institute of Botany and Botanical Garden, Belgrade, Serbia and Montenegro, [2]Institute of Biology, University of Copenhagen, Copenhagen, Denmark, [3]Institute of Botany, Bulgarian Academy of Sciences, Sofia, Bulgaria.

The project “Mapping the endemic flora of the Balkans” began in 2002. It is estimated that c. 30% (2600-2700 species and subspecies) of the total Balkan flora is endemic. 2000 taxa have been mapped, representing c. 75% of the flora; this is adequate for reliable floristic and phytogeographical analysis. The distribution is mapped using 50 x 50 km UTM squares. The maps are presented for genera and families as well as summarized for c. 2000 taxa. The type of distribution and centres of diversity for large and important groups are provided. Numerous squares (regions) have extremely high numbers of endemics and several squares have more than 100 mountain endemics. Numerous endemics are restricted to only one or two adjacent squares. Similarity indices of particular squares clearly demonstrate floristic correlations in certain Balkan regions. For each endemic taxon, the distribution of its closest relative(s) from a taxonomic section or series is provided thus indicating floristic relationships and affinities between the endemic Balkan flora and that of the surrounding regions, e.g., Turkey, Caucasus, Alps, Iberian and Apennine peninsulas and the Mediterranean.

4.7.2. Differentiation of Turk’s cap lilies in Balkan region: molecular-cytogenetic approach

E. Muratovic[1], O. Robin[2], F. Bogunic[3,1], D. Soljan[1], S. Siljak-Yakovlev[2,1];
[1]Laboratory for research and protection of endemic resources, University of Sarajevo, Faculty of Science, Department of Biology, Sarajevo, Bosnia and Herzegovina, [2]Ecologie, Evolution, Systématique, UMR CNRS 8079, Université Paris-Sud, Bat. 360, Orsay Cedex, France, [3]Faculty of Forestry, University of Sarajevo, Sarajevo, Bosnia and Herzegovina.

Taxonomical status of the Balkan endemic Turk’s cap lilies (*Lilium albanicum*, *L. bosniacum*, *L. jankae*, and *L. chalcedonicum)* is still remained unresolved. The most of these taxa are frequently included in *Lilium carniolicum* complex. We report the first data demonstrating molecular-cytogenetic differentiation among these closely related lilies. In this comparative study of four endemic taxa with *L. carniolicum,* we used fluorochrome banding for detection of GC and AT rich DNA regions, fluorescence *in situ* hybridization (FISH) to determine the number and position of 18S-5.8S-26S and 5S rDNA loci, silver staining to study NORs activity and DAPI after FISH experiment that revealed the number and position of heterochomatic bands. The genome size of these taxa, estimated by flow cytometry, were also considered. The results based on molecular-cytogenetic markers allowed distinction among these lilies on nuclear and chromosomal level and revealed a clear taxonomical differentiation within this endemic group.

4.7.3. The evolution of the Balkan flora with particular reference to Greece

A. Strid;
Göteborg Botanical Garden, Göteborg, Sweden.

The Balkan flora is predominantly of temperate origin and has Central European and Anatolian affinities. Tertiary relicts of tropical affinities include a few mountain endemics such as *Jankaea heldreichii* and some widespread woody lowland species such as *Cercis siliquastrum* and *Ficus carica*. The degree of endemism increases in a southerly direction and with increasing latitude, being highest in the mountains of Crete. The endemics are predominantly diploid. Edaphic endemism is common especially on serpentine substrate which is widespread in the mountains of NW Greece and occurs intermittently through Albania to Bosnia. The Aegean islands, which are remnants of a broad land bridge once connecting Greece with Asia Minor, have a somewhat impoverished flora. The phytogeographical subdivision of the Aegean area originally proposed by Rechinger has been largely corroborated by experimental studies of differentiation in certain species groups and also by statistical analyses of the whole flora. The Flora Hellenica Database currently holds 620.000 records and is becoming a powerful tool in biogeographical analyses.

4.7.4. The Bulgarian flora - present state and future challenges

A. Petrova, V. Vladimirov;
Institute of Botany, Bulgarian Academy of Sciences, Sofia, Bulgaria.

Intensive botanical exploration of the Bulgarian flora began in the late 19th century. The first Bulgarian flora, "Flora Bulgarica" by J. Velenovský included 2542 species and was published in 1891. This flora stimulated many Bulgarian botanists to contribute the results of their researches towards a more comprehensive, two-volume publication in 1924-25, "Flora na Balgaria" by N. Stojanov and B. Stefanov. The work enumerated 2936 species. Three later editions were issued, in 1933 (with 2957 species), 1948 (3089 species) and 1966-67 (3072 species). The first volume of a projected 12-volume, modern, critical and illustrated work, "Flora Reipublicae Popularis Bulgaricae" was published in 1963. Ten volumes have been published so far and the project continues. The flora of Bulgaria is currently estimated to comprise c. 3900 species of vascular plants. The taxonomic composition and endemism are briefly considered and the distribution of species in the different floristic regions. Contemporary major projects are presented. The problems and challenges facing the writing of the modern Flora of Bulgaria are discussed in the context of a broader Balkan perspective.

4.7.5. The distribution of Balkan endemics related to the Central European mountain element

V. Stevanovic[1], **M. Tomasevic**[1], G. Tomovic[1], K. Tan[2], A. Petrova[3];
[1]Institute of Botany and Botanical Garden, Belgrade, Serbia and Montenegro, [2]Institute of Biology, University of Copenhagen, Copenhagen, Denmark, [3]Institute of Botany, Bulgarian Academy of Sciences, Sofia, Bulgaria.

It is estimated there are 2600-2700 endemic species and subspecies in the Balkans. The origin and phylogeny of each is of particular interest. Most Balkan endemics have Mediterranean and oro-Mediterranean relatives. A small number (c. 200 taxa or 7% of the total) have distinct connections with the mountain flora of temperate Central Europe, from the Pyrenees across the Alps, N Apennines towards the Carpathians and to the Arctic. According to size and range of distribution, the related taxa can be classified as widespread (Pyrenees to Carpathians), or narrow (restricted to one mountain massif). The distribution of the endemic Balkan vicariants is mapped using 50 x 50 km UTM squares; the majority occur in the high mountains of W and C Balkans and indicate floristic links to the Alps and Carpathians, much less so to the Pyrenees. Two main groups of Central European mountain flora can be distinguished, viz., the well-differentiated and distinct vicarious species which indicate early, Tertiary connections between the Balkans and Central European mountains, and the geographical races or subspecies which indicate more recent differentiation during the Ice Age.

4.7.6. Systematics and phylogeny of *Eryngium* L. (Apiaceae, Saniculoideae)

A. Wörz[1], J. W. Kadereit[2], N. Schmalz[2];
[1]Staatliches Museum für Naturkunde Stuttgart, Stuttgart, Germany, [2]Institut für Spezielle Botanik und Botanischer Garten der Johannes Gutenberg-Universität, Mainz, Germany.

A complete revision of *Eryngium*, comprising ca. 250 species, is presented for the first time since more than 90 years. This new revision (Wörz) is based mainly on morphological and ecological characters and chromosome numbers. A new subgeneric and sectional classification based mainly on morphological characters is presented. This classification is compared with a molecular analysis (ITS, rps16) of *Eryngium* and relatives (Schmalz/Kadereit), which partly supports the classification and allows some conclusions on inter- and intrageneric relationships: 1) *Eryngium* may be paraphyletic in relation to *Sanicula, Hacquetia*, and *Petagnia*. 2) The two major subgroups of *Eryngium* are the Old World subg. *Eryngium* and the (largely) New World (plus Australia) subgg. *Foetida, Fruticosa, Monocotyloidea* and *Semiaquatica*. These two clades are supported by the structure of basal leaves. These are palmate in subg. *Eryngium* (plus *Sanicula, Hacquetia, Petagnia*) but pinnate or monocotyledonoid in the remainder of *Eryngium*. In New World *Eryngium*, the basalmost lineages (subg. *Semiaquatica*) are distributed in Europe. This may suggest an Old World origin of New World *Eryngium*.

4.7.7. Evolution and taxonomy of *Veronica* in the Balkan Peninsula

D. C. Albach, M. A. Fischer;
Institute of Botany, Vienna, Austria.

With more than 6500 species of native seed plants on the Balkans and almost a third of them endemic, the Balkan Peninsula is known to be a place for diversification and formation of new species and an important source for colonization after the ice ages. One plant group, which is very species-rich on the Balkan Peninsula, is the genus *Veronica* (Plantaginaceae s. l.). Our current estimate for species diversity of the genus in Europe shows that 55 of 70 species in Europe occur on the Balkan Peninsula with 20 of them (sub-)endemic there. This shows the importance of the region for speciation in *Veronica*. Based on their distribution and that of their relatives they can be grouped in alpine, Mediterranean, eastern Steppe, Anatolian, introduced and in-situ elements. Detailed DNA-based systematic and phylogeographical analyses in *Veronica* help further demonstrate origins, patterns of diversification and centers of genetic diversity within the Balkan Peninsula for those elements. Phylogeographical analyses of two alpine species (*V. alpina*, *V. bellidioides*) and the *V. spicata*-complex (*V. sect. Pseudolysimachium*) are presented in more detail.

4.8.1. Systematics of Euphorbiaceae s.l. lineages

P. Hoffmann[1], K. J. Wurdack[2], H. Kathriarachchi[3], R. Samuel[3], M. W. Chase[4];
[1]Herbarium, Royal Botanic Gardens, Kew, Richmond, United Kingdom, [2]Department of Botany, Smithsonian Institution, Washington, DC, United States, [3]Department of Higher Plant Systematics and Evolution, Institute of Botany, University of Vienna, Vienna, Austria, [4]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Following APG II, Euphorbiaceae s.l. have been split into five families that remain more or less closely related as members of Malpighiales. Molecular data from 2-5 genes for each lineage have allowed the construction of robust generic-level phylogenetic trees that depict new relationships and necessitate revised classifications. With reference to prior s.l. classifications: Pandaceae include Acalyphoideae-Galearieae, Phyllanthaceae include Phyllanthoideae (with *Croizatia* and *Dicoelia* but excluding *Centroplacus* and Drypeteae), Picrodendraceae include Oldfieldioideae (except *Croizatia* and *Paradrypetes*), Putranjivaceae include Phyllanthoideae-Drypeteae (excluding *Lingelsheimia*), and Euphorbiaceae s.s. include the remaining uniovulate euphorbs. A recent 8-gene analysis shows Phyllanthaceae and Picrodendraceae to be well-supported sister taxa. Infrafamilially, Phyllanthaceae and Euphorbiaceae s.s. are least concordant with prior groupings. Non-molecular data support new suprageneric groups. Pollen morphology, seed coat structure, and the presence of petals and laticifers are especially important arbiters of relationships.

4.8.2. Phylogenetic relationships in *Phyllanthus* and relatives (Phyllanthaceae): Evidence from nuclear ITS and plastid *matK* sequences

H. Kathriarachchi[1], **R. Samuel**[1], P. Hoffmann[2], K. J. Wurdack[3], M. W. Chase[4];
[1]Department of Higher Plant Systematics and Evolution, Institute of Botany, University of Vienna, Vienna, Austria, [2]Herbarium, Royal Botanic Gardens, Kew, Richmond, United Kingdom, [3]Department of Botany, Smithsonian Institution, Washington, DC, United States, [4]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Phyllanthus, the largest genus of Phyllanthaceae, is a taxonomically challenging group due to the high species number (c. 850; including many pantropical weeds) paired with minute unisexual flowers. Webster’s current classification is mainly based on architecture, pollen and floral morphology. Our previous molecular studies have shown *Phyllanthus* to be paraphyletic, with *Breynia*, *Glochidion*, *Reverchonia*, and *Sauropus* (totalling a further c. 450 species) embedded. This more detailed study analyses ITS and *matK* sequence data of over 100 species, including all subgenera except *Cyclanthera* and several undescribed and hitherto unplaced groups. The resulting trees are well resolved and reveal more complex relationships than previously thought. The unique architecture (‘phyllanthoid branching’) of most *Phyllanthus* taxa has been lost (and/or gained) several times independently. Subgenera *Isocladus*, *Kirganelia* and *Phyllanthus* are polyphyletic. Taxonomic divisions based on similar pollen morphology are confirmed, and related taxa share similar geographic distributions.

4.8.3. Systematics and biogeography of *Croton* and tribe Crotoneae

P. E. Berry;
University of Wisconsin-Madison, Madison, WI, United States.

Croton is the second largest genus in Euphorbiaceae and was judged by Govaerts et al. (2000) to include 1,223 valid species. Our studies have focused on using nuclear and chloroplast DNA sequence evidence to evaluate the monophyly of the group and determine relationships within the genus and within tribe Crotoneae. Based on the analysis of over 300 taxa sequenced for ITS and trnL-F, we hypothesize that the Crotoneae consists of approximately six genera, with Croton remaining monophyletic with the exception of one small group, as follows: outgroup Jatropha (Sagotia + Sandwithia)+((Astraea + Acidocroton) + (Brasilicroton + Croton)). Within Croton there is a basal trichotomy with one group comprising Moacroton, Cubacroton, C. alabamensis, and sect. Corylocroton; the second with C. megistocarpus; and the third a very large clade consisting of two New World clades and one Old World clade of Croton. Biogeographically, Crotoneae and Croton both appear to have New World origins, and Croton is so far showing a single Old World radiation.

4.8.4. Phylogenetic relationships of *Mallotus*, *Macaranga* and related genera (Euphorbiaceae): Taxonomic consequences and Afro-Asian dispersal patterns

K. K. M. Kulju, S. E. C. Sierra, S. G. A. Draisma, P. C. van Welzen;
Nationaal Herbarium Nederland, Leiden University Branch, Leiden, The Netherlands.

The paleotropical euphorb genera *Mallotus* and *Macaranga* together comprise more than 400 species. Although currently classified in separate subtribes, the morphology suggests a close relationship between them. Furthermore, previous phylogenetic analyses have placed *Macaranga* nested within *Mallotus*, implying a need for drastic nomenclatural changes. A few additional mono- or bitypic genera also closely resemble *Mallotus* and should perhaps be merged with it. Plastid (*trnL* intron and *trnLF* intergenic spacer) and nuclear (ncpGS, ITS etc.) regions were sequenced to clarify the phylogenetic relationships among these genera. A combined analysis resulted in three strongly supported main clades: 1) a basal clade comprising *Cordemoya*, Madagascan *Mallotus* species and two Asian *Mallotus* sections; 2) a *Mallotus s.s.* clade including all other *Mallotus* species plus *Trewia* and *Neotrewia*; and 3) a *Macaranga* clade. Thus, *Mallotus* and *Macaranga* can be maintained as distinct genera, if the former is re-circumscribed. The phylogeny also indicates a dispersal from Asia to Africa and Madagascar in both the *Mallotus s.s.* and the *Macaranga* clades.

4.8.5. Phylogeny and biogeography of *Acalypha* (Euphorbiaceae)

G. A. Levin[1], V. W. Steinmann[2], V. G. Sagun[3,1];
[1]Illinois Natural History Survey, Champaign, IL, United States, [2]Instituto de Ecologia, Patzcuaro, Michoacan, Mexico, [3]University of Illinois at Urbana-Champaign, Urbana, IL, United States.

Acalypha, with about 450 species, is the fourth largest genus in Euphorbiaceae s.l. Its monophyly is strongly supported by a series of reproductive morphology characters, including small brevicolporate pollen, elongate vermiform anthers, no floral disc, and laciniate styles, all of which appear to be associated with anemophily. The genus is pantropical, with a few temperate species. We sequenced ITS and *ndh*F from over 100 species to reconstruct phylogenetic relationships within the genus. DNA sequence data support the monophyly of the genus and of subgenera *Acalypha* and *Linostachys*. Most other previously recognized infrageneric taxa are not monophyletic, however, and the characters used to define them are highly homoplastic. We have yet to find morphological characters that delimit most clades supported by the DNA sequence data. The phylogenetic results suggest that although the greatest species diversity is found in the neotropics, *Acalypha* originated in Africa where the greatest morphological diversity is found, colonized Asia several times, and colonized the Americas only three times.

4.8.6. Genetic diversity and evolution in *Manihot* (Euphorbiaceae)

K. M. Olsen, B. A. Schaal;
Washington University, St. Louis, MO, United States.

Cassava (Manihot esculenta, Euphorbiaceae), is the 6th most important crop globally and serves as the as main calorie source for over 500 million of the world's poorest people. Enhancement of cassava as a food crop must rely on the genetic resources from its closest wild relatives. The evolutionary relationships between cassava, its putative wild ancestor (M. e. flabellifolia) and a closely related congener (M. pruinosa) were determined by assessing DNA sequence variation at 3 nuclear genes and 5 SSRs. Populations of the wild taxa were collected throughout their range in Brazil. Genetic variation in cassava was assessed in a representative collection of cultivars obtained from CIAT. Both the SSRs and sequence data indicate that cassava is derived from M. e. flabellifolia. Genetic variation in cassava is a subset (<20%) of that detected in M. e. flabellifolia. These data refute the longstanding hypothesis that cassava is a "compilospecies" derived from many hybridizing progenitor species. The geographic distribution of genetic variation in M. e. flabellifolia suggests that cassava was likely domesticated from southern Amazonian populations of this taxon.

4.9.1. A brief history of gymnosperms: diversity trends

J. M. Anderson;
South African National Biodiversity Institute, Pretoria, South Africa.

A comprehensive overview of gymnosperm families globally, extant and fossil, provides a new and distinctive perspective on the biodiversity trends of the group at higher taxonomic levels through their 375 million-year history. Total diversity figures are: 84 families, 37 orders, 10 classes. The 71 extinct families are based on reference whole-plant genera (with the focus on ovulate fruit), an approach dictated by the highly varying availability and grade of data on affiliated organs, and the relative rarity of microsporangiate fruit. The stratigraphic ranges of the 84 families of gymnosperm are plotted according to first and last appearance at the resolution of the geological stage. The biodiversity histogram based on these data clearly reveals four broad phases in the history of the gymnosperms: three periods of radiation and extinction, followed by an interval of stasis. The ‘Secondary radiation’ through the first 25 million years of the Triassic is clearly the most explosive and leads to the diversity heyday of the gymnosperms in the Carnian_with 30 families in 23 orders and 8 classes.

4.9.2. The Gnetales: fossils and phylogenies

C. Rydin[1,2], K. Pedersen[3], E. Friis[4], P. R. Crane[5];
[1]Stockholm University, Stockholm, Sweden, [2]Swedish Musesum of Natural History, Stockholm, Sweden, [3]University of Aarhus, Århus, Denmark, [4]Swedish Museum of Natural History, Stockholm, Sweden, [5]Royal Botanic Gardens, Kew, Richmond, United Kingdom.

The Gnetales have often been considered a small remnant of a former greater diversity, but few megafossils have been found. We have described Early Cretaceous fossils from Portugal, USA and China which share several unique features with modern *Ephedra*, such as the peculiar naked male gametophyte and papillae on the seed envelope. The paucity of information in most gene regions has resulted in a young age (8-32 Myr) for modern species in molecular dating analyses. However, the fossils are often more or less identical to modern *Ephedra* in vegetative morphology and detailed reproductive structures, and indicate that the crown group could be much older (110-127 Myr). While the relationship of *Ephedra* as sister to *Welwitschia* plus *Gnetum* is clear, the relationship of Gnetales to other seed plants is still not fully understood. We found conflicts within two chloroplast genes, and different topologies can be obtained from different substitution models and character codings. Taxon sampling error may be another problem. Seemingly well-supported, but conflicting, topologies can be obtained simply by substituting a few terminals in bayesian and parsimony analyses of *rbcL*.

4.9.3. Reassessing seed ferns in seed plant systematics, evolution and phylogeny

J. Hilton[1], R. M. Bateman[2];
[1]University of Birminhgam, Birmingham, United Kingdom, [2]The Natural History Museum, London, United Kingdom.

Seed plants first evolved in the late Devonian and include a large number of extinct groups as well as five extant lineages (cycads, ginkgos, conifers, Gnetales, and angiosperms). This presentation makes a holistic assessment of seed plant relationships, evolution and phylogeny by presenting results of a new morphological cladistic analysis of lignophytes (seed plants plus their progymnosperm ancestors). The analysis includes a significantly expanded taxon selection, augmented by reassessments of the individual anatomical, morphological and developmental characters used. Results show the importance of seed ferns in determining the higher level relationships within seed plants, and emphasise the importance of seed ferns for the origins of extant seed plant lineages. Results place the extinct seed plant *Caytonia* as sister to angiosperms, and shows conifer to be monophyletic and to exclude Gnetales. Taxon selection is demonstrated to have a profound effect on the topologies generated by the analysis, and highlights the need for further whole plant reconstructions from fossil data to fill known gaps in fossil record of seed plants.

4.9.4. Systematics of the most ancient conifers

G. R. Hernandez-Castillo[1], R. A. Stockey[1], G. W. Rothwell[2], G. Mapes[2];
[1]University of Alberta, Edmonton, AB, Canada, [2]Ohio University, Athens, OH, United States.

Conifers play a central role in seed plant phylogeny but phylogenetic relationships of living and fossil conifers are unresolved. Recent studies have cast serious doubts on the hope that deep branches within seed plants, can be resolved using only living species. The fossil record of the most ancient conifers (Upper Paleozoic) is most often characterized by fragmentary branching systems, that do not allow us (1) to assign newly described specimens to a species with confidence, or (2) to score enough characters to conduct phylogenetic analyses. New whole plant reconstructions from the Hamilton Quarry, Kansas have been used in cladistic analyses of morphological characters, and these support some of the previously proposed relationships among the most primitive conifers and other Paleozoic coniferophytes. However, they question the validity of all previously proposed families for walchian conifers. This whole plant approach suggests the need for a complete systematic reevaluation of the most ancient conifers and their relationships to conifer families with living species.

4.9.5. A phylogeny of *Cycads* (Cycadales) inferred from chloroplast *matK* gene, *trnK* intron, and nuclear rDNA ITS region

S. Chaw[1], T. W. Walters[2], C. Chang[1], S. Hu[1], S. Chen[1];
[1]Research Center for Biodiversity, Taipei, Taiwan Republic of China, [2]Montgomery Botanical Center, Miami, FL, United States.

Phylogenetic relationships among the 3 families and 12 living genera of cycads were reconstructed using three markers: the chloroplast *matK* gene and *trnK* intron and the nuclear *ITS/5.8S rDNA* sequence. All datasets indicate that Cycadaceae is remotely related to other cycads, in which *Dioon* was resolved as the basal-most clade, followed by *Bowenia* and a clade containing the remaining 9 genera. *Encephalartos* and *Lepidozamia* are closer to each other than to *Macrozamia*. The African genus *Stangeria* is embedded within the New World subfamily Zamiodeae. Therefore, *Bowenia* is an unlikely sister to *Stangeria*, contrary to the view that they form the Stangeriaceae. The generic status of *Dyerocycas* and *Chigua* is unsupportable as they are paraphyletic with *Cycas* and the *Zamia*, respectively. Nonsense mutations in the *matK* gene and indels in the other two datasets lend evidence to reinforce the above conclusions. According to the phylogenies, past geography of the genera of cycads and the evolution of character states are hypothesized and discussed. Re-delimitations of Zamiaceae, Stangeriaceae, subfamily Encephalartoideae and subtribe Macrozamiineae are necessary.

4.9.6. Evolution of female cones of extant conifers - Conflicting data from morphological and molecular studies?

M. Mundry, A. Jagel, I. Mundry, C. Schulz, T. Stützel;
Spezielle Botanik, Bochum, Germany.

In spite numerous cladistic analyses that try to resolve the phylogeny of conifers and to find the origin of this group, a convincing model of this group is still lacking. Moreover recent molecular studies based on several genes, support topologies, which seem to be in conflict with morphological analyses. Crucial for the reconstruction of conifers phylogeny is the interpretation of the ovuliferous dwarft-shoot of the female cones. Although it is generally accepted that the female cones of the conifers represent compound structures, a convincing model of the evolution of the different cones in the extant groups is still lacking. Based on our investigation on the female cones of extant conifers, we discuss the critical boundary of „homology“ in respect to the female cones of conifers. We believe that it is fundamentally for reliable cladistic analyses to define frame homologies and detail homologies to avoid topologies that are based on the summation of analogisms. We present alternative scenarios for the evolution of the female cones of the conifers and illustrate that the woody cone was evolved at least twice.

4.9.7. Molecular control of seed cone development in Norway spruce (*Picea abies*)

A. Carlsbecker, F. Vergara-Silva, A. Vazquez-Lobo, L. Izquierdo, J. Sundström, K. Tandre, P. Engström;
Evolutionary Biology Centre, Uppsala University, Sweden.

We have shown that MADS-box C-type genes are expressed in the ovuliferous scale of the female cone, and together with B-type genes in the microsporophylls of the male cone. In the ABC-model of flower development C-gene expression results in pistil and C together with B expression in stamen development. Hence, our data indicates that, despite great morphological and evolutionary divergence between the cone and the flower, common genetic pathways regulate reproductive organ development in angiosperms and gymnosperms. We have now performed a detailed analysis of the expression patterns of a set of MADS-box and LFY genes during the development of the female cone. Our current study corroborates previous data, but adds also putatively conifer/gymnosperm specific factors without apparent orthologues in angiosperm genomes, that may act together or parallel with the B and C-genes in cone development. Based on these expression profiles we present a model on how MADS- and LFY transcription factors may act to regulate spruce cone development.

4.10.1. The invasion of *Bromus tectorum* in North America: the role of pre-immigration evolution

R. N. Mack;
Washington State University, Pullman, WA, United States.

The annual grass Bromus tectorum L. (cheatgrass or downy brome) is one of the most widespread and destructive plant invaders in North America. As an almost exclusively cleistogamous species, the opportunity for post-immigration out-crossing and selection among new genotypes has probably been minimal. Instead this grass's continental spread and proliferation illustrates amply that invasions usually arise from multiple introduction events, each with a mixture of genotypes that are the product of random genetic sampling in different parts of the donor range(s). If out-crossing is minimal or nil, any subsequent invasion occurs through pre-adaptation. Although at least 7 genotypes (introductions) can be detected, only three are widespread. The on-going invasion in the mid-continent largely consists of the most common genotype detected in Eurasia. In striking contrast, the most destructive invasion in the arid Intermountain West has been caused by a genotype (Got-4c) that is rare or undetected east of the Rocky Mountains. The evolution that explains this grass's invasion across North America occurred before the first immigrants arrived.

4.10.2. Evaluating the role of different evolutionary forces during a biological invasion: Is natural selection enough?

L. M. Wolfe;
Georgia Southern University, Statesboro, GA, United States.

One explanation for invasiveness is that selection resulting from enemy escape favors a shift in investment from defense to traits enhancing growth and reproduction. Silene latifolia was introduced from Europe (EU) to North America (NA) approximately 200 years ago. Field studies and common garden experiments conducted in EU and NA have revealed major differences between the two continents: 1) Silene has escaped a number of specialist enemies during colonization and the resulting damage levels are lower in NA; 2) NA plants display a 'weedier' and more reproductively prolific phenotype, and; 3) NA plants invest less in defense and have lower resistance to fungal infection and fruit predation. These results are consistent with the notion that the invasive NA phenotype has evolved at the expense of defensive abilities due to altered selection pressures in enemy-free NA. Yet, while it may be parsimonious to invoke natural selection as the driving force, the presence of genetic structure in EU and certain aspects of Silene's colonization history suggest it is also important to consider the role of genetic drift in the evolution of novel phenotypes during invasion.

4.10.3. Preadaptation or adaptation - which is more important in plant invasions?

P. J. Edwards, H. Dietz;
Geobotanical Institute, Zurich, Switzerland.

Of the many plants introduced by humans into new areas, why do a few become abundant? Although there have been many attempts to find an ecological answer to this problem, no plant traits have been identified that are consistently associated with an ability to invade; indeed, many biologists now argue that the capacity of a species to adapt may be more important than any particular ecological characteristic. In this presentation, we evaluate the present state of the adaptation versus preadaptation debate. We argue that one reason for the present confusion is a failure to treat invasions as dynamic processes in which selection pressures change over time. While the initial success of a species may be due to ecological traits associated with the introduced genotypes, adaptation to changing conditions is likely to be important if the species is to expand its range and establish itself in a wider range of communities.

4.10.4. The evolutionary consequences of plant invasions

K. A. Schierenbeck;
California State University, Chico, Chico, CA, United States.

Invasive species provide ideal systems to understand evolutionary processes that determine and accompany expansion of a species. Invasions have two fundamental evolutionary consequences; they can result in rapid evolution of introduced populations, and they can promote reticulate gene flow with related taxa at the population, ecotype, or species level. It is clear that invasions can result in rapid evolution via a number of genetic mechanisms. Examples are provided for the geographic and evolutionary origin of invasive species, identification of parental genotypes involved in the formation of new invasive species, possible genetic exchanges between invasive and native species, genome evolution of invasive species compared to related non-invasive species, the molecular basis of adaptive traits that may promote invasiveness, and the importance of neutral vs. adaptive processes that have accompanied genome evolution of invasive species. The genetics of invasive species are interesting and important from an evolutionary perspective, provide an ideal context for the synthesis of ecology and genetics, and merit consideration at the management level.

4.10.5. Genetic differentiation versus morphological plasticity in Verbascum thapsus invading across an elevation gradient

S. Ansari[1], **C. C. Daehler**[1], P. Pysek[2];
[1]Department of Botany, University of Hawaii, Honolulu, HI, United States, [2]Institute of Botany, Academy of Sciences of the Czech Republic, Pruhonice, Czech Republic.

Since its introduction from Europe to Hawaii nearly a century ago, the biennial weed Verbascum thapsus (common mullien) has invaded across a broad elevation gradient, exhibiting substantial morphological and life history variation, including an unusually high frequency of fasciation. To assess the contributions of genetic differentiation and phenotypic plasticity to the observed phenotypic variation, we established field common gardens in Hawaii and Europe using seeds from seven populations collected across an elevational range of 1000 m in Hawaii. Initially, there was significant variation among populations and within populations for germination rate, rosette diameter and number of leaves. However, beyond the end of the first growing season, there were no significant differences in plant size or other morphological measures among populations, and the fasciated morphology was not heritable. By the third year, most plants surviving in Hawaii remained in the rosette stage, indicating a delayed life history. Observed morphological differences across the elevation gradient appear to be mainly due to plasticity in response to environmental conditions.

4.10.6. Evolution of life cycle in invasive plants and implications for biocontrol

H. Mueller-Schaerer[1], T. Steinger[1], U. Schaffner[2], A. Guisan[3];
[1]Ecologie et Evolution, Département de Biologie, Université de Fribourg, Switzerland, [2]CABI Bioscience, Delémont, Switzerland, [3]Département d'Ecologie et Evolution, Université de Lausanne, Switzerland.

Rapid adaptive evolution of invasive plants during the process of range expansion might also affect plant-antagonist interactions. We will specifically explore how altered selection in the new range might influence the evolution of life cycle and how this might affect subsequent biological control efficacy. Using the model species Centaurea maculosa, introduced from Central Europe into North America during the late 19th century, we will explore the hypothesis that a polycarpic habit (flower several times) may have been negatively selected by specialist herbivores in the native range, resulting in predominantly monocarpic populations (plants die after flowering), but positively selected in the introduced range where the specialist herbivores are absent. Invasive populations should, thus, be highly susceptible to introduced biocontrol herbivores and their release could reverse the presumed evolutionary shift towards a polycarpic life cycle in the introduced range. We will discuss available evidence of this hypothesis and present recently initiated collaborative studies linking biological control and evolutionary biology.

4.10.7. Interspecific hybridization between invasive and native plant species

W. Bleeker;
University of Osnabrück, Department of Systematic Botany,
Osnabrück, Germany.

It has been argued that hybridization, either between formerly isolated populations of the same species, or between invasive and native plant species, may provide a source of genetic variation leading to the evolution of increased invasiveness. During my talk I will focus on interspecific hybridization between invasive and native species in Central Europe. A quantitative estimate of how many invasive species are actually known to hybridize and the results of a case study in *Rorippa austriaca* (Brassicaceae) will be presented. *R. austriaca* is native in southeastern Europe and western Asia and invasive in Central Europe. Hybridization between *R. austriaca* and the closely related *R. sylvestris* has been analysed using molecular markers (chloroplast DNA, AFLP). This system provides the rare opportunity to analyse the effect of age on hybrid zone structure since *R. sylvestris* is native in large parts of Eurasia. In a comparative analysis of genetic variation in five different hybrid zones, older hybrid zones in the native range of *R. austriaca* showed higher degrees of admixture than young hybrid zones in the invaded range.

4.11.1. The role of plant diversity for grassland ecosystem dynamics under global change

J. F. Soussana, P. Loiseau, F. Louault, K. Klumpp, S. Fontaine, C. Picon-Cochard;
INRA, Clermont-Ferrand, France.

Grasslands are a major contributor to the biosphere - atmosphere exchange of radiatively active trace gases in Europe, with fluxes intimately linked to management practices. Plant-plant (e.g. competition and facilitation), plant-soil and plant-herbivore interactions contribute to the regulation of C and N fluxes in grassland ecosystems and mediate community and ecosystem responses to external drivers like climate and land use changes. We discuss results from long term experiments and from mesocosms, exposed or not to elevated CO_2, which show the role of above and below-ground plant functional traits for C and N cycling in semi-natural grasslands. We conclude that mechanistic models coupling community dynamics, food webs and biogeochemistry will be required to improve our understanding of global change impacts on semi-natural grasslands. Some first simulation results obtained with such a model (GEMINI) are discussed.

4.11.2. Changes in plant community structure of European grasslands in response to elevated CO_2 and management

M. B. Jones[1], F. Teyssoneyre[2], J. Soussana[2], Z. Tuba[3], B. Winkler[4], H. Harmens[5];
[1]Trinity College Dublin, Dublin 2, Ireland, [2]INRA-Agronomie, Clermont Ferrand, France, [3]Szent Istvan University, Godollo, Hungary, [4]GSF-National Research Centre for Environment and Health, Neuherberg, Germany, [5]Centre for Hydrology and Ecology, Bangor, United Kingdom.

We have tested the hypothesis that long-term exposure of mixed species communities of grassland to elevated CO_2 will result in significant changes in structure. We report on a series of experiments at six locations in Europe where we have exposed local grassland communities to elevated CO_2 in combination with management regimes of either different cutting intervals or different fertiliser inputs. Monoliths of semi-natural grasslands were exposed to elevated CO_2 for at least two whole growing seasons using mini-FACE exposure systems. We show for all the grassland communities that increased atmospheric CO_2 concentration leads to species-specific responses, which alter the plant community structure in different ways, depending upon the management provided. We conclude that the dominance and successional patterns of mixed species grasslands will be subject to gradual changes as the atmospheric CO_2 concentration rises. Also, the management applied to multi-species grasslands may need to be revised in order to maintain (or increase) herbage quality and plant diversity.

4.11.3. Identification of spatial distributed carbon sink within a grassland canopy

M. V. Marek;
Laboratory of Ecological Physiology, Institute of Systems Biology and Ecology, Academy of Sciences, Porici, Czech Republic.

Assimilatory and respiratory activity of grassland community shows distinctive spatial and temporal heterogeneity. The reason for this can be found in the different ontogeny stage of participated grass species and, more important, the spatial differentiation of plant canopy, which is responsible for different solar radiation regime within canopy. Thus, final carbon assimilatory activity of whole grassland canopy is possible sense as clusters of active or inactive assimilatory points. The basic investigation on carbon deposition within grassland canopy is based on comprehensive investigation of photosynthetic characteristic (based on gasometry and chlorophyll fluorescence measurements) of individual grass species within grassland stand. It makes possible to evaluate basic response function of assimilation to absorbed quantum yields and to temperature, respectively. The whole stand assimilatory/respiratory balance, i.e. Net Ecosystem Exchange of investigated stand, is possible to evaluate by the application of eddy covariance technique. To be able to evaluate spatial distribution of individual components of NEE the combination with remote sensing and appropriate parameters (PRI for example) is of great advance. An example of this type of spatial investigation of carbon sinks within a mountain grassland canopy is presented.

4.11.4. Net ecosystem dynamics of grasslands on different soils in Hungary

Z. Nagy[1], Z. Csintalan[1], K. Pinter[1,2], J. Balogh[1], S. Czóbel[1], S. Fóti[1], A. Juhász[1], T. Weidinger[2], Z. Tuba[1];
[1]Szent Istvan University, Godollo, Hungary, [2]Eötvös Loránd University, Budapest, Hungary.

Net ecosystem exchanges at two grassland sites have been measured by the eddy covariance technique in 2003 and 2004. At the Bugac site the vegetation is a temperate semiarid sandy grassland. At the Mátra site the vegetation is seminatural grassland on a clay soil. Management at the Bugac site is based on grazing, while in the Mátra mountains the management is partly dependent on the weather, mainly on rainfall.The two grasslands proved to be different in their drought tolerance in terms of NEE in the years of 2003 and 2004. Vegetation at the sandy grassland site started to grow earlier and showed better drought tolerance than the mountain grassland. One of the factors causing these differences is that the sandy grassland lies more to the South, so the vegetation period starts earlier, resulting in a longer growth period with optimal water supply. On the other hand the heavy soil at te mountain site, dominated by the clay fraction is characterized by worse water economy than the sandy soil. The sandy grassland prove to be a stronger sink in the wetter year (2004) than the mountain grassland, and tolerated the 2003 extreme drought also better than the mountain grassland.

4.11.5. Mediterranean grasslands under elevated carbon dioxide

A. Raschi[1], G. Lanini[1], F. Miglietta[1], F. Selvi[2], F. Vaccari[1];
[1]CNR, Firenze, Italy, [2]Università di Firenze, Firenze, Italy.

The response of natural Mediterranean grasslands to elevated atmospheric carbon dioxide concentrations was studied in different experiments done in the open, using different fumigation techniques. The effect of long term carbon dioxide enrichment on the grass species growing in a carbon dioxide spring was studied both in situ, as well as transplanting turves of the grassland community in miniFACE fumigation rings. The effect of fumigation was scarce, while a stronger effect was exerted by fertilization. Scarce effects of elevated carbon dioxide on above ground productivity were also evidenced in a grassland fumigated in situ by miniFACE rings. In this experiment, the variations of ground cover of perennial and annual species, and the changes in their phenological cycles, were also recorded. Perennial species showed some increase in ground cover, while annual species displayed a quicker phenological cycle. Yet the response was typically species-specific. Most of the examined species showed a reduction in transpiration.

4.11.6. From Mediterranean to desert ecosystems: an integrative approach for climate change research

M. Sternberg[1], K. Tielboerger[2], J. Kigel[3], P. Sarah[4], H. Lavee[4], F. Jeltsch[5], M. Koechy[6];
[1]Tel Aviv University, Tel Aviv, Israel, [2]Tuebingen University, Tuebingen, Germany, [3]The Hebrew University of Jerusalem, Rehovot, Israel, [4]Bar-Ilan University, Ramat Gan, Israel, [5]Potsdam University, Potsdam, Germany, [6]Ptsdam University, Potsdam, Germany.

We established a novel and integrative project focused on the main limiting factor driving the ecosystem functioning in desert and Mediterranean ecosystems: changes in precipitation patterns. Our multidisciplinary project employs, in addition to a natural aridity gradient, climate manipulations that intend to close the gap between descriptive and empirical research approaches, and theoretical modeling. The goals of the project are: (1) to provide empirical data for modeling and predicting ecosystem responses to climate change in an environmentally sensitive area, and (2) to obtain knowledge of the factors that control ecosystem functioning and structure in the face of global climate change. Our contribution is based on an integrative study of soil, overland-flow, vegetation and landscape processes affecting the ecosystem, combined with socio-economic methodology. Thus, a holistic approach is applied, where we assess the impact of climate changes on plant and human communities.

4.11.7. Effects of land use change on temperate seminatural grasslands

S. Czóbel[1], J. Balogh[2], Z. Nagy[1], S. Fóti[1], E. Péli[2], J. Nagy[1], O. Szirmai[2], L. Horváth[3], K. Pintér[1,4], Z. Tuba[1,2];
[1]Department of Botany & Plant Physiology, Szent István University, GödöllŖ, Hungary, [2]Plant Ecological Research Group of Hungarian Academy of Sciences, Szent István University, GödöllŖ, Hungary, [3]Hungarian Meteorological Service, Budapest, Hungary, [4]Department of Meteorology, ELTE University, Budapest, Hungary.

The specific objectives of this study were to determine the effects of different land use changes (extensive grazing, fertilization and irrigation) on the botanical and soil composition, production and greenhouse gas exchanges and to provide data for model development. Experimental work has been carried out for 3 years in two characteristic semi-natural temperate grasslands of Hungary. The selected loess steppe located in the north-central hilly part of the country (near Isaszeg) from where monoliths were transplanted to Gödöllö, while the sand grassland situated in the Hungarian Plain (around Bugac). Small grassland plots were positioned along two transects at fertilized and irrigated sites. At the Isaszeg site, mineral fertiliser was applied once a year at the beginning of the vegetation period, while top spray irrigation was operated continuously during each vegetation period at the Gödöllö site. On the plain site an area of 6 ha was fenced off from the extensively grazing cattle herd. The observed changes were strongly correlated to climatic conditions, emphasized the importance of the water regime.

4.12.1. Living inside rock - survival strategies of the lichen *Verrucaria rubrocincta* in a desert habitat

F. Bungartz[1], L. A. J. Garvie[2], T. H. Nash III[3];
[1]Botanische Staatssammlung München, München, Germany,
[2]Department of Geological Sciences, Arizona State University, Tempe, AZ, United States, [3]School of Life Sciences, Arizona State University, Tempe, AZ, United States.

The lichen *Verrucaria rubrocincta* occurs in one of the most extreme habitats of the Sonoran Desert, inside caliche plates on desert pavements. These surfaces are exposed to high solar radiation. In the summer thalli survive air temperatures regularly exceeding 40 °C. Rock surface temperatures are even more extreme; reaching 60 °C during the day, rarely falling below 30 °C at night. In the absence of precipitation, relative humidity attains a maximum c. 30 minutes after sunrise, then dropping rapidly. On average 5 to 7 days per month have rainfall; relative humidity exceeds 75% only during winter months. The endolithic anatomy can be interpreted as strategy against these extremes. The lichen deteriorates its substrate establishing entirely inside the rock simultaneously inducing biomineralization of a calcite surface. This new formation is a modification of the pseudocortex previously described from endolithic lichens. It occurs in close proximity to substrate deterioration caused by hyphae forming a pseudomedulla. Using x-ray diffraction and isotope analysis, we propose a simple model as first step towards understanding the interaction of both processes.

4.12.2. Symbiont selection in lichens with different modes of propagation

S. Wornik, M. Grube;
Karl-Franzens University Graz, Institute of Plant Sciences, Graz, Austria.

Trebouxioid algae are the most common photobionts in the large order Lecanorales. Our overall phylogeny of these photobionts and an increased sampling of lichen species provide new insights in patterns of symbiont selectivity. These data show that there are significant differences in the photobiont selectivity in different lichen species. Here we present our growing data about symbiont selectivity in *Physconia*, where we focus on the common species *Physconia distorta* and *Physconia enteroxantha*. The two species differ by their propagation mode: *Physconia distorta* is mainly fertile with ascospore dispersal, while *Physconia enteroxantha* is sterile and jointly distributes both symbionts. These species are restricted to symbiosis with *Trebouxia impressa*. We observe a higher variation of *Trebouxia impressa* in Mediterranean habitats. Haplotype networks will be presented for *Trebouxia impressa* and different photobionts in other lichens. These show the extremely wide geographic distribution of certain common algal genotypes, while others seem to be rarer or limited to certain environmental conditions.

4.12.3. Colonization strategies and symbiont selectivity of lichens on leaves

M. Grube, E. Baloch;
Institute of Plant Sciences, Karl-Franzens-University Graz, Holteigasse 6, Graz, Austria.

Finding the appropriate partner is the initial step in the life cycle of exosymbiotic associations. Thus the establishment of symbioses depends on the presence of compatible partners in more or less close vicinity of germinating propagules. The optimization of interactions between the partners and the efficiency to acquire a partner are major forces towards the evolution of symbiont selectivity patterns and diverse life history strategies. In principle, symbionts may either passively wait or actively move towards their potential partners, which are spread in the habitat. In the lichen symbiosis, algae usually lack active dispersal, whereas the fungal partners capture photobionts by diverse ways. Examples for different propagation and colonization strategies and the consequences on symbiont selectivity are discussed with examples. This will focus on lichen associations on leaves, which are an outstanding model due to their short life cycles.

4.12.4. Where does the lichen photobiont come from? II. Photobionts of the *Acarosporetum sinopicae*.

A. Beck;
Botanische Staatssammlung München, München, Germany.

Lichen fungi reproducing by spores, need to find compatible algae in order to form a new lichen thallus (re-lichenisation). Sexually reproducing lichens can only grow, where suitable photobionts are available and thus the occurring photobionts determine to some extend the composition of lichen communities. A possible source of photobionts may be free-living populations of algae (the existence of these is controversial) or parts of thalli of other lichens (e. g. vegetative diaspores, thallus fragments) which contain the compatible photobiont. To investigate possible sources of photobionts, it is necessary to know the algal partners of all lichen species occurring in the same community, because the taking over of photobionts is only meaningful, when the lichen fungi in question form lichens with the same algal species. These relations may vary between different communities and therefore, it is important to know the composition of the photobiont pool in the lichen communities. Such a photobiont composition will be discussed using light microscopical and molecular data (ITS rDNA sequencing).

4.12.5. Can culture experiments with lichen fungi and algae/cyanobacteria elucidate essential morphogenetic steps in lichen life cycles?

E. Stocker-Woergoetter;
Department of Organismic Biology, Salzburg, Austria.

Experiments to separate and recombine lichen symbionts can be considered as the “birth” of “experimental lichenology”. As most early manipulations with lichen bionts did not have success to reconstitute a fully developed thallus from its bionts (resynthesis) or to grow a lichen thallus in culture, experimental lichenology remained a nearly unexplored field for decades. With new concepts and novel methodological approaches we are able to do “case” studies in our laboratory and simulate major steps in the establishment of the lichen symbiosis. Three types of investigations will be reported: 1) How can we handle a three partite symbiosis and complex thallus morphologies under lab conditions? 2) What are the differences between the different starting “units” for re-establishing a lichen thallus by spores and algae (sexual repoduction) and by diasporas (vegetative propagation)? 3) Do aposymbiotically grown mycobionts form fruiting bodies? Is reproduction in culture induced by external factors? The presentation will give an overview both about the most successful and also the “failure” trials to reconstitute lichen life cycles under laboratory conditions.

4.12.6. Acclimation of the photobiont and mycobiont partners in the foliose lichen X*anthoria parietina* to seasonal changes in solar radiation

M. McEvoy[1], H. Vrablikova[2], K. Solhaug[1], M. Bartak[2], Y. Gauslaa[1];
[1]Norwegian University of Life Sciences, Ås, Norway, [2]Masaryk University, Brno, Czech Republic.

Xanthoria parietina (L.) Th. Fr. is a sunshine tolerant foliose lichen. We studied the capacity of both the green-algal photobiont *Trebouxia* and the mycobiont to acclimate to seasonal changes in sunlight levels. We firstly focused on the fungal partner, specifically, on the seasonal acclimation of the sun-screening orange cortical anthraquinone, parietin in a natural population. A distinct seasonal variation, with low parietin contents at winter solstice increasing two fold at summer solstice was recorded. The annual cycle is consistent with a solar radiation protective function of parietin operating also on a temporal scale. The second part studied the seasonal dynamics of various chlorophyll fluorescence parameters and xanthophyll-cycle pigments as a possible indicator of photobiont acclimation to solar radiation. The seasonal course in susceptibility to photoinhibition was also evaluated. Both parietin-free and -intact thalli were measured. Results showed that the photobiont also acclimates to seasonal solar radiation levels. Parietin-free thalli were more seasonally susceptible to photoinhibition than controls.

4.13.1. The physiological functions of nitrogenous osmolytes accumulated by higher plants subjected to osmotic stress

F. Larher, D. Gagneul, C. Deleu, A. Boucherau;
Equipe Osmoadaptation et Métabolismes de stress, Université de Rennes I, Rennes, France.

The yield lost occurring in crops submitted to drought and salinity often associated with high temperature is mainly related to the damages induced at the cell level by dehydration. Upon exposure to these environmental stresses higher plants are known to accumulate low molecular weight organic compounds. For a long time, these compounds have been supposed to behave as osmolytes contributing to the re-establisment of the turgor needed for survival and hopefully for a low growth rate. Considerable efforts have been directed over the past four decades to investigate, *via* correlative physiology and genetic engineering the contribution of osmolytes (i.e. the so-called compatible solutes) to osmotolerance of higher plants.However their physiological function(s) still remain(s) a matter of debate. This oral presentation will be devoted to the changes induced under stress conditions in specific metabolic pathways which allow accumulation of nitrogenous substances expected to participate in osmoprotection. These pathways will be evaluated in terms of cost and benefits for plant cells. In addition the relevance of the criteria used to assess the compatibility of their terminal products will be discussed. Recent findings concerning the toxicity of proline and glycine betaine, when supplied to non-stressed plants will be shown to stress that the dogmatic compatibility of these solutes remains debatable. This should be of special interest because a number of crop plants are currently being genetically modified at the level of relevant genes involved in osmolytes synthesis with the aim to improved tolerance to osmotic stress. Data suggesting that the so-called compatible solutes do not behave just as inert osmo-balancers but also as signal molecules that counteract injuries induced by osmotic stress will also be presented.

4.13.2. Hydraulic and hormonal signals are involved in plant adaptation to water stress

V. P. Kholodova, A. B. Meshcheryakov, V. V. Kusnetzov;
Timiryasev Institute of Plant Physiology, Russian Academy of Sciences, Moscow, Russian Federation.

Many stress factors affect only certain parts of plants but cell metabolism may change very rapidly in cells located far from the place of stress factor action. *Mesembryanthemum crystallinun* L., a facultative halophyte, shifts from C3-type of photosynthesis to *Crassulacean* acid metabolism (CAM) under soil drought or salinity. PEPC gene expression in leaves was induced in 4-6 hours after the decrease of water potential in rooting medium with NaCl or PEG 6000 which witnessed for CAM initiation. But at this time mass water flow from roots to aerial parts of plants was strongly limited due to reversal water potential gradient. Nevertheless, as early as in 10 min of stressor action, the sharp decrease of turgor pressure in leaf cells was registered while ABA started to accumulate there not early than in 6-9 hours. It has been concluded that hydraulic signal serves as a primary signal of inter-organ communication being followed by much slower chemical signal (ABA) under acute water stress.

4.13.3. Lipid signalling pathways differently modulates proline accumulation in *Arabidopsis thaliana* and in *Thellungiella halophila*

A. Savouré[1], M. Bordenave[1], M. Ghars[1,2], D. Lefebvre[1], A. S. Leprince[1], E. Parre[1], L. Richard[1];
[1]Laboratoire de Physiologie Cellulaire et Moléculaire des Plantes, FRE 2846 CNRS, Université Pierre et Marie Curie, Paris, France,
[2]Laboratoire d'Adaptation des Plantes aux Stress Abiotiques. INRST, Hammam – Lif, Tunisia.

Accumulation of proline is a wide spread plant responses upon environmental stresses, especially drought and salinity. Despite the importance of proline accumulation in plant adaptive responses to stress and extensive knowledge on proline metabolic pathways, signalling cascades involved in the regulation of these pathways are still unclear. Our current efforts are focused on elucidating the signalling pathways involved in the regulation of proline metabolism, and understanding the role of proline accumulation in whole-plant response to osmotic-stress tolerance in the two model species, the glycophyte, *Arabidopsis thaliana,* and the halophyte, *Thellungiella halophila*. We provide experimental evidence that positive and negative regulators are involved in the fine regulation of proline metabolism under hyperosmotic stresses. Different *Arabidopsis* mutants tagged in genes related to these signalling components are under molecular and phenotypic analysis. Our data suggests the implication of lipid signalling in the regulation of proline metabolism in *A. thaliana* and *T. halophila* but in an opposite fashion.

4.13.4. A role of the plastid compartment in age- and methyl jasmonate-induced senescence

C. Reinbothe, A. Springer;
Lehrstuhl für Pflanzenphysiologie, Bayreuth, Germany.

Senescence occurs naturally as last step of leaf development (age-induced senescence). However, it can also be induced by certain phytohormones, such as abscisic acid, brassinolides and jasmonates. Here we studied ultrastructural changes occurring in the plastid compartment in conjunction with changes in expression of plastid and nuclear genes encoding photosynthetic proteins during natural and jasmoinate-induced leaf senescence in barley. Both senescence types were characterized by a dramatic decrease in the number and size of chloroplasts per cell and a reduction in expression of photosynthetic proteins. Thylakoid disintegration was accompagnied by the formation of plastoglobuli. Our results unveil a hitherto unrecognized role of the plastid envelope in programmed organelle destruction during either senescence type and identify the envelope membranes as a source of jasmonate precursors and origin of novel signal transduction pathways.

4.13.5. Salt tolerance in plants: the ASR1 case

D. Bar-Zvi, Y. Kalifa, S. Rom, D. Scolnik, Z. Konrad;
Department of Life Sciences, Ben-Gurion University, Beer-Sheva, Israel.

Exposure of plants to salinity results in a massive change in gene expression. The role of many of these gene products is not known. It is therefore necessary to study the role of stress-induced proteins to better understand plant stress response. Tomato ASR1 is a plant specific protein, whose role could not be deduced from sequence homology. The levels of *Asr1* transcripts and ASR1 protein are transiently increased in response to salt-stress, osmotic-stress or treatment with abscisic acid. ASR1 is localized in both cytoplasm and nuclei. Purified ASR1 protein posses a sequence specific zinc-dependent DNA-binding activity. The novel DNA and zinc binding sites of ASR1, and its protein and oligomeric structure were studied. Tobacco and Arabidopsis plants over expressing ASR1 demonstrated improved salt tolerance: they had improved germination and improved survival in the presence of salt than non-transformed plants. Overexpression of ASR1 resulted in the induction of other genes under control conditions. We suggest that ASR1 protein play a role in the signal transduction pathway resulting in the alternation of gene expression upon salt- stress.

4.13.6. Adaptive cellular autophagy (ACA) as new markerof plant stress tolerance and plant diversity

Y. Zuily-Fodil;
Laboratoire d'Ecophysiologie Moléculaire, Université Paris 12 (CMC, P1), Créteil, France.

Most abiotic stresses induce water deficit in the cells. As a response, plants escape water loss. However, over long periods of water shortage, adaptation occurs at the cell level and allows plants to tolerate drought-stress. We have shown that water stress-induced cell membrane damage was correlated with the stimulation of hydrolytic activities (lipolytic and proteolytic). To study drought-induced protein catabolism, we build an experimental system responding to dosage effect that allowed us to relate our results with field drought-tolerance capacities. It includes related species of the *Fabaceae* family (*Phaseolidae* tribe) with various degrees of drought tolerance. In our experiments, cultivars are submitted to four level of controlled water stress and followed by rehydration. Results showed that water stress induced a rise in proteolytic and lipolytic activities parralleded with an increase in the expression of the corresponding genes. Tolerant plants are able to express protective genes, such as kininogen-like cystatins involved in maintenance of adequate cell catabolism to anabolism balance. On the contrary susceptible plants showed higher hydrolytic activities and lower inhibitor transcript contents leading to shortening of cell life and plant death.

4.13.7. Improvement of crop tolerance to drought and salinity: Application of biotechnology and nuclear-related techniques

R. Serraj, P. J. Lagoda;
Joint FAO/IAEA Division, Vienna, Austria.

The joint FAO/IAEA division is evaluating opportunities for using nuclear and related technologies to improve crop tolerance to abiotic stresses such as drought and salinity. An important project is currently being implemented for the identification and development of crop germplasm with superior resource use efficiency and nutritional value and adapted to harsh environments. Two coordinated research programs have been recently launched under this project dealing respectively with (i) the identification and pyramiding of mutated genes, and novel approaches for improving crop tolerance to salinity and drought, and (ii) the selection for greater agronomic water use efficiency in wheat and rice using carbon isotope discrimination under drought and saline environments. This paper reviews the recent progress made at the joint FAO/IAEA division in deciphering the complexity of drought and salinity problems and developing drought- and salt-tolerant varieties and presents future perspectives for the use of isotopes and nuclear techniques for the improvement of crop adaptation to these stresses.

4.14.1. A counterrevolution in historical biogeography: the resurrection of oceanic dispersal

A. de Queiroz;
None, Ely, NV, United States.

Geographical distributions of terrestrial or freshwater taxa that are broken up by oceans can be explained by either oceanic dispersal or vicariance. The validation of plate tectonics theory provided a global vicariance mechanism and, along with cladistic arguments for the primacy of vicariance, helped create a view of oceanic dispersal as an explanation of last resort. I review recent work that suggests that the importance of oceanic dispersal has been strongly underestimated. In particular, molecular dating of lineage divergences favors oceanic dispersal over tectonic vicariance as an explanation for disjunct distributions in a wide variety of taxa. Various other kinds of evidence also indicate unexpectedly high frequencies of oceanic dispersal. If vicariance biogeography was a revolution, we are now in the midst of a more strongly dispersalist counterrevolution. This new view implies that biotas are more dynamic and have more recent origins than had been thought. A high frequency of dispersal also suggests that a fundamental assumption of many studies -- that vicariance is a priori a more likely explanation than dispersal -- needs to be re-evaluated.

4.14.2. The influence of dispersal on neotropical biogeography

L. G. Lohmann[1], A. Graham[2], J. R. Pirani[1], R. C. Winkworth[3];
[1]Universidade de SÃ£o Paulo, SÃ£o Paulo, Brazil, [2]Missouri Botanical Garden, Saint Louis, MO, United States, [3]Yale University, New Heaven, CT, United States.

Arrival of lineages by long distance dispersal has strongly influenced the composition of the neotropical flora. However, the role of dispersal in shaping distribution patterns within the neotropics is less clear. For example, even though explanations for the disjunct distribution of seasonally dry neotropical forests favor vicariance, the floras of Central and South America appear to be linked either by population migration or dispersal. Here, we review paleoecological data and phylogenetic studies on several neotropical plant groups. In particular, Bignonieae (Bignoniaceae), the largest clade of lianas in the neotropics, occurs in many ecological zones and provides an excellent model for investigating neotropical biogeography. We use a broad-scale phylogeny and species range modeling to investigate distribution patterns in this morphologically diverse clade. These data favor a complex picture, in which dispersal and population migration have been important factors for shaping distribution patterns. Understanding the relative contribution of these different processes will require detailed phylogeographic analyses of many different groups.

4.14.3. Seed dispersal and species distributions in tropical forests today and in the future

H. C. Muller-Landau[1], **S. Wright**[2], J. Zimmerman[3], N. Beckman[1];
[1]University of Minnesota, Saint Paul, MN, United States, [2]Smithsonian Tropical Research Institute, Panama City, Panama, [3]University of Puerto Rico, San Juan, PR, United States.

Dispersal ability is expected to relate to both historical species distributions and current and future changes in these distributions in response to anthropogenic changes in habitat extent and spatial pattern. We quantify the relationship of dispersal mode and estimated dispersal distance to estimated range size among neotropical woody plant species. We then use 12 years of seed rain data within a mapped plot including primary and secondary forest to estimate and relate seed production, seed dispersal, and ability to disperse into cleared land and secondary forest for 25 Puerto Rican tree species. Further, we analyze seed rain and seedling data from protected and hunted forests in Panama to assess how hunting differentially influences dispersal of tree species varying in seed size and dispersal mode. Finally, we integrate these results with data on the relative frequencies of different dispersal characters among tropical woody plant species and with projections of the future area and distribution of intact and disturbed tropical forests to predict how seed dispersal characters and species distributions are likely to covary in the future.

4.14.4. Wind as a long-distance dispersal vehicle in the Southern Hemisphere

J. Muñoz[1], Á. M. Felicísimo[2];
[1]Real Jardín Botánico, Madrid, Spain, [2]Escuela Politécnica, Universidad de Extremadura, Cáceres, Spain.

Although Southern Hemisphere landmasses are separated by considerable oceanic barriers to biotic exchange, they share strong biotic affinities. A long-lasting debate resolves around whether these affinities are the result of past Gondwanan connections or recent long-distance dispersal events. We used global winds coverage from the NASA SeaWinds scatterometer to test whether biotic similarities of Southern Hemisphere landmasses conform better with (i) the anisotropic long-distance dispersal (LDD) hypothesis, which predicts that connection by “wind highways” increases biotic similarity, (ii) a direction-independent LDD hypothesis, which predicts that biotic similarity among sites increases with geographic proximity, or (iii) a vicariance hypothesis, which predicts that biotic similarity increases with decreasing separation time between landmasses. We find a stronger correlation between floristic and faunistic similarities and wind connectivity than with the other two hypotheses, a result that supports the idea of wind as a dispersal vehicle for many organisms in the Southern Hemisphere.

4.14.5. Interfacing paleobotanical with molecular/systematic data in biogeography

A. K. Graham;
Missouri Botanical Garden, P. O. Box 299, St. Louis, MO, United States.

Biogeography is in a transition phase in that plate tectonics, climatic change, vicariance, and dispersal are acknowledged as important for understanding patterns of distribution, while more subtle refinements are emerging from a synthesis of paleobiological and molecular data, and from a systems approach that integrates observations from seemingly unrelated disciplines. The syntheses reveal, for example, that in *Rhizophora* different histories are suggested by the fossil and preliminary molecular evidence. Both are equally valid and probably represent the typical situation as both approaches are utilized. The systems approach reveals that some African Elements in the Caribbean-South American region may have originated from increased hurricane numbers and intensity during warm intervals of the past (e.g., Paleogene, Middle Pliocene), a relationship documented by modern global warming. Full integration of paleobotanical and modern systematic evidence now requires new efforts to database the global plant fossil record.

4.14.6. Constructing biogeography: patterns of dispersal in the Southern Hemisphere

R. C. Winkworth, S. A. Smith;
Yale University, New Haven, CT, United States.

Molecular phylogenies and divergence time estimates indicate that long-distance dispersal has played an important role in shaping southern hemisphere floras. Although molecular analyses have provided many important insights into the origins of floristic similarities between Australia, New Zealand, and South America, these studies may be limited by extinction. Specifically, extinction of populations established following dispersal will confound inferences about dispersal frequency and pathways. Although uncertainty about the historical biogeography of specific lineages is always likely to remain, simulation studies may offer an important tool for understanding biogeography. Here we use a neutral biogeographic model to simulate diversification and dispersal of a lineage within a spatial scenario that represents the southern hemisphere over the last 20 my; in particular we explore whether dispersal could result in a tree topology consistent with that expected from vicariance. Our results are consistent with observations from molecular and fossil data, but also suggest novel insights into dispersal in the southern hemisphere.

4.15.1. Basic and applied plant ecology research in tropical field stations in Mexico: perspectives, challenges and opportunities.

M. Martinez-Ramos;
Centro de Investigaciones en Ecosistemas, UNAM, Morelia, Mexico.

The most urgent challenge in tropical forest research is exploring the interface between ecology and the socio-economic forces that cause ecosystem transformation and degradation. World-wide, deforestation and land use change causes the rapid loss of tropical forests with dramatic, negative consequences for biodiversity, ecosystem function, and environmental services. Biological reserves play a major role in protecting tropical forests, but alone do not ensure forest preservation. There is an urgent need to generate scientific knowledge and tropical forest management techniques that promote human well being in a context of ecological sustainability. The next step is the adoption of an interdisciplinary research approach, where the natural and social sciences join in an effort to provide the basis for sustainable forest management. Studies being conducted at Los Tuxtlas, Chamela and Chajul Field Stations in Mexico will be used to show how interdisciplinary research teams can develop scientific basis for sustainable tropical forest management.

4.15.2. Tropical forests of Asia: long-term changes in dynamics

S. J. Davies;
Center for Tropical Forest Science-Arnold Arboretum Asia Program, Cambridge, MA, United States.

Human impacts on biogeochemical processes have the potential to significantly alter the dynamics of ecological communites. For tropical rain forests, these impacts may have important consequences for the long-term sustainable utilization of forest resources, and for the long-term conservation of biological diversity. However, until recently baseline information on tropical forests in Asia had not been systematically collected. In 1985, the Center for Tropical Forest Science - Arnold Arboretum Asia Program, a joint initiative of the Smithsonian Tropical Research Institute and Harvard University, embarked on an ambitious program to monitor representative samples of tropical rain forests in South and Southeast Asia. Seven large-scale research plots have been established in five countries. These plots together include more than a million trees comprising over 2,500 tree species. In this talk, the dynamics of several forests are compared to investigate whether there are region-wide directional changes in the dynamics of Asia’s forests. The results are used to infer likely future changes in Asia’s forests.

4.15.3. Ecological studies of Australian rainforests at CSIRO’s Tropical Forest Research Centre

D. W. Hilbert, C. Margules, D. J. Metcalfe, D. Westcott;
CSIRO Tropical Forest Research Centre, Atherton, Queensland, Australia.

The Tropical Forest Research Centre (TFRC) is centrally located within the Wet Tropics Bioregion which comprises the largest extent of Australia’s tropical rainforests and associated tall open forests and swamp forests. There are approximately 30 staff and facilities to house both long and short-term students, visitors and collaborators. The centre has excellent computing, GIS and library services and includes an herbarium with the world's most comprehensive collection of Australia's tropical flora, and an arboretum containing c. 1500 trees. Ecological research includes studies of the processes and consequences of seed dispersal, climate change impacts on forests and biodiversity, and the dynamics of rainforests. The TFRC also manages 20 long-term permanent plots which cover a wide range of forest types existing across different geological facies, temperature and rainfall regimes. The talk will summarise the key results in these areas. For example, our research has highlighted the great sensitivity of tropical highland species to future climate change. It will also identify some key gaps in our understanding and opportunities for future research.

4.15.4. Successional vegetation dynamics in the Caribbean lowlands of Costa Rica

R. L. Chazdon;
University of Connecticut, Storrs, CT, United States.

To examine successional changes in vegetation dynamics and species composition of woody vegetation, we conducted annual or sub-annual censuses from 1997-2004 in four 1-ha monitoring plots in secondary forests initially 12-25 yr old. Younger stands showed dramatic changes in size class distribution and species composition. Common tree species changed dramatically in abundance within plots, reflecting high mortality of early colonizing tree species and high rates of recruitment of shade-tolerant tree and palm species. Similar trends were observed for woody seedlings; shade-tolerant palm and canopy trees increased in species richness and relative abundance due to low mortality and disproportionate recruitment of tree and palm species. Shrub and liana species generally showed poor recruitment and high mortality and populations declined over time within and across sites. Species richness of trees and palms increased in all sites. Although chronosequence studies suggest that succession in tropical forests leads to convergence in species composition, these findings are not generally supported by long-term studies within individual sites.

4.15.5. “Tropenstation La Gamba” - a field station in the species-rich lowland rain forest of Piedras Blancas National Park, Costa Rica

W. Huber, A. M. Weissenhofer;
Inst. f. Botanik, Vienna, Austria.

The “Tropenstation La Gamba”, Costa Rica, is an Austrian research station and education centre, whose aims are to contribute to the exploration and conservation of tropical forests in the neotropics. The station is situated in southeastern Costa Rica, 8°41'N - 83°13'W, at the western edge of the Piedras Blancas National Park. For detailed information see www.lagamba.at. The park area holds various types of rain forests which are among the most species-rich plant communities in Central America (up to 179 species per hectare). Special features include: • strong spatial structure at the landscape scale, that is providing numerous microhabitats and ecological niches • high annual precipitation (nearly 6000 mm), absence of a dry season • high edaphic heterogeneity and diversity of soil types • high vegetation dynamics. Analysis of the distribution patterns of the woody plants recorded in selected plots reveals a strong phytogeographical affinity to the Chocó region (coastal Colombia and adjacent Ecuador) in South America.

4.15.6. Tropical field stations and their role in scientific biodiversity research: the Kuala Belalong Field Studies Centre in Brunei (Borneo)

A. N. Muellner[1], C. M. Pannell[2], M. W. Chase[1];
[1]Royal Botanic Gardens, Kew, Surrey, United Kingdom, [2]University of Oxford, Oxford, United Kingdom.

The forests of Brunei are among the richest in the world and represent the greatest living natural resource of the country. About 80% of Brunei is under forest cover, the majority of which is undisturbed primary forest. The Kuala Belalong Field Studies Centre (KBFSC) was built in 1990 and served as a logistic base for the Brunei Rainforest Project 1991-1992, a collaborative effort between the University of Brunei Darussalam and the Royal Geographical Society as well as a number of associated institutions in the UK and other nations. Geographical and biological disciplines were brought together to describe climate, regional geology, landform processes and soils and the complexity of tropical rainforest biodiversity and ecology. This has set the course for continuing research, undergraduate training and school visits from all over the world. We present a two-year EU project on biodiversity and conservation in Meliaceae (“mahogany” family) currently underway at the Royal Botanic Gardens, Kew and involving collaboration with the Forestry Department of the Ministry of Industry and Primary Resources in Brunei, the University of Brunei Darussalam and KBFSC.

4.15.7. The dynamics of a neotropical forest: results from a 25-year study

S. P. Hubbell;
University of Georgia, Athens, GA, United States.

For the past quarter century, we have been studying the dynamics of the neotropical moist forest on Barro Colorado Island (BCI), Pamama, with the goal of testing the major hypotheses for the maintenance of alpha tree diversity in tropical rain forests. In 1980 we established a permanent 50 ha plot on BCI, in which all woody stems of free-standing trees and shrubs with a diameter of 1 cm or larger at breast height were measured, mapped, and identified to species, over 200,000 stems of more than 300 species. We have followed the individual fate of these plants for 25 years, recording growth, survival, and new recruitment. These data are supplemented with a long-term study of seed rain and seedling germination in the plot, and data on canopy height and gap dynamics. In this talk, we will summarize the principal findings concerning five major hypotheses for the maintenance of tree diversity in the BCI forest: the regeneration niche hypothesis, the intermediate disturbance hypothesis, the Janzen-Connell enemies hypothesis, the Chesson-Warner hypothesis, and the Hurtt-Pacala recruitment limitation hypothesis.

4.16.1. The significance of the tyrolean iceman for the archaeobotany of Central Europe

K. D. Oeggl;
Botanical Insitute, Innsbruck, Austria.

More than ten years of investigations on the find assemblage of the Tyrolean Iceman “Ötzi” reveal a great deal of information about the living and environment of this Neolithic man in the Alps. The palaeoethnobotany of his artefacts discloses a skilled person, well adapted to the alpine environment. Since the discovery of an arrow head in his left shoulder a strong evidence for a violent death is on hand, but still several questions are unanswered about his demise and deposition on the Tisenjoch in 3200 m altitude. Furthermore, besides the dispute about the Iceman’s personal fate, a discussion about the significance of the find assemblage for the Alpine Neolithic has started. At the moment only circum alpine settlements are well investigated and provide an analogy for the find. Archaeobotanical studies in the Alps have to be enhanced to assess the impact of the Iceman on the Alpine Neolithic.

4.16.2. Bryophytes and the iceman

J. H. Dickson[1], W. Hofbauer[2];
[1]Institue of Biomedical and Life Sciences, Glasgow G12 8QQ, United Kingdom, [2]Leopold Franzens Universitat, Innsbruck, Austria.

There are many thousands of fragments of bryophytes (mosses and liverworts) that have direct or indirect relevance to the life and times of the Iceman. The fragments range from pieces less than 1mm long (half a leaf of *Antitrichia curtipendula*) to a mass of *Neckera complanata* of leafy stems 60 mm long. Totalling more than 80 species, the fragments have been: 1. Recovered from the mineral sediments that partly filled the hollow in which the Iceman lay and from mammalian droppings found in the sediments. 2. Washed from his clothes and gear. 3. Found in preparations of his intestinal contents made for pollen counting. The interpretations of such abundant data have great importance for the elucidation of the palaeoclimate and vegetation, for the understanding of the usefulness of mosses for prehistoric people and for the deduction of the Iceman’s provenance and the details of his last journey.

4.16.3. The plant remains from the Iceman's find spot - new results on the glacier mummy’s environment

A. G. Heiss, K. Oeggl;
University of Innsbruck, Institute of Botany, Innsbruck, Austria.

Numerous plant remains recovered from the Iceman’s find spot in the Ötztal during the 1991 campaign were analysed. The material, embedded in the glacier ice for more than 5,000 years, was in an excellent state of preservation. The identified macro remains derived from different sources: - fragments of the Iceman’s artefacts, such as slivers of his wooden tools and weapons - plants adhering to the Iceman’s clothes and grass mat - local alpine vegetation at or near the discovery site - plant remains transported to the site by other human/animal activity, or by wind. The results provide further information on ecosystems and climate in the Eastern Alps during the Neolithic. The presence of alpine species from crevices and snow pocket plant communities may indicate a climate slightly milder in the Neolithic than today, supporting multi-proxy data (e.g. Patzelt 2000) on a reduced glacier extent during the Iceman’s lifetime. Furthermore, the remarkably even distribution of plant remains across the samples suggests one or more phases of less ice at the discovery site in the past. During these the ice in the gully had thawed, and the find assemblage had floated in the melting water.

4.16.4. Origin and seasonality of subfossil caprine dung from the iceman’s discovery site (Eastern Alps)

A. Schmidl, W. Kofler, K. Oeggl;
Institute of Botany, University of Innsbruck, Austria.

Macrofossil and pollen analyses of 103 caprine dung pellets from the Iceman’s discovery site at 3,200 m a.s.l. were conducted to ascertain if some derived from livestock. Such an evidence would confirm Neolithic transhumance for the inner alpine area. The proof should result from the analysis of the animal’s diet: animals grazed in anthropogenic habitats of low altitudes would indicate the presence of livestock, whereas diet consumed only in the alpine grasslands argues for game. Analogues were established by collecting modern pollen surface samples along an altitudinal transect in the area and modern caprine faeces at the discovery site over a vegetation period. Fruits and epiderms of alpine herbs occurred frequently in the subfossil samples and indicate grazing in alpine grasslands. This conclusion is supported by the ratio of arboreal to non arboreal pollen in the subfossil dung and by the comparison of the dung pollen samples with recent surface samples. The calibration with the modern dung pollen spectra reveals that the subfossil dung was deposited at the Tisenjoch in late summer.

4.16.5. Plant economy of the late 4th millenium BC cal in the Northern Alpine Foreland

S. Jacomet;
IPAS, University of Basel, Basel, Switzerland.

In Neolithic Lakeshore settlements, millions of subfossil plant remains are found, and therefore a detailed reconstruction of the economy is possible. Of the time of the Iceman, however, not very much such settlements are preserved. There are a few exceptions like the site Arbon Bleiche 3 at Lake Constance (Canton of Thurgau, Switzerland), who lasted only 15 years, from 3384 to 3370 BC (dendrochronological dating). The cultural layer of that settlement was evaluated during a multidisciplinary research project, founded by the Swiss National Foundation. The main cultivated plants were a tetraploid naked wheat, emmer and a multi-rowed barley. Beside of that, flax and opium poppy played an important role. Agricultural practices could be reconstructed with the help of weeds. Beside agriculture, gathering was very important. Botanical investigations of the ruminant dung allowed to reconstruct in detail the keeping of sheep/goat and cattle. In the lecture the most important results of the Arbon Bleiche 3 site will be presented, and compared with the spectra of other settlements of the second half of the 4th millennium BC cal.

4.16.6. Late neolithic agriculture in eastern Austria - archaeobotanical results from sites of the Jevisovice culture (3000 BC).

M. Kohler-Schneider, A. M. Caneppele;
Institute of Botany, Dept. of Integrative Biology, University of Natural Resources and Applied Life Sciences, Vienna, Austria.

Charred plant remains from huts destroyed by fire have provided first informations on late neolithic agriculture in eastern Austria. The two Jevišovice sites investigated show us that farmers around 3000 BC were relying on the use of *Hordeum vulgare* and *Triticum monococcum* as cereals with *T. dicoccum* and *Panicum miliaceum* as additional crops. *Pisum sativum* and *Lens culinaris* provided vegetable protein, *Papaver somniferum* and *Linum usitatissimum* vegetable fat. The record of *Panicum miliaceum* documents a remarkably early westward spread of this species. Among the wild plants, the occurrence of *Stipa sp., Teucrium chamaedrys, Asperula cynanchica* and *Plantago media* point to the presence of dry steppic grassland in the vicinity of the settlements, which was probably used for grazing. Woodland species were mainly represented by fruit-bearing plants growing in clearings and forest edges, reflecting both the purposeful collection of wild fruits and the growing human impact on the vegetation.

4.16.7. Diet of pile dwellers and formation of the cultural landscape south of the Alps: a case study from Slovenia

M. Jeraj[1], S. Jacomet[2];
[1]University of Wisconsin, Madison, WI, United States, [2]Institute for Prehistory and Archaeological Science IPAS, Basel University, Switzerland.

Analyses of plant remains from the Eneolithic pile dwelling Hocevarica on Ljubljana Moor, Slovenia, were performed. Seeds, fruits, macroscopic charcoal and pollen from the cultural layer were analysed. Numerous remains of nuts and berries, especially of *Quercus sp.*, *Cornus mas, Rubus fruticosus* and *Corylus avellana* demonstrate that gathering presented an important part in the economy of early settlers south of the Alps. In addition, the pollen of Cerealia, charred grains of cultivated barley (*Hordeum vulgare*) and wheat (*Triticum monococcum, T. dicoccum ssp. turgidum*), poppy seeds (*Papaver somniferum*) and seeds of Chenopodiaceae indicate early cultivation in the area. Data from Hocevarica further suggest that cleared Neolithic land was used for agriculture and pasturing, and that different wood was cut for construction and for firewood. In comparison to rather similar paleobotanical evidence from Northern Alpine lake dwelling areas, a few different taxa (e.g. *Lathyrus sativus*, *Vicia sp.*) were identified. Grape seeds (*Vitis vinifera ssp. sylvestris*), dated to about 3600-3500 cal B.C., represent the oldest remains of grapevine from Slovenia.

4.17.1. Biochemical basis for quality differences of green coffees

D. Selmar;
Institute of Plant Biology, Braunschweig, Germany.

Green coffee is obtained by either wet or dry processing of coffee fruits (*Coffea arabica*), i.e. the coffee cherries are mechanically depulped, then the residue of the pulp is degraded by fermentation and the seeds are dried, or the entire coffee cherries are dried directly. Wet processed green coffees reveal a higher quality than dried processed ones. Up to recently, the basic causales for these quality differences have not really been understood. Due to new biochemical approaches and considering that freshly harvested green coffee seeds represent viable organisms that are able to respond to their environment, a novel perspective of interference of quality with an active seed metabolism was elaborated. Two major metabolic processes are executed within the coffee seeds during post harvest treatment: germination and a stress metabolism. Their extent depends on the mode of processing and thereby determines coffee quality. These considerations are the basis to understand the generation of related quality differences and can be used to work out feasible approaches to alter the ancillary conditions of coffee processings and thus to enhance coffee quality.

4.17.2. Medicinal and aromatic plants in Bangladesh: ethnobotanical survey and identification of endangered species in the barind tract

M. B. Miah;
Institute of Biological Sciences, Rajshahi, Bangladesh.

An ethnobotanical survey has been made in the Barind tract to address the endangered medicinal plants still existing over the area. Four thousand folk medicinal practitioners were interviewed under prescribed questionnaires enquiring the uses of medicinal plants and their availability. Two hundred plants belonging to 56 families were identified, to have important medicinal values, were analyzed and categorized according to the respondent percentage. The degree of threat to the individual taxon was distributed on respondent performance following the guidelines of IUCN. Nineteen medicinal plants named as *Withania somnifera*, *Aristolochia indica*. *Hemidesmus indicas*, *Mimosa pudica*, *Curculigo orchiodes*, *Ipomoea mauritiana*, *Leea microphylla, Gloriosa superba*, *Scindapsus officinalis*, *Cassia alata*, *Tinospora cordifolia*, *Plumbago zeylanica*, *Vitex negundo*, *Asparagus recemosus*, *Andographis paniculata, Rauvolfia serpentina*, *Rauvolfia tetraphylla*, *Smilax xeylanica* and *Abrus precatorius* were determined as the endangered medicinal plants falling the highest rating score of 90% - 100%.

4.17.3. Cocoa seed fermentation: Factors influencing quality - a survey

C. Rohsius[1], D. A. Sukhar[2];
[1]Biocentre Klein Flottbek and Botanical Garden, Hamburg, Germany, [2]Cocoa Research Unit, The University of the West Indies, St. Augustine, Trinidad and Tobago.

The fermentation process of cocoa beans is of paramount importance for the formation of cocoa aroma. There are over 400 different aroma related compounds that have been identified in fermented, dried and roasted cocoa beans. The quality and quantity of these substances are influenced by different parameters such as: the conditions of fermentation and drying, genetic background as well as genotype × environment interactions (e.g. the temperature regime during the ripening process). However, without the fermentation process, no cocoa aroma precursors are formed. This paper will discuss recent findings on the influence of pulp condition, the importance of testa morphology on acetic acid diffusion into the cotyledons, and tissue acidification. The importance and influence of the seed testa on transport processes and its impact on aroma formation as it varies with the genotype will be a central point of discussion. The data presented will support the hypothesis that maternally influenced aroma precursor formation is due to biochemical precursors of the fresh seeds and on structural parameters influencing the kinetics of import and export of solutes during fermentation.

4.17.4. Could semi-desert plants used for production of bio-pharmaceuticals and needed secondary metabolite?

H. H. Hashemi sohi[1], D. Forouzan[2];
[1]NRCGEB, Tehran, Islamic Republic of Iran, [2]Agriculture Faculty, University of Tehran,, Karaj, Islamic Republic of Iran.

Considering the climate condition there is a wide region of semi desert and desert area with variety of plants that are living there. Analytical and industrial methods for extraction and identification of natural products from semi desert plant now widely used. This make a huge potential for using of these plant as a factory for production of Biopharmaceuticals. The central Iranian sector hosts the most typical vegetation of Iran's steppe and desert plant. From these, Atriplex and Artemisia cover wide area in this region. In this project we studied, introduction of Human growth hormone (hGH) by agro bacterium to these semi-desert plant (*Atriplex lentiformis*)by transient (Vacuum agro infiltration) and expression analysis of this pharmaceutical gene was done .The produced hormone was analysied by ELISA , Western and RIA assay.The produced hormone was Bioactive and has a Band in 22 Kd in western analysis.

4.17.5. Chemical relevance of the epicuticular wax of mango fruit

W. Du Plooy[1], T. Regnier[2], L. Prinsloo[3], B. M. Botha[1];
[1]Department of Chemistry and Physics, Tshwane University of Technology, Pretoria, South Africa, [2]Department of Microbiology and Plant Pathology, University of Pretoria, Pretoria, South Africa, [3]Department of Physics, University of Pretoria, Pretoria, South Africa.

High levels of solarisation in South Africa affect the development and ripening of mango fruit (*Mangifera indica* L.) during commercial production. However, the naturally dense and complex epicuticular fruit wax is an effective protective barrier. This wax occurs in two chemically identifiable layers that were characterised with Raman and IR spectroscopy. The layers develop in distinguishable stages with increasing complexity in both constituency and architecture, as found with SEM. Lenticels on the fruit surface are also lined by some of the wax fractions, with the quantity and structure dependent on the mango cultivar. A correlation was found between the amount of wax in lenticels and cultivar susceptibility to lenticel discolouration, an economically unacceptable condition. Although the trigger for development of the discolouration is uncertain, HPLC results and TEM have indicated intracellular and wall bound phenolics as the cause of visible symptoms. Fluorescence microscopy has indicated that wax in less susceptible lenticels contains phenolics. Current studies are investigating volatile compounds as a possible trigger mechanism.

4.17.6. Chemical constituents of *Salacia reticulata*

M. Terazawa[1], Y. Ueno[1], Y. Tamai[1], K. Takata[2], P. Kitin[2];
[1]Hokkaido University, Sapporo, Hokkaido, Japan, [2]Akita Prefectural University, Noshiro, Akita, Japan.

Kothala himbutu (Salacia reticulata) is woody liana, distributed in Sri Lanka and south India. The stem tissue is used for a traditional herbal medicine in Sri Lanka. Since hot water extratives from the stem reduce sugar content in blood, being effective for diabetes, the plant is valuable commercially. Mangiferin, isomangiferin, and (-)-4'-O-methyl-epi-gallocatechin were isolated and identified by spectroscopic analysis. HPLC analyses clarified the fact that almost all these compounds have been lost during the traditional drying process of the raw materials. The extraction efficiency is extremely low when the extractives are obtained after drying the material, leading economical loss in commercial activities. Chemical constituents of Salacia reticulata and the economical loss by the change of the amounts of the chemical constituents during drying the raw matrials are discussed.

5.1.1. Studying abiotic stress in plants: from gene networks to desert plants.

R. Mittler;
University of Nevada, Reno, NV, United States.

Within their natural habitat plants are subjected to a combination of different abiotic stresses. Key to plant acclimation to these conditions is a network of pathways that enables plants to mount a rapid and flexible defense response. We are using a combination of transcriptome, metabolome, and proteome profiling to study how plants acclimate to a combination of drought and heat stress. A systematic approach of characterizing mutants and transgenic plants altered in the expression of key defense and regulatory genes is in progress. Our findings suggest that the response of plants to a combination of two different abiotic stresses is distinct from the response of plants to each of the different stresses applied individually. To complement our analysis of lab-grown plants, a field study of desert plants is being conducted to test whether some of the hypotheses generated in the lab hold true for desert plants growing within their natural habitat.

5.1.2. Gene expression profiles during salt stress in poplar

M. Brinker[1], M. Brosché[2], J. Kangasjärvi[2], J. Saborowski[3], A. Cullmann[3], T. Teichmann[1], **A. Polle**[1];
[1]Institut für Forstbotanik, Georg-August-Universität, Göttingen, Germany, [2]Plant Biology, Department of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland, [3]Institut für Forstliche Biometrie und Informatik, Georg-August-Universität, Göttingen, Germany.

Among tree species, the genus *Populus* harbours a huge variety of ecotypes with different degrees of stress resistance. The species *Populus euphratica* has the ability to cope with saline environments. In order to identify genes regulated under salt stress we performed microarrays studies with arrays harbouring a unigene set (7745 ESTs) from *Populus euphratica*. These arrays were hybridized with cDNA from leaves resp. roots from salt treated *P. euphratica* plants and controls without stress treatment. Transcript levels of 135 genes were altered significantly, 86 in roots and 55 in leaves, 5 in both tissues. Based on these data we present candidate genes for the salt tolerance in poplar and formulate hypotheses about the relative importance of various physiological processes during salt stress. This work was performed with financial support of the DFG to Poplar Research Group Germany.

5.1.3. Nitric oxide induces callose formation in plant cells

R. Kartusch;
Dept. for Ecophysiology and Functional Anatomy of Plants, University of Vienna, Vienna, Austria.

If onion inner epidermal cells are incubated in a Na-nitroprusside solution (as NO-Donor), callose deposition on cell walls is observed. First small plaques are seen after 5 - 6 hours. Callose deposition continues, after 20 - 24 hours one or more, often nucleus-sized, lens shaped bodies are seen in each cell.The optimal concentration of Na-nitroprusside lies between 1.0 and 0.5 mM. The callose-inducing effect of NO is inhibited by the nitric oxide scavenger methylene blue , the calcium channels antagonists nifedipine or ruthenium red, and the non-hydrolyzable guanosine-nucleotide analogs GTP-ɔ-S and GDP-ɔ-S. The phosphodiesterase inhibitor isobutyl-methylxanthine enhanced callose formation. It is concluded, that downstream signalling involves formation of cGMP as a second messenger and activation of ion channels. Callose formation seems to be a defence mechanism against the disturbance of the cytoplasmic Ca^{2+}-balance.

5.1.4. Nitric oxide - key component of plant innate immunity

J. Durner;
GSF-National Research Center for Environment and Health, Munich/Neuherberg, Germany.

As recently as 1987, NO was widely considered to be just an air pollutant and a toxic gas. However, by 1988, the evidence was overwhelming that NO was an integral part of normal physiological function in animals. Subsequently, it was realized that plants not only respond to airborne NO but that NO was a novel messenger in plant defence signalling. Not only is it important in pathological processes but it is also a crucial player in the regulation of physiological processes including seed germination and stomatal closure. The observation that NO regulates the expression of many genes suggests that it elicits numerous physiological processes in plants. The evidence presented to date suggests that crucial players in animal NO signalling also operate in plants. These include major direct targets of NO through S-nitrosylation, and the second messengers cGMP and cADPR The major challenges ahead are to determine which of the NO-producing enzymes in plants participates in a particular physiological process, and how the correct specific response is evoked despite shared use of the NO signal.

5.1.5. Regulation of plants by herbicide safeners

R. Edwards;
University of Durham, Durham, United Kingdom.

Safeners are agrochemicals which enhance tolerance to herbicides in cereal crops by increasing the expression of protective detoxifying enzymes. The proteins concerned include the cytochrome P450 mixed-function oxidases, glutathione transferases, glucosyltransferases and ATP-binding cassette transporters. Effectively safeners are causing a specific stress response representing a co-ordinated induction of the first three phases of xenobiotic detoxification. It has recently been shown that similar enzyme induction is also shown in dicots such as *Arabidopsis thaliana* and soybean even though herbicide-safening is restricted to monocot crops . This suggests that safeners are interfering with a conserved signalling pathway of unknown function which regulates specific branches of primary and secondary metabolism in different plants. Using a combination of proteomics and metabolite profiling, progress toward defining these changes in metabolism will be presented. The objective of these studies is to develop a new paradigm as to the functions of the safening response in plants and to ultimately use this trait in biotechnological applications.

5.1.6. Lupins as model plant for translocation and long distance signalling

C. A. Atkins, P. M. C. Smith, M. Jordan, A. Mann;
University of Western Australia, Crawley, Australia.

As a potential model for studies of translocation of assimilates and nutrients, as well as signalling molecules involved in regulation of plant development, lupins are unsurpassed. From a number of species in the Genus, including *Lupinus angustifolius*, *L. albus* and *L. mutabilis*, prolonged phloem exudation permits direct collection of translocated sieve tube contents in quantities sufficient for detailed transcriptomic, proteomic and metabolomic analysis. A sound physiological basis has been established that relates xylem and phloem fluxes of solutes containing C and N, inorganic nutrients, plant growth regulators (ABA and cytokinins) and alkaloids to establishment of source/sink features and the functioning of specific organs. In addition to providing the vascular network for translocation of assimilates, phloem also provides a pathway for long-distance signalling. As well as the known plant hormones phloem exudates contain at least 200 proteins and peptides, mRNA, si and miRNAs. The potential for exploiting these features in lupin to document phloem mobile regulatory RNA signals and RNA-mediated signalling processes is significant.

5.1.7. Evaluation of natural and synthetic stimulants of plant immunity

U. von Rad[1], M. J. Müller[2], J. Durner[1];
[1]GSF - National Research Center for Environment and Health, Oberschleissheim, Germany, [2]Julius-von-Sachs-Institut fuer Biowissenschaften, Wuerzburg, Germany.

Induction of local defence as well as systemic resistance of plants is associated with transcriptional reprogramming. Here we report on defence gene induction by natural and synthetic stimulants of plant immunity. Gene expression changes in Arabidopsis thaliana were monitored in response to several plant immunity stimulants (plant activators) using an application based array representing about 750 genes involved in several aspects of plant defence and/or plant stress. The commercial plant activators Bio-S®, Neudo-Vital® and PRORADIX® have been shown to induce systemic resistance. Here, Neudo-Vital®, PRORADIX®, and Bio-S® treatment induced different patterns of salicylic acid (SA) and jasmonic acid (JA) accumulation. Rather than simply mimicking one of the known defence pathways induced by SA or JA, the response to the plant activators showed aspects of both major defence systems. A general feature was the transient activation of JA-dependent responses, combined with a much more sustained, SA-associated defence gene induction.

5.2.1. Transgenic plastids as expression factories in biotechnology

R. Bock;
Max-Planck-Institut f. Molek. Pflanzenphysiol., Potsdam-Golm, Germany.

There are considerable attractions of the plastid genome as a target for the expression of foreign genes, including (i) high level foreign protein accumulation, (ii) absence of epigenetic effects and gene silencing mechanisms, (iii) simultaneous expression of several genes linked together in an operon and (iv) lack of pollen transmission of the transgene due to maternal plastid inheritance in most crops, allaying concerns over environmental consequences of GM crop cultivation (Bock, J. Mol. Biol., 312, 425-438; Khan and Bock, Trends Biotechnol., 22, 311-318). We have recently developed a first plastid transformation system for a food crop with an edible fruit (Ruf et al., Nature Biotechnol., 19, 870-875). Transplastomic tomato plants are fertile and express foreign genes to high levels even in non-green plastids (chromoplasts) of the ripe tomato fruit. This system now paves the way to safe metabolic engineering and efficient production of nutraceuticals and biopharmaceuticals in consumable plant organs. Technological aspects, new tools for transgene expression in plastids as well as selected applications will be discussed.

5.2.2. Next generation plastid transformation technology

C. Eibl, T. J. Golds, S. Herz, S. Muehlbauer, C. Stettner, H. U. Koop;
Icon Genetics AG, Freising, Germany.

Plastid transformation presents an attractive platform for expression of recombinant proteins due to the potential of high yield, the avoidance of transgene spread via pollen and the precise insertion of transgenes by homologous recombination. We have developed expression control elements, based on the insertion of transgenes into existing plastid operons, on use of heterologous expression control elements and on N-terminal fusions. Efficiently expressed recombinant proteins include somatotropin, interferon alpha and phenyl ammonia lyase (PAL). A novel marker gene, *aph*A6, was established for selection of transplastomic lines. Use of a visible marker, based on the reactivation of artificially created mutants, facilitates selection of homoplastomic transformants. Novel transformation vectors, exploiting co-integrates, which are formed during plastid transformation, lead to automatic removal of selection markers. Using lac repressor/operator elements controlled expression of plastid transgenes can be achieved through direct induction of plastid gene transcription via an externally applied chemical signal such as IPTG.

5.2.3. Site-specific recombinases for engineering the plastid genome of higher plants

P. Maliga, K. A. Lutz, A. K. Azhagiri, M. H. Bosacchi, Z. Svab;
Waksman Institute, Rutgers University, Piscataway, NJ, United States.

We developed new tools to manipulate the tobacco plastid genome with phage site-specific recombinases. CRE is used for targeted excision of marker genes flanked by lox sites (floxed) after expressing the plastid-targeted recombinase from a nuclear gene. The gene encoding CRE may be stably integrated in the nucleus, or expressed transiently after Agroinfiltration. Transient CRE expression significantly shortens the time required to obtain a marker-free transplastomic plant and avoids going through a seed progeny to segregate away the integrated nuclear cre gene. Floxed marker genes are now incorporated in new plastid vectors so that plastid transformation and marker gene removal can be executed efficiently. INT, a second site-specific recombinase, is used to facilitate integration of transforming DNA by recombination between an attB site integrated in the plastid genome and an attP site in the vector. We now explore the feasibility of employing INT to overcome low plastid transformation efficiency in Arabisopsis thaliana, a species recalcitrant to plastid transformation.

5.2.4. Plastid transformation in the moss *Physcomitrella patens*

M. Sugita, C. Sugiura, Y. Miyata;
Nagoya University, Nagoya, Japan.

The moss *Physcomitrella patens* is widely used as a model plant because it has the highest known homologous recombination ability among land plants. We have recently succeeded in plastid transformation and demonstrated that the moss arginine tRNA-CCG gene, *trnR-CCG*, is not essential for plastid function (Sugiura and Sugita, 2004). For the targeted disruption of *trnR-CCG*, the gene was replaced with a selectable spectinomycin (spec)-resistance (*aadA*) gene cassette from pZS197 (Svab and Maliga, 1993) on a plastid gene fragment in the plasmid. The transforming plasmid DNA digests were introduced into protonema protoplasts in the presence of polyethylene glycol. The correct insertion of *aadA* into the targeted plastid genome in transformants was verified by Southern blot and PCR analyses. The spec-resistant phenotype of the transformants was confirmed to be inherited via the plastid genome. Thus, plastid transformation successfully achieved targeted gene-disruption in the moss. This will allow investigation of the molecular basis of the regulation of plastid gene expression and cost-effective production of proteins in the moss plastids.

5.2.5. Ethanol-inducible transcription of the *Ralstonia eutropha* phb operon in transplastomic tobacco and formation of polyhydroxybutyric acid (PHB)

A. G. Lössl[1,2], K. Bohmert[3], H. Harloff[4], C. Eibl[5], H. Koop[1,5];
[1]Ludwig-Maximilians-Universität München, München, Germany, [2]University of Natural Resources and Life Sciences, Vienna, Austria, [3]Metabolix Inc., U.S.A., Cambridge, MA, United States, [4]Christian-Albrechts-Universität, Kiel, Germany, [5]ICON Genetics AG, München, Germany.

Constitutive transgene expression can be accompanied by deleterious effects if gene products are harmful to the transformed plant. Constraints like growth inhibition and male sterility have been observed in plastid transformants containing the *phb* operon encoding the genes required for the production of the polyester polyhydroxybutyric acid (PHB). In order to induce PHB synthesis in tobacco in a well-timed manner, we have constructed an inducible system to regulate transcription of the *phb* operon in plastids. This system consists of a nuclear located, ethanol inducible T7RNA polymerase which is targeted to plastids harboring the *phb* operon under control of T7 regulatory elements. Following treatment with ethanol, moderate induction of PHB synthesis was found. PHB amounts reached up to 1383 ppm in dry weight and an overall background activity of 171 ppm was measured in uninduced tissues. Without ethanol application the plants developed flowers and fertile seeds. Thus, the main problem of inhibitory transgene expression was solved. Our results show that this inducible system could serve as an alternative to constitutive expression of plastid transgenes.

5.2.6. Bacteriophage T7 RNA polymerase directed regulated expression of foreign genes transformed into tobacco plastid genome

V. S. Reddy[1], H. T. Nguyen[1,2], S. Leelavathi[1];
[1]International Centre for Genetic Engineering and Biotechnology, New Delhi, India, [2]Brookhaven National Laboratory, Biology Department, 463, Upton, New York 11973-5000, NY, United States.

There is an increasing interest to express genes coding for subunit vaccines in traditionally non-medicinal plants. Such plant expressed vaccines were found to be immunogenic when administered through injection or orally. However, a critical factor that determine the success of this approach depend on high level expression of antigens in plants. We have transformed tobacco plants to overexpress Hepatitis B surface antigen (HBsAg) in chloroplasts. However, overexpression of the antigen had a profound effect on the normal growth of transplastomic plants. Such a problem was addressed through the development of an inducible expression system based on the transcription of HBsAg by T7 RNA polymerase. This was achieved by introducing HBsAg under T7-expression signals into plastid genome followed by the transformation of tetR under CaMV 35S promoter into nuclear genome. Again, the same plant was transformed with a modified T7 RNA polymerase fused with the rbcL transit peptide sequence placed under CaMV 35S promoter containing tetR binding sites into nuclear genome. Results from the new expression system will be presented.

5.2.7. Plastid transformation for the production of pharmaceutical proteins in tobacco

J. C. Gray, C. A. Newell, I. Birch-Machin, S. Tangphatsornruang, J. Badillo;
University of Cambridge, Cambridge, United Kingdom.

Plastid transformation has great potential for the high level production of foreign proteins, particularly for pharmaceutical proteins that might be used for oral vaccines. We have used the green fluorescent protein reporter gene to compare the effects of different promoters and 3' untranslated regions (UTRs) on expression in tobacco chloroplasts. Chimeric gene constructs in a pZS197-based vector have been introduced into the *rbcL-accD* intergenic region of the tobacco plastid genome following microprojectile bombardment. The tobacco plastid *rrn* promoter with the *rbcL* 5' UTR gave higher amounts of *gfp* transcripts and GFP than the tobacco *psbA* promoter and 5' UTR or the *E. coli trc* promoter. Transcripts containing the *E. coli rrnB* 3' UTR were more stable than *gfp* transcripts with the tobacco *rbcL, psbA, rpoA* or *petD* 3'UTRs. The tobacco plastid *rrn* promoter and *E. coli rrnB* 3' UTR have been used for the expression of rotavirus and HIV genes in tobacco chloroplasts. Rotavirus VP6 protein was produced at ~3% total soluble protein in young leaves, but disappeared as the leaves aged. Accumulation of rotavirus VP6 appears to be limited by protein stability in older leaves.

5.3.1. Models of phyllotaxis

C. Kuhlemeier[1], D. Reinhardt[1], E. Pesce[1], T. Mandel[1], J. Friml[2], P. Prusinkiewicz[3];
[1]Institute of Plant Sciences, Bern, Switzerland, [2]ZMIP, Tuebingen, Germany, [3]Department of Computer Sciences, Calgary, AB, Canada.

A major determinant of plant architecture is the arrangement of leaves and flowers around the stem, known as phyllotaxis. Spiral phyllotaxis is of particular interest, because the divergence angle between successive leaves approaches the golden ratio of 137.5?, and the spiral arrangements are characterized by Fibonacci numbers. Although mathematical models can recreate phyllotactic patterns, experimental support for them has largely been lacking. I will present experiments that establish the plant hormone auxin as a central regulator of phyllotaxis. These experiments provide the basis for biologically meaningful models that can guide the design of new experiments. Ultimately, models should account for all aspects of phyllotaxis, for its reiterative nature, regularity and stability, as well as for the transitions between phyllotactic systems.

5.3.2. The Arabidopsis elch mutant: Part of a new ubiquitin-dependent protein degradation pathway in plants?

S. Schellmann, M. Hülskamp;
Botanical Institute Lehrstuhl III, Cologne, Germany.

In a forward genetic screen for trichome mutants we have identified the Arabidopsis *elch* mutant. Mutant plants have multinucleate trichomes with multiple stems . The cell-cycle defect is not trichome-specific but also affects other cell types as pavement cells or hypocotyl cells. Cloning of the *ELCH* gene revealed homology to the yeast vps23 gene, which is involved in sorting of monoubiquitylated proteins into the inner vesicles of multivesicular bodies resulting in delivery of the cargo to the lumen of the yeast vacuole, where it is subsequently degraded. As its yeast counterpart, the ELCH protein can bind ubiquitin. In yeast, vps23 acts in concert with a large number of other proteins forming three complexes termed ESCRT I-III. Homologs of all ESCRT components can be found in the Arabidopsis genome. We performed a Two Hybrid analysis of the Arabidopsis ESCRT homologs and could establish an interaction network similar to the one existing in yeast involving ELCH and the other Arabidopsis ESCRT candidates. Taken together, our data suggest that a monoubiquitylation-dependent protein sorting pathway exists in plants that is involved in the regulation of the cell cycle.

5.3.3. 100 years of flowering: the pros and cons of dominant concepts

N. H. Battey;
The University of Reading, Reading, United Kingdom.

In the field of flowering, research has progressed along lines determined by a small number of dominant concepts. 'Turning points' in the field are the times when these concepts have been adopted by the research community. In this paper I shall describe these dominant concepts: where they arise, what they mean, and how they set the research agenda. I shall also describe two aspects of flowering that demonstrate how progress is made by combining data derived from different conceptual eras. One example connects floral signalling and the genetics of flowering time; the other concerns phase change. In the case of phase change, meristem fate is controlled both by the temporal expression pattern of key genes within the meristem, and by signals arriving from other parts of the plant. Its full significance will emerge as the topic of perennial flowering is explored in future research. The conclusion is that concepts are useful but if they are too dominant they inhibit not just research progress, but also synthesis of knowledge.

5.3.4. Auxin gradients as common module for plant patterning

J. Friml, P. Brewer, P. Dhonukshe, M. Michniewicz, J. Mravec, T. Paciorek, K. Ruzicka, M. Sauer, A. Vieten, J. Wisniewska;
ZMBP, Tübingen, Germany.

Plant hormone auxin is a prominent intercellular signal in plants. Directional, active, cell-to-cell transport over short distances mediates local, differential auxin distributions (gradients), required for various patterning processes, including apical-basal axis formation and organogenesis. Also growth responses to environmental cues such as light or gravity utilize a similar mechanism involving auxin asymmetric auxin distribution. Differentially expressed auxin transport facilitators of the PIN family, each with specific polar, subcellular localization form a network for auxin distribution and formation of these local gradients. The activity of PIN proteins can be regulated at the single cell level by changes in their vesicle trafficking-dependent polar targeting in response to developmental and environmental cues. Thus, this auxin distribution network, whose directional throughput is modulated by both endogenous and exogenous signals, provides, by means of mediating auxin fluxes and creating local gradients, a common mechanism for the plasticity and adaptability of plant development.

5.3.5. MicroRNA regulation of gene expression during Arabidopsis leaf development

B. Reinhart[1], N. Bao[1], A. Mallory[2], M. Jones-Rhoades[2], D. Bartel[2], M. K. Barton[1];
[1]Carnegie Institution of Washington, Stanford, CA, United States, [2]Whitehead Institute for Biomedical Research, Cambridge, MA, United States.

Organisms are patterned by the complex regulation of gene expression and activity during development. A recently discovered class of gene regulator, the microRNAs (miRNAs), consists of ~22-nucleotide noncoding RNAs that regulate gene expression by directing mRNA degradation or inhibiting productive translation. We discovered miRNAs in plants and computationally predicted their targets. Two related miRNAs, miR165 and miR166, regulate the activity of HD-ZIP III transcription factors such as *PHABULOSA* (*PHB*) and *PHAVOLUTA* (*PHV*) in patterning the adaxial and abaxial domains of the *Arabidopsis* leaf. MicroRNAs may regulate HD-ZIP III gene expression at multiple levels; miRNAs can direct degradation of the PHB mRNA but also influence the methylation state of the PHB and PHV genomic loci. We are currently exploring the roles of transcriptional and post-transcriptional regulation of HD-ZIP III gene expression in the developing leaf primordium.

5.3.6. Physiological and molecular evidence for Darwin's "brain hypothesis" ofthe plant root cap: the case for maize seedlings

H. Edelmann[1], D. Wanke[2];
[1]Botanisches Institut, 50931 Köln, Germany, [2]Zentrum für Molekularbiologie der Pflanzen, 702076 Tübingen, Germany.

Plant roots cope during their entire life with changing surroundings concerning water, nutrients, mechanical impedance, temperature, and pathogens. They perceive and process external and internal signals, thereby enabling the plant to develop optimally. Earlier studies demonstrated ethylene to interfere with root elongation growth and root hair formation. Here we investigated the relevance of the root cap in maize seedlings for ethylene-dependent growth and -root hair formation, also employing RT-PCR and GC-ethylene measurements. Cap removal prevents seedling roots to respond towards ethylene as well as towards its precursor aminocyclopropane-1-carboxylic acid (ACC). We are trying to elucidate the causal scenarios and provide evidence that root caps operate as command centres for the development of the root also affecting the shoot. They coordinate ethylene action on root-growth and -hair formation. Root caps apparently play a crucial role in determining the developmental fate of the plant by intervening with the expression and realization of signals in remote tissues; - they therefore appear to “act like the brain of one of the lower animal” (Darwin)

5.3.7. Revealing the genetic mechanisms regulating the vascular cambium and secondary growth in woody plants

A. Groover;
Institute of Forest Genetics, Pacific Southwest Research Station, USDA Forest Service, Davis, CA, United States.

Recent studies are defining the genetic mechanisms regulating secondary growth (the radial growth of woody stems). The emerging paradigm suggests that many of the key genes and mechanisms that regulate the meristematic “stem cells” of the shoot apical meristem also function in the cambium region of woody stems. I present experiments describing the cloning and characterization of the *Populus* ortholog of two key regulators of the shoot apical meristem, *SHOOTMERISTEMLESS* (STM) and *BREVIPEDICELLUS* (*BP*, also known as *KNAT1*). I show that the *Populus* orthologs of *STM* and *BP* are expressed in the cambium region, and that misexpression of these genes result in phenotypes with defects in secondary growth and wood formation. These results are discussed within the context of the evolution of secondary growth and the relationships of woody plants to one another and to herbaceous plants.

5.4.1. Observations on the History and Future of Liana Biology

F. E. Putz;
Department of Botany, University of Florida, Gainesville, FL, United States.

Although lianas play critical roles in the ecology and management of many forests, the firm foundation for liana biology provided by Darwin, Schenk, and others in the 19th Century was only sporadically reinforced by researchers until relatively recently. Although recognition of liana contributions to forest structure, composition, dynamics, and productivity has recently increased, interspecific differences among lianas are seldom reflected in community-level studies. Similarly, while interesting physiological features of climbing plants have been revealed, scaling up from autecology to community ecology remains challenging. We also still struggle to predict where lianas will proliferate and for how long they will persist, deficiencies in our knowledge that frustrate simulation modelers who recognize that forests are more than just trees. We also need to grapple with the fact that lianas are not restricted to growing upright, which makes them challenging to map, and have roots that spread more widely, grow more deeply, and colonize resource-rich patches more rapidly than those of the trees with which they so effectively compete.

5.4.2. Climbing habits in palms: South East Asia versus South America

S. Isnard;
Botanique et Bioinformatique de l'Architecture des Plantes AMAP, Montpellier, France.

Climbing growth forms have appeared several times during palm evolution in at least three out of six subfamilies. With about 650 climbing species (22 % of all palms), the climbing habit is a successful growth form in the family. Dicotyledonous lianas can show extreme changes of mechanical properties during development, often due to modifications of cambial activity. This has been reported to reduce mechanical stresses resulting from swaying or fall from the support. Without secondary growth, climbing palms must retain part of the primary vascular system viable throughout their life history. This might appear to be a significant developmental constraint. It is of much interest to know how climbing palms, often with stem diameters, heights and lengths comparable to dicotyledonous lianas, can maintain a scandent habit without secondary growth and specialized mechanical and wound-healing properties. This study focuses on the subfamilies Arecoideae (*Desmoncus*, South America) and Calamoideae (*Calamus*, South East Asia) with the objective of highlighting whether diverse origins of climbing in the family involve different “scandent strategies”.

5.4.3. Evolution of mechanical innovations and self repair in climbing plants

T. Masselter[1], T. Speck[1], N. P. Rowe[2];
[1]Botanischer Garten der Universität Freiburg, Plant Biomechanics Group, University of Freiburg, Freiburg, Germany, [2]Botany and Plant Architecture Bioinformatics, UMR 320 CNRS, Montpellier II, France.

Climbing plants have attachment organs for support and may rely on a stiff outer cortex as the main contributor for flexural stiffness of their axes. This tissue allows both stems and branches to have a long “searcher phase” and support by interlocking with other stems. However, during secondary growth the expansion of tissues can cause significant stresses and strains in cortical tissues. *Calamopitys* sp.(340 Myr) has a large parenchymatous inner cortex that can compensate these deformations so that the outer hypoderm remains intact and flexural stiffness is not reduced by secondary growth. In *Lyginopteris oldhamia* (300 Myr), the outer cortex also permits a relatively long stiff phase, which involved some degree of self-repair, but secondary growth eventually caused sloughing of the hypoderm marking a significant drop in stiffness.This development represented an improvement for the ability of the stem to resist damage via high bending and torsion stresses. Some recent lianas such as *Aristolochia macrophylla* have further evolved repair mechanisms for hypodermal steromes, enabling these plants to actively readjust their mechanical properties.

5.4.4. Secondary growth and formation of included phloem in stem of *Salacia reticulata* wight.

P. Kitin[1], K. Takata[1], M. Terazawa[2], Y. Tamai[2];
[1]Akita Prefectural University, Noshiro-shi, Japan, [2]Hokkaido University, Sapporo, Japan.

Samples of stems of Salacia reticulata were obtained at several locations in Sri Lanka, and studied by conventional light or confocal microscopy (CLSM) or SEM. The formation of successive cambia and ‘included phloem’ were analyzed in series of cross sections along portions of stems. When a stem reaches one-two centimeters in diameter, some segments of cambium cease formation of xylem and grooved xylem boundary is formed. At a further stage, a ‘successive cambial layer’ forms in the middle portion of cortex. The ‘new cambium’ produces xylem inwards and phloem outwards that separate the bark into ‘outer bark’ and ‘included phloem’. The ‘included phloem’ consists of the previously formed phloem and cortical cells that have remained at the inner side of the new cambium. Successive cambia and alternating rings of included phloem and xylem are formed during the further growth of the stem. The rings of included phloem are connected with each other and the outer phloem at younger parts of the stem. The width of outer bark remains relatively constant during the secondary thickening of stem due to regular formation of successive cambia.

5.4.5. The hydraulics and wound repair of lianas

F. W. Ewers, F. W. Telewski;
Michigan State University, East Lansing, MI, United States.

Liana stems tend to have long and wide vessels and, relative to the leaf area they supply, narrow stems. Compared to free-standing growth forms, lianas have less requirements for mechanical tissue and their stems often contain relatively large amounts of unlignified parenchyma and phloem tissue. As a result, liana stems are flexible and better able to regenerate if damaged compared to trees or shrubs. Although some lianas have positive root pressures that can serve to refill embolized vessels, most liana species do not. When hybrid poplar trees were staked, they tended to form narrower stems and wider vessels than in mechanically flexed controls. The staked stems have higher specific conductivity and lower flexural stiffness than controls. However, contrary to results reported for the liana *Toxicodendron diversilobium*, in the case of hybrid poplars staked plants had a greater Modulus of Elasticity than in flexed controls; flexing of poplar stems increased the amount of xylem but reduced the lignin content. The evolution of the liana habit may include fundamental changes in gravitropic and thigmomorphic responses, especially with regard to lignin deposition.

5.4.6. Light and development in climbing plants

F. Gallenmüller, T. Steinbrecher;
Plant Biomechanics Group, D-79104 Freiburg, Germany.

The neotropical species *Croton nuntians* occurs as juvenile, freestanding growth phases and as adult climbing growth phases. When plants of *C. nuntians* start to climb they show an accelerated growth in length, leading to the formation of long, slender and unstable stems which get entangled in the surrounding vegetation. Cross-sections of climbing stems show a transition from a dense wood type formed in early growth phases to a very different one with large vessels, as reported for many other tropical lianas. In this species the transition to the formation of the flexible wood type with large vessels does not take place simultaneously with the shift to the climbing growth phase. Plants continue to form the dense wood type for at least half a year after transition to the climbing growth phase. Light availability has a strong influence on growth, stem and wood anatomy in *C. nuntians*, but cannot be considered as the exclusive factor triggering the shift from the freestanding to the climbing growth phase. Experiments with climbing species of temperate zones have shown that a combination of shade and support has a significant influence on the growth in length of tested species.

5.4.7. Lianas and tropical forestry

M. Parren[1,2], F. Bongers[1];
[1]Forest Ecology and Forest Management (FEM), Wageningen, The Netherlands, [2]Validation of Legal Timber Programme,, Accra, Ghana.

Many tropical forests have been repeatedly logged over short felling cycles leading to a substantial loss in biomass and accordingly have given rise to a very open forest structure often aggravated by fires which penetrated them occasionally. Lianas often become gregarious having an advantage over tree seedlings and saplings as lianas hardly have to invest in supporting tissue and so can outcompete the former. Trees harvested often are infested by multiple large sized lianas causing large felling gaps, additional damage to surrounding trees and a deviation of the predicted felling direction. Not surprisingly, forest managers often see lianas as a nuisance and cutting of lianas prior to or after logging is often prescribed to reduce felling damage. Forest fires and liana cutting interventions both seem to have a long lasting effect on the liana populations in fragmented forests. However, on the longer term the numbers do not matter but the species diversity. In this presentation we will highlight some of the major aspects, illustrate them with examples from West Africa and put them in a pantropical perspective.

5.5.1. Deceptive pollination in Mediterranean orchids: past, present and future

A. Dafni;
Laboratory of Pollination Ecology, Institute of Evolution, Haifa University, Haifa, Israel.

The present contribution is an attempt to review the field along an artificial time scale.
Past: this stage includes the recognition and description of the various deception and mimicry types and the shaping of the main hypotheses; most of which are based on field observations. The basic reviews were published from 1970 to 1992. Present: 1. Experimental testing of the role of actual density dependent selection in the evolution of empty flowers including artificial adding of nectar and the study of colour morphs. 2. Fine chemical analysis of floral volatiles of ophrys accompanied with field experiments and eag to identify the attractive compounds and their role in specific attraction in relation to evolutionary pathways of the system 3. Analysis of floral coulors from the viewpoint of bees' colour perception, especially the similarity between models and
the mimic, also in relation to odour chemical analysis and odour's pattern activity in the brain of the honey bee. 4. Application of molecular techniques to reconstruct phylogenetic affinities among taxa in relation to speciation, breeding systems, isolating barriers and pollination syndromes. Future: 1. There is an urgent need to study neglected deceptive genera as: *Himantoglossum, Cephalanthera, Traunsteinera and, Serapias.* 2. There is a room for more multidisciplinary studies as: combination of morphological analysis, breeding systems, molecular genetics, colour analysis, odour analysis and behavioural experiments e.g. in the study in closely related species and in hybrids of *Ophrys, Orchis and Serapias* to elucidate processes of sympatric speciation. 3. Use of optical pattern analysis to compare the similarity between female bees and *Ophrys* in relation to male response. 4. Study of the possible adaptive value of the high variability of colour patterns (especially in *Orchis* s.l.) in relation to bee's perception and the individual plant variability.

5.5.2. Scent variation and its role in hybridisation and speciation of sexually deceptive orchids of the genus *Ophrys*

J. Stökl, M. Ayasse;
Department of Experimental Ecology, Ulm, Germany.

Ophrys orchids mimic the sex pheromones of female insects and thereby attract males for pollination. We investigated intra- and interspecific variation of pollinator attracting scent with the aim to see whether speciation is driven by changes in floral odour. In different populations within a species, the pollinator attracting compounds show only minor differences, whereas the differences are greater in compounds that do not have a function in pollinator attraction. This finding suggests a pollinator driven selection on the male attracting scent. This hypothesis is supported by our finding that *Ophrys* species with the same pollinator - independent of their phylogenetic relationship - use almost identical odour bouquets for pollinator attraction. The results of a further investigation, in which we compared the scent of hybrid swarms and sympatrically occurring *Ophry*s taxa of the *O. fusca* group, support the hypothesis that hybridisation can be a first step for speciation in sexually deceptive orchids and that speciation is probably driven by changes in floral odour. Supported by the DFG (AY 12/1-1)

5.5.3. Lying to Pinocchio: deceptive mimicry in orchids pollinated by long-proboscid flies

S. D. Johnson;
University of KwaZulu-Natal, Pietermaritzburg, South Africa.

Plants that lack floral rewards may nevertheless be attractive to pollinators if their flowers effectively mimic those of co-occurring rewarding species. This form of mimicry (floral Batesian) has evolved in several lineages within the orchid genus *Disa* and is strongly associated with specialized pollination by long-proboscid flies belonging to the families Nemestrinidae and Tabanidae. Mimicry may be especially prevalent in long-proboscid fly pollination systems because scent (a trait difficult to mimic because of its chemical complexity) appears to play little or no role in attraction of these flies. Experiments show that flies generally do not distinguish between these orchids and their models, presumably due to their closely matched spectral reflectance and morphology. The orchids thus achieve high rates of pollination when intermingled with models, and are ecologically dependent on them. Although flies do not discriminate between the orchids and their models, they probe far fewer flowers on the orchids. This behaviour is a response to the lack of nectar and effectively reduces geitonogamous self-pollination.

5.5.4. How pollination webs unravel: landscape-scale variation in pollination in a guild of oil-secreting orchids at the Cape of Africa.

A. Pauw[1], W. J. Bond[2], J. A. Hawkins[3];
[1]Stellenbosch University, Stellenbosch, South Africa, [2]University of Cape Town, Cape Town, South Africa, [3]Reading University, Reading, United Kingdom.

The diversity and composition of a community of oil-secreting orchid species (Coryciinae) was found to be related to the rate of pollination by oil-collecting bees (*Rediviva spp*.). Species diversity was positively correlated with increasing pollination rate. Species composition followed a predictable sequence. Species with high demographic dependence on pollination occurred only where the pollination rate was high. Low demographic dependence was indicated by a capacity for self-pollination or vegetative reproduction, features lacking in species with high demographic dependence on pollinators. Sharp boundaries in the distribution of oil-collecting bees were detected. These boundaries coincided with soil-type boundaries. Outside the distribution range of oil-collecting bees, populations of some oil-secreting orchid species persisted by forming massive clones, others evolved novel floral features to attract alternative pollinators or facilitate self-pollination.

5.5.5. Pollinator attraction in orchids: from molecules to evolution

F. P. Schiestl[1], J. G. Mant[1], R. Peakall[2];
[1]Geobotanical Institute, Zürich, Switzerland, [2]School of Botany and Zoology, The ANU, Canberra, Australia.

Sexually deceptive orchids mimic mating signals of female insects and attract males which pollinate the flowers in an attempted mating. Pollinator attraction is usually species-specific and mediated by the floral odor. In the Australian Chiloglottis trapeziformis, one compound attracts a thynnine wasp, the sole pollinator of this orchid. In other Chiloglottis species, similar molecules are the pollinator attracting signals. Small changes in genes encoding odor producing enzymes may thus be responsible for reproductive isolation mediated by species-specific floral odor in this genus. In the European genus Ophrys, blends of many biologically active compounds attract the bee-pollinators. In O. sphegodes and O. exaltata, we found the same active odor compounds, but in significantly different relative amounts. In these species, the different expression of genes encoding odor producing enzymes may thus be the mechanism for species-specific odor signals. In both the Australian and European system, sympatric speciation is imaginable through changes in floral odor, a signal that is linked to reproductive isolation through specific pollinator attraction.

5.5.6. Food is good but sex is better: the evolution of deceptive pollination in the tribe Diurideae (Orchidaceae)

P. H. Weston[1], M. A. Clements[2], J. O. Indsto[3], J. Mant[4], R. Peakall[4], A. J. Perkins[1];
[1]National Herbarium of New South Wales, Sydney, Australia, [2]Centre for Plant Biodiversity Research, Australian National Herbarium, Canberra, Australia, [3]Institute for Conservation Biology, University of Wollongong, Wollongong, Australia, [4]School of Botany and Zoology, Australian National University, Canberra, Australia.

A molecular phylogeny for genera of the tribe Diurideae was used as a framework for reconstructing character phylogenies for published data on reproductive attributes, including nectar production, mimetic system, breeding system and pollinator families. For some of these, results are equivocal but sexual deception has evolved independently in at least five different lineages, usually from food-mimicking ancestors. The only unequivocal evolutionary transformations from sexual deception are to autogamy and apomixis. Selective pressures that might have driven these trends will be discussed. The hypothesis of co-speciation between orchids and pollinators has been tested and rejected in the sexually deceptive genus *Chiloglottis*. Pollinator switching is the dominant mode of pollinator diversification in this genus and is probably so in other sexually deceptive clades. The genus *Diuris*, which includes both rewarding nectar producing species and deceptive food mimics, offers novel opportunities for future comparative and experimental analyses of the evolution of deceptive pollination systems.

5.5.7. Floral mimicry in Costan Rican Oncidioid orchids

M. P. Powell[1,2], M. W. Chase[1], F. Pupulin[3], J. Warner[3], V. Savolainen[1];
[1]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [2]University of Reading, Reading, United Kingdom, [3]Jardin Botanico Lankester, Cartago, Costa Rica.

Oncidioid orchids (subtribe Oncidiinae) demonstrate an extraordinary radiation, comprising over 1700, largely non-rewarding, species in tropical America and have been hypothesised to mimic oil-producing members of Malpighiaceae on the basis of floral morphology. We evaluate the role floral mimicry has played in the radiation of these orchids in Costa Rica by analyzing colour distributions and floral reflectance of sympatric plants from 32 sites, where either an oncidioid orchid, or a yellow-flowered Malpighiaceae species, was central to the site. As bees are the most common pollinators in these communities and almost certainly the pollinators of both Malpighiaceae and oncidioid orchids, we measured floral colour reflectance from 300-700nm to conduct the study. Preliminary analyses of the data indicate that two principal types of orchid mimicry are in operation: (i) oncidioid orchids of the genera *Oncidium* and *Erycina* reflect both yellow and ultra-violet light, a characteristic shared with some yellow-flowered Malpighiaceae; and (ii) other oncidioid orchids tend to converge on the rest of the community without displaying any unique differences.

5.6.1. It is not just a flora anymore

W. L. Wagner[1,2];
[1]Botany Department, Smithsonian Institution, Washington, DC, United States, [2]National Tropical Botanical Garden, Kalaheo, HI, United States.

We live in a time of unprecedented loss of biodiversity and global homogenization. With funding for exploration, description, and a refined understanding of species being a low global priority, traditional approaches to writing floras are no longer adequate. Therefore, we need to find more efficient methods to increase productivity. We must develop an internet-based system to reduce the high level of redundancy in floristic and monographic work, in which descriptions and other detailed (including phylogenetic) information on species, genera, etc., are written into an online database and made available for online and paper-based flora projects, monographs and publication of new taxa. Some data by their nature must be maintained by distributed data centers linked via portals (e.g., collections) while other information should be centralized (e.g., taxon information and nomenclature). Plant information developed in a collaborative online system would allow data on species and higher level groups to appear on Web sites as soon as they are written and edited, and immediately after new information or taxa are published.

5.6.2. Floristics and global information infrastructure

G. Baillargeon[1], G. Guala[2];
[1]Agriculture and Agri-Food Canada, Mont-Joli, PQ, Canada, [2]USDA, NRCS National Plant Data Center, Baton Rouge, LA, United States.

Stimulated by the establishment of the Global Biodiversity Information Facility (GBIF) in 2001, a large network of distributed biodiversity resources is quickly developing worldwide. In its first phase, GBIF has focused on providing access to metadata, taxonomic names, and to specimen and observation data, by establishing XML-based web services, a collection of protocols and standards used for exchanging data between computer applications. Much of the information associated with floristic work such as keys and descriptions has remained unused by lack of appropriate standards to meaningfully aggregate data from various sources. A key challenge is that providers of this information do not use the same terminology for similar concepts. Emerging solutions include the development of a TDWG standard to deal with descriptive data (SDD). Emerging challenges include integration with existing ontology efforts.

5.6.3. Floristics for the 21st century: Flora of North America as a case study

N. R. Morin;
Flora of North America, Point Arena, CA, United States.

Flora of North America (FNA) has the goal of providing authoritative information on the plants of North America north of Mexico to a wide range of users. The project has been guided by “Floristics for the 21st Century,” which concluded that computer technology could be an important operational tool and a powerful vehicle for making information available. With 1/3 of the project completed, we find that technology has done both more and less than anticipated. FNA meets two key requirements for analysis of floristic data: comparable descriptions and geographic distribution, which are provided in a relational database format. On the Internet, hypertext and search engines have been more important than relational databases for accessibility of data, however. The online availability of references and herbarium collections have improved the quality of treatments. Review and editing processes have been served better by simple off-the-shelf programs than by computer-assisted collaborative work processes. Perhaps most importantly, the fundamental requirement to complete floras is an expert botanical and editorial workforce, which cannot be replaced by computers.

5.6.4. The Jepson Flora Project: An integrative approach to floristics

B. G. Baldwin, B. D. Mishler;
University of California, Berkeley, CA, United States.

The Jepson Flora Project is a worldwide botanical collaboration dedicated to providing detailed, rigorous, and current information on the California flora through innovative use of electronic and printed media. Rapid documentation of newly discovered, native and naturalized plant taxa in California and advances in understanding of relationships, ecological attributes, distributions,

and endangerment of California plants makes integrative approaches to floristics an urgent need. Such integration depends on using classifications that reflect phylogeny and that represent the full diversity of well-supported, minimal evolutionary lineages. Achieving that goal is challenging for California, where recent diversification of lineages, sometimes accompanied by unequal rates of phenotypic evolution, has resulted in much cryptic diversity and in groups of phenetically similar taxa that are not clades. Floristic integration by the JFP also involves continuing development of on-line resources for uses ranging from plant identification, to horticulture, to flora-wide analyses of ecological and biogeographic questions in a phylogenetic framework.

5.6.5. Bryophyte floras in the digital age: floras for those who cannot afford them

B. J. O'Shea;
Natural History Museum, London, United Kingdom.

Africa is a country desperately in need of floras for bryophytes and other lower plants. There are significant difficulties in encouraging and supporting studies in this area, when all the literature and specimens that are needed are outside of Africa, and where only South Africa has a published bryophyte flora (although not yet complete). Bryology is not well-funded, and attempts to get funding have had only limited success. Nevertheless, good progress is being made on a generic flora for bryophytes (approximately 60% completed), but in the longer term the target is Bryologia Africana, a species level flora for tropical Africa. It will take some time to describe almost 5000 taxa, so we intend initially to publish the generic flora, as it is produced, on the web, and then add keys to species and descriptions as they become available, as part of a future Bryologia Africana: a full, free, on-line bryophyte flora for tropical Africa. If we can publish on paper we will, but the most important factor is making the information available as a free resource.

5.6.6. Floristic challenges in Latin America at the beginning of the XXIst century

P. Dávila[1], V. Sosa[2];
[1]FES-Iztacala, UNAM, Tlaneplantla, Edo. de México, Mexico, [2]Instituto de Ecología A.C., Xalapa, Veracruz, Mexico.

Molecular biology, biotechnology and genetic engineering are main scientific areas receiving interest and support from the scientific community and funding institutions. Along with this situation, there has been a significant decline in supporting basic research activities that still deserve attention. This is the case of the floristic work that includes data of plant inventories such as checklists, floras, species distribution pattern data and assessments of plant diversity and endemism in different regions. In the beginning of the twenty first century, many megadiverse countries of the world still lack a catalogue of their flora, and some of them are far away of having one in the near future. In Latin America, many countries have developed important programs to increase the knowledge of their plants, either by their own efforts or with the help of other countries. Each country has designed its own approach for cataloguing its flora, thus, the results and accomplishments obtained are diverse. A summary of the major floristic programs currently being undertaken in Latin America and a discussion regarding their present and future activities is presented.

5.6.7. Flora brasiliensis revisited - a website to improve knowledge of the Brazilian flora

V. Bittrich[1], M. C. E. Amaral[1], G. J. Shepherd[1], **P. E. Berry**[2];
[1]UNICAMP, Campinas, Sao Paulo, Brazil, [2]University of Wisconsin-Madison, Madison, WI, United States.

A century after the completion of Martius´ *Flora brasiliensis,* the Brazilian flora is still poorly known. Estimations of the number of angiosperm species there vary from 30,000 to over 60,000. Taxonomic work there is a good example of the “taxonomic impediment” for exploration and management of the earth´s biodiversity. Progress on the Brazilian flora continues with too few taxonomists and difficult access to historical specimens, literature, and associated data and imagery. Our project works on creating a database-fed website that will allow the user to quickly find the most relevant data for each taxon. A wide array of specialists will be asked to participate for different angiosperm families. The starting point is the 40-fascicle *Flora brasiliensis* (1840-1906), which includes nearly 25,000 described species and close to 4,000 high quality lithographs. The initial steps include updating the names in the *Flora*, which is still widely used to identify specimens, and digitizing the illustrations. Other historical works, more recent data, and other illustrations and photographs will complement the historical data on the website.

5.7.1. The streptophyte algae: thirty years after

M. Melkonian, B. Becker, A. Gontcharov, B. Marin;
Universität zu Köln, Cologne, Germany.

In two seminal contributions, Jeremy Pickett-Heaps (1975) and Ken Stewart and Karl Mattox (1975), shifted the prevailing paradigm about the phylogeny and systematics of the green algae, namely that green algal evolution followed a linear sequence of organizational levels starting with flagellates and terminating with differentiated thalli. These authors identified ultrastructural characters (mostly of the flagellate and mitotic/cytokinetic cytoskeleton) which strongly suggested that there exists a motley assemblage of morphologically diverse green algae (which they termed Charophyceae) specifically related to embryophyte plants and from whose ancestors the latter were postulated to have evolved. This proposal has been spectacularly confirmed by molecular phylogeneticists during the 1990s and remains one of the best examples of congruence between morphology and molecules. The exact relationships of the streptophyte algae to each other and the likely steps that led to the evolution of embryophyte plants, however, are still eluding us today. Multi-gene (genome) phylogenies and transcriptome comparisons are helping to unravel these questions.

5.7.2. EST analysis of the scaly green flagellate *Mesostigma viride* (Streptophyta): Implications for the evolution of green plants (Viridiplantae)

B. Becker[1], A. Simon[1], G. Glöckner[2], M. Felder[2], M. Melkonian[1];
[1]Botanical Institute, Koeln, Germany, [2]IMB, Jena, Germany.

The Viridiplantae are grouped into two monophyletic groups: the Chlorophyta and the Streptophyta. The Streptophyta include all embryophytes and a diverse group of freshwater algae known as Charophyceae. The only scaly flagellate included within the Streptophyta is Mesostigma viride. The exact position of M. viride within the Streptophyta is still controversial. We present an EST-analysis of Mesostigma viride and compare the ESTs of Mesostigma with the available plant genomes (Arabidopsis, Oryza, Chlamydomonas) and ESTs from Physcomitrella. In general, plastidic and mitochondrial metabolic pathways, proteins of the cytoskeleton and proteins involved in protein folding are better conserved between Mesostigma and Chlamydomonas than between Mesostigma and the embryophytes. In contrast, cytosolic metabolic pathways, and proteins involved in vesicular transport, transcription, regulation, DNA-structure and replication, cell cycle control, and RNA-metabolism are better conserved between Mesostigma and the embryophytes than between Mesostigma and Chlamydomonas.

5.7.3. Charophyte green algae and the origin of embryophytes from the perspective of 2005

C. F. Delwiche[1], K. G. Karol[1], J. D. Hall[1], R. M. McCourt[2];
[1]University of Maryland, College Park, MD, United States, [2]Academy of Natural Sciences, Philadelphia, PA, United States.

In recent decades application of ultrastructural methods, formal phylogenetic analysis, and most recently molecular systematic data, has provided a clear view of the evolutionary origin of embryophytes (land plants). Multi-gene molecular analyses support the idea that the Charophyta sensu Mattox and Stewart are a fundamental lineage of green algae that also includes embryophytes. The Charales appear to be the sibling taxon to embryophytes, confirming the Streptophyta sensu Jeffrey 1967. The Coleochaetales are sibling to that clade. The highly diverse Zygnematophyceae have been considered problematic because of their distinctive mode of reproduction, but they are clearly placed among the charophytes, and are more closely related to embryophytes than are any algae other than the Charales and Coleochaetales. Also important are structurally simple, basal taxa that represent extremely ancient lineages. As phylogenetic relationships among these organisms becomes more definite, the challenge will be to combine phylogenetic information with knowledge of the biology of the organisms to provide new insights into the origin and evolution of embryophytes.

5.7.4. Morphological variation and genetic diversity in *Chara braunii* (Charales, Charophyceae) in Japan

S. Kato[1], H. Sakayama[2], S. Sano[3], F. Kasai[2], M. M. Watanabe[2], J. Tanaka[4], H. Nozaki[1];
[1]Department of Biological Sciences,Graduate School of Science, University of Tokyo, Tokyo, Japan, [2]Environmental Biology Division, National Institute for Environmental Studies, Ibaraki, Japan, [3]Ichikwa-nishi Senior High School, Chiba, Japan, [4]Department of Oceans Sciences, Faculty of Marine Science, Tokyo University of Marine Science and Technology, Tokyo, Japan.

Chara braunii (Charales, Charophyceae) is a cosmopolitan species, and occurs in various environments, such as small/shallow ponds, paddy fields, large/deep lakes etc. *C. braunii* exhibits large morphological variation and R. D. Wood (1965) classified this species into seven forms, on the basis of differences in morphology of bract-cell, stipulode, and oospore (zygote). However, no studies on the relationships between morphological variation, habitats and genetic diversity in *C. braunii* have been carried out. The present study was undertaken to evaluate the species concept of *C. braunii* using culture methods and DNA sequence data. We have collected many samples from various localities in Japan including paddy fields and lakes etc. The present *rbc*L gene sequence data resolved robust two clades of *C. braunii*, and samples collected from lakes belong to only one of the two clades. Morphological variation and habitats of *C. braunii* will be discussed in relation to the phylogenetic relationships within the species.

5.8.1. Angiosperm phylogeny - progress and prospects

K. Bremer;
Stockholm University, Stockholm, Sweden.

The publication of the APG system in 1998 summarized a decade of unparalleled progress in understanding angiosperm phylogeny. The robustness of the results was demonstrated by the few changes that were made in the APGII update in 2003. Unresolved issues include some major interrelationships at and above the ordinal level and many unclear interrelationships within orders and families, where extensive work remains to be done. Furthermore, the APG principles of classification may be debated. This presentation discusses what could be expected from a future APGIII update. The expanding area of dating angiosperm phylogenies is also addressed. The identification of all angiosperm 100-my-clades is an important future goal. Many orders and even some families of the APG classification comprise several such 100-my-clades and some 100-my-clades comprise several APG orders. Orders and families of the APG classification are essentially arbitrarily circumscribed (albeit monophyletic) and not of comparable age. The 100-my-clades are of similar age and hence more useful entities in research on angiosperm evolution.

5.8.2. Life under stress: order Caryophyllales

M. D. Lledo;
Royal Botanic Gardens, Kew, Surrey, United Kingdom.

The broadly defined order Caryophyllales (sensu APGII) includes families adapted to extreme environments, from dry, salty conditions to oligotrophic soils. Since publication of the first angiosperm DNA analysis, composition of the order has relatively remained unchanged. Nevertheless, two main areas of research need to be addressed: relative position of the order within eudicots and relationships among families. Although Dilleniaceae are consistently placed as sister group, support for this relationship remains weak. In addition, the position of Caryophyllales/Dilleniaceae within eudicots remains unresolved. Analyses of individual genes consistently recover two main lineages, but many relationships within these two groups are still difficult to assess. Non-monophyly of some widely accepted families (e.g. Cactaceae, Portulacaceae, Phytolacaceae) makes complex, or at least controversial, attempts to reclassify the group. Synapomorphies defining the caryophyllids will be discussed.

5.8.3. Rosid angiosperms: circumscription, issues, and systematic advances

K. J. Sytsma[1], J. Hall[2];
[1]University of Wisconsin, Madison, WI, United States, [2]Harvard University, Cambridge, MA, United States.

The rosid lineage comprises nearly one-third of all angiosperm species and is classified into 140 families, most of which are placed in 15 orders. The position of Vitaceae relative to other rosids and to other tricolpates is still uncertain. Two major lineages, fabids and malvids, are recognized within rosids. Three other orders, most notably Myrtales, are still unplaced within rosids. Familial relationships within many orders are now clarified, although some, especially Malpighiales, are not due to apparent rapid rates of diversification early in their evolution. Rosids are relatively heterogeneous with respect to diagnosable morphological features as compared to asterids. Major breakthroughs in delimiting rosid subclades include those defined by the propensity to fix nitrogen or by the production of glucosinolates with specialized myrosinases. Morphological and anatomical characters define many orders, but few more inclusive groups within the rosids. Rosids are the focus of several large scale studies incorporating fossils into molecular phylogenies to understand both temporal and spatial diversification of the group.

5.8.4. Phylogenetic relationships and evolution in basal angiosperms

D. E. Soltis, P. S. Soltis;
University of Florida, Gainesville, FL, United States.

Recent collaborative, multigene analyses have identified the basalmost nodes of angiosperm phylogeny. Amborellaceae are generally sister to all other angiosperms, followed by Nymphaeaceae and Austrobaileyales. Other lines of evidence further support these relationships. For example, a deletion in exon 5 of homologues of the floral MADS-box gene PISTILLATA unites all angiosperms except Amborella and Nymphaeaceae. Despite considerable progress in angiosperm phylogenetics, critical deep relationships remain unclear. “Above” the three basal branches, monocots, Ceratophyllaceae, Chloranthaceae, the magnoliid clade, and eudicots essentially form a polytomy. Genomic studies have provided key insights into the evolution of basal angiosperms. For example, basal angiosperms are ancient polyploids. Furthermore, they have a complex array of floral developmental genes, comparable to those in core eudicot models such as Arabidopsis. However, expression patterns of floral MADS-box genes are generally broader in basal angiosperms than in core eudicot models, perhaps accounting for differences in floral organization.

5.8.5. Higher-level relationships in the monocotyledons: multi-gene analyses

M. W. Chase;
Jodrell Laboratory, Richmond, United Kingdom.

Phylogenetics relationships among monocots have over the past ten years been the focus of a number of large-scale phylogenetic studies, which have to a large degree resolved most of the major questions. Based on analyses of seven genes representing all three genomes, *Acorus* (Acorales) is sister to the rest, followed at the next several nodes by Alismatales (including Araceae and Tofieldiaceae), Petrosaviales, Dioscoreales/Pandanales, and finally Asparagales sister to the commelinids. All of these receive at least moderate bootstrap support, but most are greater than 90%. Within commelinids, Commelinales are well supported as sister to Zingiberales, but it is not yet clear how this pair or orders is related to Arecales, Dasypogonaceae and Poales. This general topology is consistent with an aquatic or semi-aquatic origin of monocots; leaves with reticulate venation are not the ancestral condition, in contradiction to results of some morphological cladistic analyses. Studies of molecular clocks have indicated that the crown node of monocots is 127-134 million years old, and most orders and some families are older than 100 million years.

5.8.6. Asterid phylogeny - updated and dated

J. Kårehed, B. Bremer;
Bergius Foundation, Stockholm, Sweden.

The asterids, representing ca. 1/3 of all angiosperms or over 80 000 species, was one of the first major clades to be molecularly investigated. Less than fifteen years later the general picture is the same but many more taxa have been investigated and several molecular markers have been analysed with similar results. Both APG classification systems (APG and APG II) accept ten orders (Cornales, Ericales, Garryales, Gentianales, Lamiales, Solanales, Aquifoliales, Apiales, Asterales, and Dipsacales) and more than 100 families (107 and 101, respectively). All ten orders have stem nodes dated back to early Cretaceous (128-106 my) and crown nodes dated from early to late Cretaceous (114-78 my). The orders are well supported but relationships between several orders are, despite intense trials, not resolved. Focus of asterid researchers today is to resolve the relationships within the families, particularly of the species rich as for example Asteraceae and Rubiaceae.

5.9.1. Phylogeny of the Ericales

A. A. Anderberg[1], J. Schönenberger[2];
[1]Swedish Museum of Natural History, Stockholm, Sweden, [2]Stockholm University, Stockholm, Sweden.

Analyses of DNA sequence data have shown that Ericales is monophyletic and comprised of 23 families from three subclasses (Asteridae, Dilleniidae, Rosidae), and that they are sister to the Euasterids. Relationships among families and several family circumscriptions have been amended. Balsaminaceae, Tetrameristaceae + Pellicieriaceae, and Marcgraviaceae are in a clade that is sister to the rest. The largest group is formed by (1) Clethraceae, Cyrillaceae, and Ericaceae as sister to Actinidiaceae, Sarraceniaceae, Roridulaceae, (2) Diapensiaceae and Styracaceae sister to Symplocaceae, and (3) Theaceae s.str. Outside of this group, (4) Sapotaceae is sister to Ebenaceae and the primuloid families, and (5) Theaceae-Ternstroemioideae group with Pentaphylacaceae and Sladeniaceae. Unresolved outside of the major clade are (6) Lecythidaceae, and (7) the Fouquieriaceae as sister to Polemoniaceae. The results are important for studies of character evolution, and although the Ericales lack apparent morphological synapomorphies, states such as sympetaly, unitegmy, and cellular endosperm are shown to be characteristic of certain clades.

5.9.2. The phylogenetic significance of wood anatomy within Ericales

F. Lens[1], S. Jansen[2], E. Smets[1];
[1]Institute of Botany and Microbiology, Leuven, Belgium, [2]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

Ericales sensu APG show a large wood anatomical variation providing significant information for systematic relationships within the order. The so-called primitive Baileyan features (e.g. mainly solitary vessels with scalariform perforations, opposite to scalariform vessel pitting, distinctly bordered fibre pits, scarce apotracheal parenchyma, heterocellular rays) are common in ericoids, Pentaphylacaceae, Symplocaceae, Styracaceae and Theaceae. On the other hand, balsaminoids, Ebenaceae, Lecythidaceae, primuloids and Sapotaceae are characterised by radial vessel multiples, simple perforations, alternate vessel pitting, and fibres with simple pits. Within the order, there is good support for the current delimitation of various subclades (e.g. balsaminoids, ericoids and primuloids). In addition, the wood structure provides evidence for a close relationship between Theaceae and Symplocaceae on the one hand, and between Ebenaceae, Lecythidaceae and Sapotaceae on the other. Below family level, wood anatomical data show systematic significance in families such as Ericaceae, Lecythidaceae and Sapotaceae.

5.9.3. Phylogeny and biogeographical comparison of Diapensiaceae, Styracaceae, and Symplocaceae.

P. W. Fritsch;
California Academy of Sciences, San Francisco, CA, United States.

Recent molecular phylogenetic analyses of order Ericales have demonstrated strong support for a clade comprising the families Diapensiaceae and Styracaceae, with Symplocaceae as sister-group. I review current knowledge on the internal topology of these families based on morphological, molecular, and combined results, summarize putative synapomorphies for the major subclades, and present proposals for revised infrafamilial classification. I also compare biogeographical patterns of these groups based on tree topologies and current understanding of fossil histories. Styracaceae and Symplocaceae share remarkably similar distributions, occurring in tropical and warm north-temperate regions of the Americas and eastern Asia, with one Mediterranean species in Styracaceae. Event-based biogeographical analyses with molecular-based topologies support an eastern Asian origin and subsequent Tertiary expansion into South America (probably via dispersal from tropical North America) in each family. A study in progress of abundant endocarp fossils of Symplocaceae will test biogeographical interpretations based on molecular phylogenetics.

5.9.4. Bayesian phylogenetic analysis of multiple chloroplast markers contributes new knowledge about Sapotoideae (Sapotaceae) phylogeny

J. E. E. Smedmark, U. Swenson, A. A. Anderberg;
Swedish Museum of Natural History, Stockholm, Sweden.

The pantropical clade Sapotoideae contains more than 500 species of trees and shrubs, whose phylogenetic relationships are poorly understood. We present a study based on a chloroplast DNA data set of more than 5 kb for 66 Sapotoideae species. Our results show that a couple of taxa previously placed in this group do not belong here. Eberhardtia aurata is the sister of the two major Sapotaceae clades; Sapotoideae and Chrysophylloideae, and Neohemsleya usambarensis belongs in Chrysophylloideae. Sapotoideae consists of the well suppoerted Sideroxyleae and a grade of taxa placed in Glueminae and Isonandreae. Short internal branches within this grade make it difficult to resolve with good support. Within the grade a strongly supported clade with more complicated floral structure is nested. This clade more or less corresponds to Mimusopinae and Manilkarinae. The effect of model choice on the resolution of short branches in Bayesian phylogenetic analysis is discussed, as well as character evolution of floral traits and possible implications for the classification of the group.

5.9.5. Systematics of Sapotaceae and a new subfamily classification

U. Swenson, A. A. Anderberg;
Swedish Museum of Natural History, Stockholm, Sweden.

Parsimony analyses of Sapotaceae, based on morphological and molecular data, confirm that the family circumscribes three main evolutionary lineages corresponding to the tribes (1) Isonandreae-Mimusopeae-Sideroxyleae, (2) Chrysophylleae-Omphalocarpeae, and (3) the genus Sarcosperma, respectively. The Sideroxyleae are monophyletic, Isonandreae are polyphyletic, and the subtribe Mimusopinae have evolved within the Mimusopeae-Manilkarinae. The large tribe Chrysophylleae are monophyletic only if the taxa from tribe Omphalocarpeae are included. This clade includes the large genera Chrysophyllum and Pouteria, neither being monophyletic in their current circumscription. An amended subfamily classification has been proposed that corresponds to the monophyletic groups Sarcospermatoideae (Sarcosperma), Sapotoideae (Isonandreae-Mimusopeae-Sideroxyleae), and Chrysophylloideae (Chrysophylleae-Omphalocarpeae), where Sapotoideae circumscribes the tribes Sapoteae and Sideroxyleae. Relationships in and among the latter tribes are yet unclear.

5.9.6. Evolution of new world Lecythidaceae

S. A. Mori[1], C. Tsou[2], A. A. Anderberg[3];
[1]The New York Botanical Garden, Bronx, NY, United States,
[2]Academia Sinica, Taipei, Taiwan Republic of China, [3]Swedish Museum of Natural History, Stockholm, Sweden.

Molecular data from the *trn*L-*trn*F and *ndh*F genes suggest that the generic limits of *Corythophora, Couratari*, *Couroupita*, *Grias*, and *Gustavia* represent distinct clades as currently defined with *Grias* and *Gustavia* basal to the remaining Lecythidoideae. *Cariniana*, on the other hand, comprises two groups: one with actinomorphic, fleshy flowers and the other with zygomorphic non-fleshy flowers. Poor resolution among the remaining zygomorphic-flowered species does not clarify the relationships of *Bertholletia excelsa* (the Brazil nut), *Corythophora*, *Eschweilera*, and *Lecythis*. Most of the species of *Eschweilera* form one large clade characterized by seeds with a lateral aril. The remaining species of *Eschweilera* are scattered among species of *Lecythis*. Species of *Lecythis* are found in at least four places in the *trn*L-*trn*F and *ndh*F trees and species that morphologically have nothing in common appear in the same clade. The currently recognized sections of *Lecythis* (*corrugata*, *pisonis*, *poiteaui*, and *Lecythis*) are only supported for section *corrugata* in the *ndh*F tree.

5.9.7. Morphological diversity and biogeography of Ericales

K. A. Kron, E. A. Powell;
Wake Forest University, Winston-Salem, NC, United States.

The newly circumscribed Ericales encompass a range of morphological diversity that rivals that of most other eudicot orders. Many taxa possess highly specialized features such as the nectariferous bracts in Marcgraviaceae and the tendency to accumulate metals such as aluminum (Symplocaceae). Members of this clade vary in their geographic distribution from highly restrictive (Pellicieriaceae) to pantropical (Sapotaceae) or cosmopolitan (Ericaceae). The core Ericacales (Actinidiaceae, Roridulaceae, Sarraceniaceae; Clethraceae, Cyrillaceae, and Ericaceae) frequently occur on acidic or nutrient poor soils. Relationships among core Ericales are analyzed via parsimony and maximum likelihood using molecular data. Morphological features mapped onto the resulting cladogram indicate that carnivory evolved once and was lost in the ancestor to Actinidiaceae. Analysis of the geographic distribution of representatives within core Ericacles indicates that North America may have been an important area of diversification during the mid- to late-Cretaceous.

5.10.1. History of botany in Austria

C. Riedl-Dorn;
Archives and History of Science NHMV (Natural History Museum Vienna), 1010 Vienna, Austria.

Already in the late 16th century emperors employed botanists like Matthioli & Clusius, who produced the first flora of higher plants & the first fungus flora. Foundation of the botanical gardens of the University of Vienna & Schönbrunn 250 years ago. Jacquin introduced the binary nomenclature of Linnaeus; Endlicher & Wettstein developed new systems of classification. Expeditions to Central and South America (Jacquin, Boos, Pohl, Schott, Mikan, Haenke), South & West Africa (Boos, Welwitsch), Australia , Southwest Asia & N. Africa (Sieber, Kotschy), Hawaii (Wawra, Rick) or China (Rick, Handel-Mazzetti) brought rich materials for the Imperial collections. Floras of Austria & its provinces & of the Balcan Peninsula were written by authors like Jacquin, Host, Schultes, Wulfen, Neilreich, Halacsy, Hayek & others. The most outstanding Flora of recent times is Rechinger's Flora Iranica. Cryptogamic botany: From Wulfen to Zahlbruckner, Petrak & Geitler. For palaeobotany Unger & v. Ettingshausen, for plant physiology pioneers like Ingen-Housz & famous representatives like Unger, Wiesner & Molisch are to be mentioned; Kerner is one of the founders of plant ecology.

5.10.2. Austrian botanical explorations in Iran

H. U. Riedl, H. U. Riedl;
Botanical Department, NHM, Vienna, Austria.

Starting from the extensive travels in northern and southern Iran of Th. Kotschy in 1842 to the voluminous “Flora Iranica” edited and partly composed by the late K.-H- Rechinger, who also excelled as a collector, since 1963 and now almost completed there was a permanent interest for the flora of this country in Austria. While Th. Kotschy, O. Stapf, K.-H. Rechinger, E. Gauba and A. Gilli were trained as botanists important contributions were also made by physicians to the court of the Shah like J. E. Pollak together with Th. Pichler and J.A. Knapp in the 19^{th}, geographers like A. Gabriel and H. Bobek or zoologists like A. Ruttner-Kolisko, F. Kasy and J. Eiselt in the 20^{th} century. Their collections either preserved at the Vienna Natural History Museum or in the herbarium of Vienna University were all identified and/or revised for “Flora Iranica” and include a great number of nomenclatural types.

5.10.3. K. K. Münch-Bellinghausen´s herbarium in the Moravian museum and its evaluation

K. Sutorý;
Moravian Museum, Brno, Czech Republic.

K. K. Münch-Bellinghausen (*10.6.1752, +11.11.1838) created a herbarium collection of more than 10 000 specimens in the years 1800-1838. Its major part was acquired by purchase from various botanists. Bold letters in the list below indicate collectors their specimens were up to this time elaborated in special studies. Thy will be object of digitalisation in the next time. Balbis, Benesch, Besser, Blandow, Bonjard, Bonjean, Buek, Burkhardt, Carl, Crome, Dierbach, Dietrich, Duval, Eisenstein, Flotow, Freyer, Gaertner (+ Meyer, Scherbius), Haller fil., Heckel, Herbich, Hess, Hinterhuber, Hoppe, Host, Hübner, Huguenin, Jahn, Kiteibel, Klotzsch, Kosteletzky, Kotschy, Láng, Lejeune, Mann, Masner, Mertens, Münch, Noe, Nolte, Opiz, Panzer, Peterman, Portenschlag, Presl, Reichenbach, Rohde, Rochel, Rudolphi, Ruprecht, Rümmelein, Sadler, Salzmann, Sauter, Schleicher, Schmalz, Schultes, Seidl, Sieber, Thomas, Traufelner, Traunsteiner, Vanderschoff, Wahlenberg, Waldstein, Weihe, Welden, Welwitsch, Wierzbitzki, Zawadski, Ziz.

5.10.4. Richard Wettstein von Westersheimb and his father in law Anton Kerner von Marilaun

M. Petz-Grabenbauer;
Akademie der Wissenschaften,, Vienna, Austria.

The research of the nature with new technologies and a big number of students at the University of Vienna at the end of the 19th century needed new structures within the universities institutions, and an appropriate arrangement with the academic learned persons. Two well known botanists of this area (the end of the Hapsburg monarchy) were Anton Kerner von Marilaun and his son in law Richard Wettstein von Westersheimb; both directors of the botanical garden of Vienna. Especially the biography of Richard Wettstein sounds absolutely phantastic. Born in Vienna in 1863, he married in the age of 27 the daughter of Anton Kerner, Adele, and, a little bit later, became director of the botanical garden in Prague. After Anton Kerner’s death, he also became director of the botanical garden in Vienna, Rennweg 14. In this function he rebuilt the building of the botanical institute in Vienna in a very short time.In 1905 he organised the Second International Botanical Congress in Vienna, exactly 100 years ago.

5.10.5. Discovery of photosynthesis. Jan Ingneousz - his experiments and life

B. Lötsch;
Natural History Museum, Vienna, Austria.

The effect of animal respiration spoiling the air and its reversal by plants was discovered by Joseph Priestly (1772). Unfortunately he did not perceive the light dependency. So he was confused by diverging results of several experiments, finally became doubtful and cannot be regarded as the discoverer of photosynthesis. Inspired by Priestley's experiments, the Dutch physician and expert on small pox inoculation at the imperial court of Maria Theresia, Jan Ingenhousz (born 1730 in Breda, died 1799 near London) found a method to observe the very moment when the restoration of bad air would begin: Putting the plants under water to see the “pure air” or “dephlogisticated air” (today we call it oxygen) oozing out as bubbles only in light, mostly from the lower side of fresh leaves and “not owing to the warmth of the sun∗ but∗ to the light”. Though - after 500 well planned experiments in summer 1779 and publishing the results end of 1779 - Ingenhousz gave full credit to the pioneering role of J. Priestley. The quarrelsome English Chemist and priest would not put up with having missed the factor and attacked Ingenhousz. Benjamin Franklin, admiring both of them, tried to mediate. Ingenhousz who was highly respected at the Viennese Court (1768-1779) had personal contacts with N. v. Jacquin (his brother-in-law), with the young W.A.Mozart , with Mesmer (the controversial doctor curing with the help of “animal magnetism”, glass organ music and hypnosis) and with A.Fontana in Florence (to whom he owed the method of analyzing the purity of “dephlogisticated air”, based on oxidation of the insoluble NO-gas to the water soluble NO_2). The author has repeated some of Ingenhousz’ experiments and traces back his life lines, his amiable character, manysidedness and scientific ingenuity.

5.10.6. The golden century of austrian botany

H. Lack;
Botanischer Garten und Botanisches Museum Berlin-Dahlem, 14195 Berlin, Germany.

The golden century of Austrian botany is an appropriate term for the years 1750 to 1850. During this period the first chair of botany and the first botanic garden were founded in what is now Austria - at Vienna University. A botanic garden was added to the imperial summer residence of Schönbrunn near Vienna, the k. k. botanisches Hofkabinett, part of the imperial collections, but effectively a public herbarium, was created, and very substantial collections of botanical books and illustrations were added to the imperial library in Vienna. The key figues were Nicolaus Joseph Freiherr von Jacquin, his son Joseph Franz and Stephan Ladislaus Endlicher, the second, third and fourth professor of botany, all focused on plant diversity then only very incompletely known. Emperor Franz Stephan of Lorraine and Franz I, Emperor of Austria greatly encouraged the Jacquins and their circle. During this period the basic dichotomy of botany in Vienna still in existence developed - the Natural History Museum and the Botanical Institute being the largest depositories of botanical collections and centres of biodiversity research in Austria.

5.10.7. The scientific significance of Ferdinand Bauer's Pacific drawings

D. J. Mabberly;
Director University of Washington Botanic Gardens, Seattle, WA, United States.

Since the pronouncements of Goethe, the work of the Austrian painter, Ferdinand Bauer (1760-1826), has been considered some of the finest of biological illustration, as it successfully combines unswerving scientific accuracy with aesthetic sensitivity. His watercolour drawings, based on field sketches made on Mathew Flinders's Investigator voyage (1801-3) and subsequently on Norfolk Island and in New South Wales (to 1805), are widely credited with being the finest ever based on specimens in the field anywhere. Bauer's career is briefly outlined, particular note being made of the influences moulding his technique. These included his key initiation in the use and elabioration of colour-coding methods and his working under harsh conditions on Sibthorp's 1786 expedition to the eastern Mediterranean, leading to the mounumental Flora graeca. The significance of Bauer's meticulous dating and localizing of his field drawings is stressed. The use of his different colour-codes is explored, particularly in his Pacific work, and it is shown that one of his codes was used in the tropics even before he left Europe for Australia. The deciphering of his most elaborate code, using living plants in Western Australia is explained. Its importance today in the 'revival' of extinct plants from Norfolk Island is examined.

5.11.1. What we should (but don't) know about plant clonality

J. F. Stuefer;
Radboud University Nijmegen, Nijmegen, The Netherlands.

Plant clonality and its direct ecological, physiological and evolutionary implication has been a major focus of attention and research activities over the past three decades. Due to this effort we have a reasonably good understanding of characteristic clonal plant features such as resource sharing, ramet dynamics, and the functional relationship between sexual reproduction and vegetative growth in a number of clonal plant species. Nevertheless, the studies which have provided this insight have also generated a considerable number of new and exciting questions, which relate - among others- to ramet communication via non-resource sharing, biotic interactions with herbivores and pathogens, likely effects of clonality on mating system evolution, somatic mutations, intra-plant genetic diversity and the importance of hierarchical selection, the evolutionary background of clonality and phylogenetic correlates between clonality and other life history traits. This talk aims at a critical analysis of the current state of the art with respect to clonal plant research and at the identification of future scientific challenges and possible research directions.

5.11.2. Solving a problem by falling apart: notes on the evolutionary origin of clonality in plants

B. Oborny;
Loránd Eötvös University (ELTE), Budapest, Hungary.

Clonality is a convergent trait in the plant kingdom. Clonal plants share the feature that the genetic individual (genet) is subdivided into multiple physiological individuals (ramets) that are autonomous to some extent. First I discuss the relationship between this subdivision and the basic, modular organisation of the plant body. Then I consider two specific consequences of modularity: 1. disposability of parts of the body, and 2. distributed control of the developmental process. Clonality opens special ways in adaptation to spatial heterogeneity. Individual ramets can parallelly interact with the environment, sampling from the habitat at several locations. Due to functional redundancy, the same genotype can be expressed in various phenotypes, and tested against various environments. Furthermore, different ramets can cooperate by exchanging resources and information. I review the potential selective forces towards and away from clonality, and outline some basic strategies in clonal growth.

5.11.3. Resource sharing in *Aegopodium podagraria*-A study at the genet level

J. M. Nilsson, T. D'Hertefeldt;
Plant Ecology and Systematics, Lund, Sweden.

Our aim was to investigate if there are local adaptations in how resources are shared in forest and weedy populations of *Aegopodium podagraria,* and if this is affected by the potential differences in immigration history. We also compared populations from southern and central Sweden to see how the proximity to the northern distribution limit affected resource sharing. We subjected one ramet of each plant to shadow treatment, shutting out 95% of the available light, while the other had regular day light. The rhizome connection between ramets was severed (no sharing possible) or left intact (sharing possible). The experiment was carried out using ramet pairs, planted in separate pots. We used 5 presumptively different genets (collected 10 m apart) from 4 populations, one forest (heterogeneous, low light levels) and one weedy (relatively homogeneous, higher light levels) population each from south and central Sweden. Ramet morphology and biomass was compared between treatments. I will discuss the results from the experiment in terms of adaptation between populations from habitats with contrasting light climates.

5.11.4. Genetic differentiation in life-history traits between populations of *Mimulus guttatus* with annual and perennial life-cycles

M. van Kleunen, **M. Fischer**;
Institute for Biochemistry and Biology, Potsdam, Germany.

The relative allocation to sexual and vegetative reproduction is among the most important life-history characteristics of clonal plants. In a greenhouse experiment, we tested for genetic differentiation in life-history traits between plants from permanently wet and temporarily wet populations of *Mimulus guttatus*. In the former plants have a perennial life-cycle with efficient vegetative reproduction, while in the latter they have an annual life-cycle. Plants grown from seed from temporarily wet populations produced more flowers, while the ones from permanently wet populations produced more and longer stolons, indicating that the differences in the field represent adaptations rather than sheer plastic responses. Moreover, plants originating from temporarily wet populations produced smaller flowers with shorter anther-stigma separation which is usually associated with higher selfing rates. Our study demonstrates a genetic trade-off between sexual and vegetative reproduction in *M. guttatus*, and strong adaptive genetic differentiation in important life-history traits between temporarily and permanently wet populations of *M. guttatus*.

5.11.5. Flooding gradients: a micro-evolutionary arena shaping trait variation in a clonal herb

H. Huber;
Experimental Plant Ecology, Nijmegen, The Netherlands.

Flooding gradients along rivers are characterized by predictable differences in environmental characteristics, ranging from high levels of disturbance at lower elevations (i.e. close to the water) to high levels of competition at higher elevations. We tested the hypothesis that flooding gradients act as strong selection agents on within-species variation. This implies that genotypes of generalist species should show significant trait differences along flooding-competition gradients (i.e. local adaptation). This prediction was tested by carrying out a common garden experiment with more than 400 genotypes of the clonal herb Trifolium repens, collected along several flooding gradients. The results revealed distinctive micro-site-specific differentiation of developmental, architectural and life-history traits within populations. However, the pattern of trait differentiation was not consistent across populations. Selection analyses revealed complex trait interactions in determining plant performance and fitness. This suggests a high potential for natural selection to shape plant traits and population structure along flooding gradients.

5.11.6. Clonal traits are related to life conditions in an Alpine massif (Vanoise)

A. Evette[1], A. Bédécarrats[1], G. Bornette[2], A. Bornard[1];
[1]Cemagref, St Martin d'Hères, France, [2]CNRS, Lyon, France.

This study aims to link clonal traits and local-scale environmental variables in 169 herbaceous species plots distributed in the Vanoise Massif (inner part of the French Alps). The clonal traits considered are: duration of clonal integration, length of spacers, and spacer production rate, using the database Clopla1 (Klimeš & al. 1997). We find a significant correlation between the patterns of those functional traits, and environmental variables. Altitude, position in the mountainside, slope, and concave meso-topography are the main structuring factors of these clonal traits. Vegetative growth ability (frequency of multiplication, duration of ramet integration) tends to increase with increasing climatic stress, although it is less significant for spacer length. This work aims to link, at large scale, clonal structure and environmental factors with harsh and contrasted conditions of stress, and disturbance. The adaptive value of those traits is discussed in the theoretical framework relating environmental restraints and clonality.

5.12.1. Thioredoxin: New functions and applications

B. B. Buchanan;
University of California, Berkeley, CA, United States.

Thioredoxins (Trxs) are small proteins that occur in all types of organisms. Nineteen different Trx isoforms grouped in 6 subfamilies and distributed throughout the cell have been identified in the *Arabidopsis thaliana* genome. Trxs contain a conserved redox active disulfide, WC[G/P]PC, that is reduced either (1) photosynthetically by ferredoxin via ferredoxin-thioredoxin reductase in chloroplasts, or (2) enzymatically by NADPH via NADP-thioredoxin reductase in other organelles. Reduced Trxs function as hydrogen donors for the reduction of substrates or, more broadly, the regulation of enzymes. For the first 25 years following its identification in chloroplasts, Trxs were linked to a limited number of proteins. The advent of proteomics has led to the identification of more than 200 potential and confirmed Trx-linked proteins functional in a wide range of processes. The work has uncovered new types of regulation and modes of communication between organelles. Trx appears to regulate processes functional at virtually every stage of plant development. In concert with these advances, new applications in medicine and technology have been described.

5.12.2. Thioredoxin network in the plant cells: what we revealed using thioredoxin affinity chromatography

T. Hisabori[1], K. Motohashi[2];
[1]Chemical Resources Lab., Tokyo Tech., Yokohama, Japan, [2]ATP System Project, ERATO, JST, Yokohama, Japan.

Thioredoxin is a small ubiquitous protein, which mediates the dithiol-disulfide exchange reaction with the specific target protein. To list up the possible target proteins of thioredoxin and the related proteins in the cells or certain organelles, thioredoxin affinity chromatography using the immobilized thioredoxin mutants, in which second cysteine is substituted with serine, (Motohashi, K. et al., *Proc. Natl. Acad. Sci. USA*, (2001) 98, 11224-11229) is a useful method. For the past few years, many novel candidate proteins were identified and reported from various organelles and organisms by the proteomics approaches including this method. Information provided by these studies is useful to reveal the complete redox networks around thioredoxins. We will report the recent progress on the analysis of the novel target proteins and will discuss on the merits and demerits of the comprehensive survey methods.

5.12.3. Redox-regulation of carbon storage in response to external signals

P. Geigenberger;
Max Planck Institute of Molecular Plant Physiology, Golm, Germany.

It is discussed how flux to carbon storage is regulated in plants in response to physiological and environmental inputs. Starch is the major storage carbohydrate in plants and ADP-glucose pyrophosphorylase the rate-limiting step of its synthesis. It has recently been shown in potato tubers that this enzyme is subject to a redox-dependent post-translational regulation, leading to a stimulation of starch synthesis in response to the sucrose supply. An analogous mechanism is also operating in photosynthesising leaves, where AGPase redox-activation is independently modulated by light and sugars. Currently, the genetic resources of *Arabidopsis* are being used to investigate the components of the signalling pathways leading to redox-activation of AGPase in response to these inputs. It will be discussed how the sugar signal is transferred to the chloroplast and by which mechanism it interferes with the ferredoxin/thioredoxin system that is involved in the light-dependent redox-activation of the enzyme. Evidence will be presented that a similar mechanism is also regulating the flow of carbon into other pathways such as storage and membrane lipid synthesis.

5.12.4. Strategies to maintain redox homeostasis under changing conditions

R. Scheibe, J. E. Backhausen, V. Emmerlich, S. Holtgrefe;
Universität Osnabrück, FB 5, Pflanzenphysiologie, Osnabrück, Germany.

Plants operate well between the extreme situations of over-oxidation and over-reduction caused by the simultaneous presence of oxygen due to oxygen evolution during oxigenic photosynthesis and strong reductants generated in the photosynthetic electron transport chain. Apart from the need for homeostasis of the redox systems, there is obviously need for redox signals that induce the adaptation of metabolism to sustained changes, i.e. during development and upon stress situations. In this presentation, we wish to put forward the hypothesis that a large number of factors is able to induce acclimation and adaptation reactions well before such damage becomes apparent, while the major redox pools are kept constant over a wide range of conditions. Apparently, the responses are broad, rather smooth and depend upon metabolic situation and developmental stage of the cell. We assume that a prolonged period of over-reduction is sensed by the plant already before major imbalances of the redox components and, moreover, long before any oxidative damage becomes apparent. When oxidative stress finally takes over, all cell functions will rapidly and irreversibly break down.

5.12.5. 2-Cys peroxiredoxins as multi-level redox regulated chloroplast antioxidants

M. Baier, J. ShaikhAli, I. Heiber, A. Pena-Ahumeda, P. Lamkemeyer, W. Li, M. Laxa, K. Dietz;
Plant Physiology and Biochemistry, University of Bielefeld, Bielefeld, Germany.

In the network of anthero- and retrograde signals controlling expression, biosynthesis and activity of the chloroplast antioxidant system and photosynthesis 2-Cys Prx are key players. In chloroplasts they reduce H2O2 and alkyl hydroperoxides by an intermolecular thiol-disulfide reaction mechanism. High reduction as well as overoxidation of the active site lead to decamerization of the enzyme. Following the conformational change, the enzyme attaches to the thylakoid membrane and modulates photosynthetic activity. The electron pressure on ferredoxin controls gene expression. Signals correlating with a higher acceptor availability of photosystem I decrease the promoter activity via kinase-mediated signalling cascades. Transmission of the redox signal depends on the availability of abscisic acid, whose biosynthesis is affected by violaxanthin cycle activity and the availability of reduced ascorbate in the thylakoid lumen. Redox regulation of gene expression, peroxidase activity and control of photosynthesis define a regulatory circuitry in which the nuclear encoded chloroplast enzyme is a sensor, a regulator and the target of redox regulation.

5.12.6. Is the salicylate signalling pathway a more general redox signalling pathway? Lessons from excess light-stressed *Arabidopsis*.

P. M. Mullineaux[1], H. R. Reynolds[2], U. Bechtold[1], G. P. Creissen[2], S. Karpinski[3];
[1]University of Essex, Colchester, United Kingdom, [2]John Innes Centre, Norwich, United Kingdom, [3]Stockholm University, Stockholm, Sweden.

The salicylic acid (SA) signalling pathway is well established as a route for the induction of genes that contribute to resistance to a range of biotrophic pathogens. Our recent work indicates that NPR1, a key redox-sensitive regulator of the salicylic acid (SA) signalling pathway, also controls the local and systemic expression of excess light (EL) stress-responsive genes. The functioning of NPR1 may be controlled in part by cellular redox changes brought about the thiol antioxidant glutathione. In addition to a requirement for NPR1, expression of some EL-responsive genes also requires the action of TGA class basic leucine zipper (bZIP) transcription factors (TFs), which have been shown to form a complex with reduced NPR1 in the nucleus. Depending on the redox state in the cytosol and the nucleus of cells in tissues of stressed leaves, it is proposed that NPR1 may interact with different TGA bZIP TF partners. This would effect changes in the expression of panels of stress-responsive genes, which in turn, would influence physiological responses to different environmental challenges.

5.12.7. Chloroplast redox control of nuclear gene expression

T. Pfannschmidt, V. Fey, R. Wagner, K. Bräutigam;
Department for Plant Physiology, Jena, Germany.

The light reaction of photosynthesis involves photosystem II (PSII) and photosystem I (PSI) which are connected electrochemically in series. Any imbalance in excitation distribution therefore results in less efficient photosynthesis as observed e.g. under natural light quality gradients. To counterbalance these effects photosynthetic organisms developed acclimation mechanisms which redirect the light energy. As a typical long-term response a photosystem stoichiometry adjustment occurs. This requires a controlled change in the expression of genes which encode the constituents of the photosynthetic apparatus. This control is exerted by redox signals from photosynthetic electron transport which govern the expression of plastid encoded PS core proteins. However, all peripheral PS proteins are encoded in the nucleus and their expression has to be adjusted to respective changes of chloroplast genes. Experiments with transgenic tobacco seedlings and transcript profiles from Arabidopsis indicate that the expression of several nuclear genes are controlled by redox signals from photosynthesis representing a new type of the so-called plastid signal.

5.13.1. The novel weapons hypothesis: the role of allelopathy, resistance, and evolution in plant invasions.

R. M. Callaway;
The University of Montana, Missoula, MT, United States.

When introduced to new habitats by humans, some plant species undergo astounding increases in dominance. Some invaders may transmogrify because they possess novel biochemical weapons that function as powerful allelopathic agents or as mediators of new plant-soil microbial interactions - the Novel Weapons Hypothesis. My colleagues and I have found that allelopathy appears to be an important mechansim by which *Centaurea maculosa* suppresses native species, and that North American species are more susceptible than related European species. Surviving individuals from North American communities have higher tolerances to the Eurasian invader than individuals from communities that did not experience invasion. Some native species grown from the seed of individuals that survived *Centaurea* invasion are more resistant to the competitive effects of *Centaurea*, root exudates from *Centaurea*, and to a chemical specific to *Centaurea*, (±)-catechin. Such effects have implications for plant invasions and the organization of plant communities. Evolved tolerance may ultimately contribute to coexistence among natives and invaders.

5.13.2. Plant root exudates: a novel source of interesting allelochemicals

L. A. Weston;
Cornell University, Ithaca, NY, United States.

Plant root exudates are novel sources of allelochemicals. Using a modified capillary mat system, we collected quantities of root exudates and chemically characterized their constituents. *Sorghum* and *Festuca* spp. produce quantities of bioherbicidal constituents in their root exudates. Sorghums release sorgoleone, a long chain hydroquinone, from living root hair cells. Its MOA in plant growth inhibition includes inhibition of electron flow in photosynthesis and respiration and inhibition of plastoquinone biosynthesis. We have recently characterized a key gene involved in sorgoleone biosynthesis, the SOR 1 gene, a novel desaturase gene. *Festuca* species produce simple novel organic structures with an MOA that involves the inhibition of root cell division or mitosis. Fescue exudates are contained in osmiophilic inclusions in living fibrous root cells. Newer cultivars of fine fescues representing *Festuca rubra* and other *Festuca* spp. provide nearly complete weed suppression of major turf weed species. Further selection and modification of fine fescue weed suppressive potential is underway using both traditional and molecular approaches.

5.13.3. Retarded reforestation: A consequence of the allelopathic potential of invasive Umbellifereae?

M. H. Meister[1], M. Kaligaric[2], S. Skornik[2], N. Oschgan[1], N. Sajna[2], H. R. Bolhar-Nordenkampf[1];
[1]Ecocenter, Department of Ecophysiology and functional Anatomy of Plants, Vienna, Austria, [2]Biology Department, Faculty of Education, University of Maribor, Maribor, Slovenia.

During the 20th century in parts of Europe socio-economic trends caused large-scale land-use changes. Especially the forest belt of Central Europe was abandoned and consequently subjected to secondary succession. A site in Slovenia with extremely invasive and competitive umbellifers, *Laserpitium siler* and *Grafia golaka* - tall herbs are very common in those post-grassland stages -, was chosen to test the hypothesis that umbellifers do not promote reforestation, but, due to the potential allelopathic effect, slow down the succession by self-promotion. Bioassays showed significant inhibition of germination and early ontogenetic development of *Linum perenne, Lepidium sativum* and *Festuca rubra* seeds, when treated with extracts or plant organs of umbellifers. Vegetation history of the site was reconstructed with aerial photographs for the last 50 years and a progression of *Pinus sylvestris,* uncommon in montane karst area, was perceived. Germination tests demonstrated that *Pinus* seeds were negatively affected, but the development of seedlings was not retarded. An explanation could be based on the same essential oils present in *Laserpitium, Grafia* and *Pinus.*

5.13.4. Rice straw: allelopathic potential and effect on herbicide efficacy

S. Kaushik;
University of Delhi, Delhi, India.

Unharvested rice (*Oryza sativa*) is often left in the fields. While preparing their field for next season crop, farmers generally incorporate rice straw (burned and/or unburned) into soil. Incorporation of rice straw into soil may have allelopathic interference to the seedlings of next season crops and adversely influence the performance of soil-applied herbicides. My ongoing research cautioned against certain agricultural practices employed in wheat-rice cropping systems of Northern India. The objectives of the study are to examine: (i) allelopathic potential of rice straw against certain crop species and weed species, and (ii) effect of rice straw incorporation into soil on phytotoxicity of soil-applied herbicides such as isoxaflutole. Results indicate the allelopathic growth suppression of mustard seedlings in soil amended with unburned rice straw; however, effects were eliminated/minimized in soil amended with burned rice straw. Phytotoxic activity of isoxaflutole, a soil-applied herbicide, disappeared when added to soil amended with burned rice straw.

5.13.5. Genetics and biochemistry of the *Sorghum* spp. allelochemical sorgoleone

S. O. Duke, S. R. Baerson, D. D. Cook, F. E. Dayan, Z. Pan;
USDA, ARS, University, MS, United States.

Several species of *Sorghum* are known to be allelopathic. The root hairs of *Sorghum* spp. produce and secrete sorgoleone and several structurally related compounds that act as allelochemicals. An EST study was performed for sorghum root hair cells, and putative candidates were found for genes encoding the four types of enzymes expected to be involved in the final steps of sorgoleone biosynthesis: a fatty acid desaturase (FAD), a polyketide synthase (PKS), a P450 monooxygenase (P450), and an O-methyltransferase (OMT). There were three or four candidate genes for each of these enzyme classes, and each was expressed 10- to 1000-fold more in root hairs than in other sorghum tissues. Heterologous expression of candidate FAD, PKS, and OMT open reading frames produced functional enzymes with substrate specificities that suggest a potential role in sorgoleone biosynthesis. The next step will be to determine if sorgoleone biosynthesis can be manipulated by altering the expression of these genes. If so, this will be an important tool in probing the chemical ecology of sorgoleone.

5.13.6. Competition and allelopathy in native and invasive populations of garlic mustard

D. Prati[1], O. Bossdorf[2];
[1]UFZ-Centre for Environmental Research Halle, Halle, Germany,
[2]SUNY Stony Brook, Stony Brook, NY, United States.

To test the hypothesis of higher competitiveness in invasive North American populations of garlic mustard, we set up an experiment containing matrix communities with either European or American species to which garlic mustard of either European or American origin was planted. To distinguish competition from allelopathy, activated carbon (AC) absorbing allelochemicals was added to half of the replicates. Invasive garlic mustard did not grow better than native ones. Instead, plants were adapted to the local community:

American garlic mustard grew better in the American than in the European community, while European garlic mustard grew better in the European than in the American community. But when AC was added, garlic mustard of either origin performed better in their respective foreign community. No direct effect of AC on the growth of any species was found, suggesting that AC suppressed chemical interference among species. These results contradict the hypothesis that invasive populations evolved higher competitiveness. Rather, local adaptation to the respective community highlights the importance of belowground interactions for community structure.

5.13.7. Implications of allelopathy in pest management

P. C. Bhowmik;
University of Massachusetts, Amherst, MA, United States.

In nature, plants produce allelochemicals which represent a vast diversity of compounds with a variety of biological activity. Such compounds are released directly or indirectly from live or dead plants into the environment through various processes, and may favorably or adversely affect co-occurring plant species. There have been considerable efforts in exploring allelopathic principles in designing alternative strategies in pest management practices. I will illustrate certain examples for the management of weeds, insects, and plant diseases. Use of cover crops and allelopathic crop cultivars in weed management will be highlighted. An attempt will be made to demonstrate if allelopathic crops or cover crops can be used to limit or reduce the use of conventional herbicides. Low activity, high cost, and narrow-spectrum selectivity of allelochemicals may pose limitations in developing successful weed management systems. With current sophisticated molecular and biotechnological tools, the concepts of allelopathy can be better exploited in the future to provide novel pest management programs.

5.13.8. Allelopathy of aquatic photoautotrophs

E. M. Gross;
Limnological Institute, Konstanz, Germany.

Allelopathy, either positive or negative biochemical interactions among plants or between plants and microorganisms (*sensu* Molisch 1937), has frequently been observed in aquatic photoautotrophs, both in marine and freshwater systems. Especially the inhibition of competitors is apparently an adaptive trait for many aquatic cyanobacteria, algae or higher plants. Several allelopathically active compounds have been isolated, yet, unequivocal field evidence for allelopathic interactions is still missing. Frequently the mode of action of active compounds is targeted on photosynthesis or extracellular enzymes, and one compound may affect multiple physiological processes. In the search for allelopathic interactions, proof for the release of active compounds, transfer to and effect on target organisms are required. Environmental conditions (light, nutrient availability) may strongly influence the strength of the interactions. Little is also known about the fate of exuded active compounds in the aquatic environment, microbial degradation, photochemical derivatization or else. Results from our model system *Myriophyllum spicatum* will be presented.

5.13.9. Cyanobacterial defence against grazers: inhibitors of digestive hydrolytic enzymes

F. Jüttner;
Limnological Station, Kilchberg, Switzerland.

Pelagic and benthic cyanobacteria are heavily grazed by crustaceans, snails, insect larvae, protozoa and other organisms. As in higher plants, physical and chemical defence mechanisms were developed by cyanobacteria to reduce the grazing pressure on them. Screening assays conducted with axenic and monoxenic strains of cyanobacteria showed the wide occurrence of trypsin-, chymotrypsin- and glycosidase-inhibiting compounds. These compounds essentially reduce the digestibility of macromolecules and hence are efficient means to control the development of grazers. The protease inhibitors were cyclic peptides and depsipeptides and the glycosidase inhibitor was an iminosugar. The inhibitors were effective in the nM to ÂµM range. The efficiency of the inhibitors and the amounts stored in the cyanobacteria are sufficient to essentially reduce the digestion of organisms in the gut of grazer. Even when these cyanobacteria are only minor food constituents, the inhibitory activity is strong enough to suppress digestion.

5.14.1. Tree reaction on stress factors - concept and results of 20 years ICP Forests

J. Eichhorn;
Hessen Forst FIV, Hann Münden, Germany.

In 1985, the fear of a large scale forest decline in Europe and the uncertain role of air pollution were driving forces to establish the International Co-operative Programme on the Assessment and Monitoring of Air Pollution Effects. Mid of the eighties, mountain forests of the Czech Republic showed a disintegration of forests, decrease in its production functions, failure of its ecological and environmental functions and disappearance of tree species genetic ressources. This has had immense ecological and social consequences (PERINA, 1984). An European wide awareness of forest condition issues was generated. Tree reaction on stress factors is a core concept of ICP Forest, the largest biomonitoring programme worldwide. The Ministerial Conference on the Protection of Forests in Europe (MCPFE) has chosen defoliation as an indicator for forest health and sustainable forest management.Today´s ICP forest Level 1-concept on the assessment of visible tree condition fulfills the ecological requirements to evaluate tree vitality. Quality assurance has been a matter of particular concern in the biological part of the ICP Forest programme. In order to detect, discuss and manage differences in methods applied by the countries inter-calibration courses are beeing offered annually. As an additional measure standardized photos of tree crowns were circulated by postal mail. The digital image analysis system CROCO gives reference values for each photo. The health of forests may be heavily influenced by biotic agents or pathogenes, such as insects or fungi. Therefore, in 2004 the submanual of crown condition assessment has been revised substantially.

5.14.2. Nutritional state of trees monitored in ICP Forests programme

P. Rautio[1], A. Fürst[2];
[1]Finnish Forest Research Institute, Parkano, Finland, [2]Federal Research and Training Centre for Forests, Natural Hazards and Landscape, Vienna, Austria.

The nutritional status of trees often indicates specific processes in the ecosystem. Inadequate nutrient supply may be a direct cause of low tree vitality or a factor that increases adverse effects of air pollution. High concentrations of certain elements in foliar tissues may be the effect of intoxication or of high air-pollution levels. Foliar sulphur concentrations followed annually since 1987 on 36 Finnish and 71 Austrian ICP Forests Level I plots have been low throughout the monitoring period. Even at this low level, the proportion of trees in the medium and high sulphur concentration classes have decreased reflecting the drastic reductions in sulphur emissions from 1980's to the present. Generally foliar N concentrations in these Finnish and Austrian plots have remained low especially in Austrian forest located in Alpine regions. Nutrient ratios detected in the monitored trees have indicated generally well-balanced nutritional status. Considering the whole Europe in half of the 109 Level II plots, which provided necessary information for calculations, unbalanced nutrition caused by high nitrogen deposition have been observed.

5.14.3. Biodiversity state and monitoring of forest ecosystems in Europe: the ICP Forests initiatives

B. Petriccione;
National Forest Service, Roma, Italy.

In the frame of the ICP Forests biodiversity test-phase and anticipating the new tasks required by Regulation (EC) n. 2152/2003 *Forest Focus*, a first biodiversity survey has been carried out in some selected Level II EU/ICP Forests permanent plots in 2004 and 2005, in the framework of the Pan-European project *ForestBIOTA*, joint project by 14 European Countries, based on 123 EU/ICP Forests permanent plots. The key parameters, assessed at stand level, include (1) vegetation, (2) epiphytic lichens, (3) stand structure, (4) deadwood, (5) insects communities, (6) naturalness and (7) landscape biodiversity. Methods for field surveys follow that adopted by the ICP Forests Working Group on Biodiversity in 2003. First results show that: (1) in very short time and relatively not expensive costs is possible obtaining valuable indications on biodiversity status of forest communities; (2) the harmonized methods are reliable and effective; (4) the surveyed forest communities have shown very high values for nature conservation; (5) qualitative results of surveys are very important to increase the basic scientific knowledge.

5.14.4. Plant diversity as an aspect of forest condition in the UNECE ICPForests programme.

R. Canullo[1], D. Aamlid[2], J. Dobremez[3], B. Petriccione[4];
[1]Dept. Botany and Ecology, Camerino University, Camerino, Italy, [2]Norwegian Forest Research Institute, Oslo, Norway, [3]LECA, Université de Savoie, Le Bourget du Lac, France, [4]National Forest Service, Ministry for Agriculture and Forestry Policies, Rome, Italy.

Intensive monitoring plots of the ICPForests gathered an amount of data about the ground vegetation in forest ecosystems throughout Europe. Each Country, applying different field techniques, conform to common rules of procedure, under the suggestions of a dedicated Expert Panel which implemented a Unified Coded Flora and comparability targets. Data series are foreseen to contribute to: definition of the forest ecosystem state and changes evaluation; assessment of the specific plant diversity at the ecosystems level. The contribution to scientific knowledge and to Global and Pan-European biodiversity initiatives and networks (ICP-IM, MCPFE, CBD, Forest BIOTA, ALTER-net, etc.) are also underlined. In spite of site-related data, first results (more than 670 plots, with large differences in plant diversity) depict the linkages with temperature, precipitation, dominant tree species and actual soil acidity. Nitrogen deposition seems to have some significant influence, which claims to further studies. Plant data series from ICPForest's plot, can be used for on-site confirmation of models including biodiversity k-factors and environment relations.

5.14.5. Effect of environmental pollution on Scots pine stands in Poland: an eleven year survey of mycorrhizal coenosis

M. Rudawska, T. Leski;
Institute of Dendrology Polish Academy of Sciences, Kornik, Poland.

Ectomycorrhizal fungi play an essential role in the forest community and anthropogenic emissions that modify fungal diversity may have ecologically and economically far-reaching effects on forest productivity. The ectomycorrhizal coenosis of Scots pine (P. sylvestris L.) were studied in order to determine how long-lasting but declining environmental pollution (acidification, increased aluminum availability, HF), influence mycorrhizal community structure and growth of P. sylvestris stands. Three different approaches were performed: sporocarp inventories, morphological analysis of ectomycorrhizal roots and molecular techniques based on PCR-RFLP method. Over eleven growing seasons (1992-2002) significant changes was observed in above- and below ground communities of ectomycorrhizal fungi between both tested sites. We will use this data to address the question "does fluctuation in mycorrhizal coenosis affect tree growth and biomass of Scots pine?".

5.14.6. A transect of vegetation and soil along a moist temperate coniferous forest

S. S. Rana;
Institute of Pure & Applied Biology, Multan, Pakistan.

The floristic variation in Asian temperate coniferous forests is poorly understood. Species composition may be either unpredictable as abundance fluctuate randomly, more or less uniform, or it may correspond to environmental heterogeneity. We tested the three hypothesis by studying the floristic variation along a transect that crossed a mixed coniferous forest in Pakistan. Vegetation Data were simplified by Cluster Analysis, Detrended Correspondence Analysis (DCA) and Spearman's Rank Correlation Coefficient was used to detect relationship between environmental factor and species distribution. Soils were physically and chemically analyzed. Plant diversities and assemblage with respect to environmental features in these forests were discussed Results suggested that substrate and tree density were significantly associated with the vegetation variation along the altitudinal gradient.

5.15.1. Implementing the GSPC at national level - progress, problems and opportunities.

S. W. Simiyu;
CBD Secretariat/BGCI, Nairobi, Kenya.

At the sixth Conference of Parties to the Convention on Biological Diversity, the delegates adopted the Global Strategy for Plant Conservation including sixteen outcome- oriented targets. The Parties emphasized that the targets should be viewed as a flexible framework within which the national and/or regional targets may be developed, according to national priorities and capacities, taking into account differences in plant diversity between countries. Further, Parties were invited to develop national and/or regional targets, and as appropriate, to incorporate them into relevant plans, programmes and initiatives, including biodiversity strategies and action plans. However, whilst major efforts have been made at international level to implement the strategy, progress at national level has been slow. The GSPC present a strategic opportunity for the botanical community to contribute to national level processes through innovative linkages and partnerships. The paper discusses the progress in implementing the GSPC at national level, challenges and opportunities and presents potential options.

5.15.2. What does the GSPC require from the world's botanists?

A. Paton, E. Nic Lughadha, M. Johansson, P. R. Crane;
Royal Botanic Gardens, Kew, Surrey, United Kingdom.

The GSPC presents plant diversity specialists with a unique opportunity to connect their work with an internationally agreed priority under the Convention on Biological Diversity, and thus to assert their relevance. However, this privilege comes with a responsibility to make real progress against the 16 outcome oriented targets before 2010. Failure to rise to the challenge will be negative for the future of plant diversity, and also for the future development of our field. Progress will require urgent and concerted action, as well as broad participation among the international botanical community. All of the targets are important, but target 1 - the completion of a widely accessible working list of known plant species - is fundamental. Success in this area will be crucial for progress with many of the other targets. It will also be of great value scientifically, allowing more effective integration of the mass of data already accumulated by centuries of scientific work.

5.15.3. The GSPC and its relationship to the activities of the IUCN Species Survival Commission

W. A. Strahm[1], **J. Smart**[1], M. Maunder[2], D. R. Given[3];
[1]IUCN--the World Conservation Union, Gland, Switzerland, [2]Fairchild Tropical Botanic Garden, Miami, FL, United States, [3]Christchurch Botanic Garden, Christchurch, New Zealand.

The Species Survival Commission (SSC) of IUCN--the World Conservation Union regards the Global Strategy for Plant Conservation (GSPC) as essential for plant conservation. SSC, the world's largest established network of conservation professionals, includes scientists and managers effectively spanning *in situ* and *ex situ* communities. A key product is the IUCN Red List of Threatened Species, and SSC is focussing on improving knowledge of plant conservation status in the Red List (GSPC target 2). With Plantlife International, IUCN is working on identification and conservation of Important Plant Areas (GSPC target 5). The strength of SSC's global conservation network comprising over 1000 botanists in 35 Specialist Groups, linking with IUCN's 1000+ membership of Governments and NGOs, is to compile experience and produce professional manuals and protocols to help plant conservation practitioners and policy-makers throughout the world. Botanists are the fundamental link if the ambitious targets in the GSPC are to be achieved by 2010, and SSC is a mechanism in which IBC participants may contribute to ensure that the plants they study remain for future generations.

5.15.4. Building capacity to implement the GSPC - the Southern African experience

B. J. Huntley;
South African National Biodiversity Institute, Cape Town, South Africa.

Southern Africa possesses an extremely rich flora (ca. 30 000 taxa) in ecosystems ranging from desert to rainforest. In 1994, the ten countries of the region established a capacity building network (SABONET) with strong support from national governments and donor agencies. SABONET has contributed significantly to reaching GSPC targets 1, 2, 3, 5, 8, 14, 15 and 16. Training has included 134 in-service trainees in 12 countries, 26 post-graduate fellowships receiving 36 higher degrees, 63 travelling internships between institutions in the region, 3 regional collecting expeditions, electronic databasing of 450 000 herbarium specimens in 17 herbaria, national checklists published for Angola, Botswana, Lesotho, Malawi, Mozambique, Namibia, Swaziland, Zambia and

Zimbabwe; Red Data Lists for all ten countries, publication of a series of comprehensive needs and resource analyses, and regular publication of *SABONET News*. The SABONET project has been underpinned by extensive training and development programmes of the South African National Biodiversity Institute that has focussed on user needs based human resource development over the last decade.

5.15.5. New initiatives from botanic gardens to implement the Global Strategy for Plant Conservation

S. L. Sharrock;
Botanic Gardens Conservation International, Richmond, United Kingdom.

The global botanic garden community, working together with Botanic Gardens Conservation International (BGCI), has been closely involved in the development of the Global Strategy for Plant Conservation, providing key support for its development following the XVI International Botanical Congress in 1999 and campaigning for its ultimate adoption by the CBD in 2002. This community is now fully committed to the implementation of the Strategy, as demonstrated by the recent adoption of global botanic garden 2010 targets directly related to the GSPC targets. Botanic garden networks around the world are also developing 2010 targets at national and regional levels. Examples of these targets are provided. BGCI, through the HSBC-funded Investing in Nature programme, is supporting implementation of the GSPC, both through in-country programmes with botanic gardens and through support to the CBD Secretariat. New BGCI in-country programmes focus on both conservation and education activities and are being implemented in countries in Asia, North, South and Central America, the Middle East, Africa and Russia. Examples of these programmes are provided.

5.15.6. Developing and implementing a national plant conservation strategy in Colombia

A. Gómez-Mejía;
Colombian Botanic Gardens Network, Bogota, Colombia.

The Colombian Strategy for Plant Conservation was created five years ago by 18 private and public organizations. The result of its work was an ambitious but realistic document outlining a plan to conserve Colombia's hugely diverse flora. The five thematic axes included in the strategy are investigation, monitoring and handling of the information, conservation in situ and ex situ, use and handling of the plants, education and public understanding and invigoration and inter-institutional cooperation. However the results have been not yet been as positive as we hoped they would be. Many native plants are disappearing and so now Colombian institutions are starting a large multi-stakeholder project, to save 2,500 threatened plants of Colombia . We need international cooperation to achieve the project aims.

6.1.1. How do plants cope with abiotic stress?

D. Bartels;
Institute of Molecular Physiology and Biotechnology of Plants, Bonn, Germany.

Abiotic stresses especially drought and salinity are the primary causes of crop loss worldwide. To maintain growth and productivity plants have developed adaptive mechanisms to tolerate stress. Drought, salinity and extreme temperature are often interconnected and can lead to similar cellular damage. As a consequence, similar signalling pathways are activated.

This presentation will focus on dehydration stress. Desiccation-tolerance, the ability to recover from almost the complete loss of cellular water, is part of the normal developmental programme of higher plants and is acquired during seed maturation, but lost during germination. Resurrection plants are a small group of plants which tolerate desiccation in vegetative tissues. Resurrection plants are an excellent experimental system to investigate the molecular basis of desiccation tolerance in vegetative parts of plants. The molecular basis of desiccation tolerance will be discussed in comparison to dehydration responses in non-tolerant plants and under evolutionary aspects.

6.1.2. Genetic and molecular dissection of adaptive responses to progressive drought

S. Merlot, M. Riera, Y. Redko, C. Valon, F. Fenzi, J. Giraudat, **J. Leung**;
Institut des Sciences du Végétal, Gif-sur-Yvette, France.

Drought adaptation involves dynamic adjustments of many cellular processes including gene expression profiles to modifications of growth patterns to optimize water usage. These processes are known to be regulated by ABA-dependent and ABA-independent signalling pathways. The most robust and immediate response is stomatal closure to limit water loss through transpiration (>95% of the water loss). Transpiration cools the leaf surface and the ensuing changes in temperature can be monitored by remote infrared thermography. Our laboratory has exploited this non-invasive technology to systematically isolate mutants that fail to close the stomatal pore as a means to identify genes specifically mediating adaptive responses to progressive drought. Among mutations belonging to six complementation groups, we have cloned the corresponding genes for two of them. One is the OPEN STOMATA 1 (OST1) which encodes an homologue of the AMP-activated kinase family. The OST1 activity is stimulated by low humidity and exogenous application of ABA. To understand its role in a biological context, our recent effort has been directed toward identifying downstream targets.

6.1.3. Functional Genomics of the heat stress transcription factor (Hsfs) family of *Arabidopsis*

P. von Koskull-Döring;
Botanical Institute, Frankfurt am Main, Germany.

Heat stress transcription factors (Hsfs) are the major regulators of the plant heat stress response. Sequencing of the *Arabidopsis* genome revealed the existence of 21 ORFs encoding putative Hsfs assigned to classes A, B and C. Here we present results of a functional genomics approach focused on the analysis of their C-terminal domains harboring conserved modules for their function as transcription factors and their intracellular localization. Short peptide motifs enriched in aromatic and large hydrophobic amino acid residues embedded in an acidic surrounding (AHA motifs) are essential for transcriptional activity of class A Hsfs. We provide also evidence for the function of a leucine-rich region at the very C-terminus as a nuclear export signal (NES) of class A Hsfs. Microarray analysis demonstrates that all 21 Arabidopsis Hsfs are expressed on the transcript level which is changed specifically in response to a variety of environmental stresses and/or developmental signals. This indicates rather specific than redundant functions for each Hsfs being integrated in diverse signaling pathways.

6.1.4. A Role for glycogen synthase kinases in plant stress signaling

M. Wrzaczek[1], W. Rozhon[1], E. Petutschnig[1], S. Kempa[1], J. Haselmayer[1], A. Verhounig[1], H. Hirt[2,1], **C. Jonak**[2,1];
[1]Max. F. Perutz Laboratories, University of Vienna, Vienna, Austria,
[2]Gregor Mendel Institute, Austrian Academie of Science, Vienna, Austria.

Plants encounter various environmental stresses. Plants respond to these threats with an array of events starting with signal perception, followed by subsequent intracellular signal transduction to finally induce a proper physiological response. Protein phosphorylation is pivotal for intracellular stress signaling. Members of the family of glycogen synthase kinase 3 (GSK-3) regulate numerous signaling pathways and homologues can be found in all eukaryotes. We are focusing on the role of GSK-3/Shaggy -like kinases (GSKs) during plant stress signaling. The activity of distinct alfalfa GSKs is modulated during the immediate response to different stresses. Wounding activates WIG (wound-induced GSK). Treatment of plant organs with cellulase or the herbicide paraquat regulates MsK1 activity levels and overexpression of MsK1 affects plant stress tolerance. Genetic and biochemical data indicate that MsK4 plays a role in salt stress adaptation. MsK4 activity is induced by high salinity. Overexpression of MsK4 enhances plant resistance to high salt stress and modulates the levels of specific metabolites.

6.1.5. Characterization of the calcium dependent protein kinase CPK3 from *Arabidopsis*

N. Mehlmer, C. Kolowrat, E. Scheikl, **M. Teige**;
Department of Biochemistry, Vienna, Austria.

Calcium signaling is a central mechanism in plants to regulate responses to diverse environmental stimuli. Plants have evolved a special grup of Calcium dependent protein kinases, the CPKs. 34 CPK genes were predicted from the genomic sequence of *Arabidopsis thaliana*. We have started to characterize the Calcium dependent protein kinase CPK3 (At4g23650) from *Arabidopsis.* We used expression of YFP fusion proteins in *Arabidopsis* leaf protoplast to analyze its subcellular localization. In contrast to the results of Damann et al. (2003), who studied the localization in roots, we observed a localization to membranes and the chloroplast. Furthermore, we analyzed *cpk3* knockout mutants and *35S::CPK3* overexpressor plants, expressing either the wild type or a loss-of-function allel of CPK3, for phenotypes under different growth conditions. In order to isolate potential CPK3 targets yeast two-hybrid screens were performed. In addition we used transient transformation of Arabidopsis protoplasts to study activation of CPK3 kinase activity in response to various external stimuli.

6.1.6. The two strategies of plants to cope with chronic low dose irradiation

D. M. Grodzinsky;
Institute of Cell Biology and Genetic Engeneering of the National Academy of Sciences of Ukraine, Kiev, Ukraine.

The adaptive responses of plants to an increase in radioactivity of environment were established in radiobiological researches carried out in the Zone of the Chernobyl Nuclear Power Station. It has been shown that there are two types of adaptive strategies to the environment contaminated with radionuclides, namely ontogenetic and phylogenetic strategies. The ontogenetic adaptive strategy is attained by induction of DNA reparation. Increasing of the genetic variability in irradiated population performs the phylogenetic adaptive strategy. The mechanism of this strategy is associated with induction of genetic instability. Rise in the frequency of genetic recombination as well as heterozygosity is at the time essential components of phylogenetic adaptation. Ontogenetic and phylogenetic adaptation strategies are an important feature in coping of plants to the elevated chronic irradiation. Most likely plant cells as a stress signal into adaptive responses perceive the low doses of irradiation.

6.2.1. The use of genomic tools to examine the responses of *Chlamydomonas reinhardtii* to its environment.

A. Grossman[1], C. S. Im[1], J. Moseley[1], S. Eberhard[2], S. Pollock[1], W. Pootakham[1];
[1]Carnegie Institution, Dept Plant Biology, Stanford, CA, United States, [2]Stanford University, Dept of Biology, Stanford, CA, United States.

We have used cDNA- and oligonucleotide-based microarrays to explore the acclimation of the unicellular, green alga Chlamydomonas reinhardtii to changes in both light intensity and quality, and to sulfur and phosphorus starvation. In one study, we have investigated the role of the PHOT1 photoreceptor in blue light regulation of gene expression and in the coordination of genes encoding LHC polypeptides and enzymes needed for chlorophyll and carotenoid biosynthesis. Extensive work has also been performed on sulfur and phosphorus limitation. While nutrient deprivation strongly influences functions involved in scavenging the limiting nutrient (e.g. expression of specific transporter genes), starved cells must also stop division, arrest growth and control metabolic processes. Sulfur and phosphorus eprivation caused dramatic changes in the activities of genes encoding proteins involved in acquiring and utilizing sulfate and phosphate, respectively, as well as in the activities of genes involved in key metabolic processes such as photosynthesis. Several mutants have been isolated that are not able to acclimate to nutrient deprivation; many of these strains die in the light as nutrient levels decline. This 'death' phenotype may reflect the inability of these cells to properly coordinate aspects of the photosynthetic electron flow (and the elimination of excitation pressure) with the potential for cell growth. My talk will focus on the use of genomic technologies to dissect acclimation responses of C. reinhardtii, and the results acquired with these technologies will be discussed with respect to the physiology of photosynthetic organisms under changing environmental conditions.

6.2.2. Extracellular thiol protease sensitizes the dinoflagellate *Peridinium gatunense* to oxidative stress thus synchronizing their cell death

A. Kaplan[1], A. Vardi[1], D. Eisenstadt[1], O. Murik[1], I. Berman-Frank[2], A. Levine[1];
[1]The Hebrew University, Jerusalem, Israel, [2]Bar Ilan University, Ramat Gan, Israel.

The phytoplankton population of Lake Kinneret is characterized by an annual winter-spring bloom of a dinoflagellate, *Peridinium gatunense*. We showed that CO_2 limitation initiate its collapse within a couple of weeks in early summer. This is mediated by oxidative stress and activation of cysteine proteases. Aging of the *Peridinium* cells resulted in DNA fragmentation and enhanced sensitivity to oxidative stress. This was accompanied by a rise in the intracellular and extracellular specific protease activities. Exposure of young *Peridinium* cells to media from older cultures enhanced their sensitivity to oxidative stress, and led to massive cell death, suggesting presence of a conditioning factor in the spent media from old cultures. Inhibition of protease activity in this media suppressed the sensitivity to oxidative stress and the resulting H_2O_2-induced cell death. In contrast, addition of papain, to the young cultures increased cell death. We show that a protease excreted by the older cells sensitizes the younger cells to oxidative stress, thereby coordinating the crash of the entire *Peridinium* population, young and old cells alike, at the end of the bloom.

6.2.3. In-situ physiology of algae by means of single cell techniques

C. Wilhelm;
University Leipzig, Institute of Biology I, Department of Plant Physiology, Leipzig, Germany.

The primary production in the aquatic environment is basically influenced by the availability of light and nutrients and the physiological activity of the phytoplankton community. The physiological activity of the phytoplankton cells depends on the genetic diversity of the cell assemblage and on the acclimation state of the species. Biodiversity can be measured by means of microscopic observation or via molecular tools, whereas physiological parameters can be measured only on the community level. Recent progress in single cell techniques allows to collect detailed physiological information with a rather high taxonomic resolution. It is shown how the combination of in-situ hybridization with flow cytometry, absorption, fluorescence and FT-IR spectroscopy can be used to quantify the contribution of different taxa to carbon acquisition and nutrient usage.

6.2.4. Iron uptake and homeostasis in marine diatoms

J. LaRoche[1], M. R. McKay[2];
[1]Leibnitz-Institut für Meereswissenschaften, Kiel, Germany, [2]Bowling Green State University, Bowling Green, OH, United States.

Iron (Fe) is an essential element for all organisms, including oceanic phytoplankton. However in the open ocean, the concentration of dissolved Fe is low (10-400 pM) since the main redox species, Fe(III) is poorly soluble at seawater pH. Mesoscale *in situ* Fe addition experiments in high nutrient, low chlorophyll regions have demonstrated that diatom production is limited by Fe availability. Diatoms are particularly important because of their ability to promote the oceanic sequestration of CO_2 through enhanced export of diatom biomass below the euphotic zone. Despite the importance of Fe for diatom growth, we know little about Fe uptake systems or Fe-regulated genes in diatoms. The sequenced genome of *Thalassiosira pseudonana* identified Fe uptake systems similar to those found in yeast. Data on the expression of Fe-regulated genes as a function of dissolved Fe concentration combined with physiological measurements are used to characterize the survival response to Fe limitation.

6.2.5. High affinity iron transport in *Chlamydomonas reinhardtii*

T. J. Buckhout, I. Reinhardt, N. Jungnick;
Applied Botany, Humboldt University, Berlin, Germany.

Using electrophoretic separation and mass spectrometric analyses, we have identified plasma membrane polypeptides, frequently of unknown function, whose synthesis and/or degradation were altered under Fe deficiency. In some cases however, the expression of the corresponding genes to these unknown proteins was regulated by Fe in a similar manner to FLP (Fox1). Fox1 encodes a ferroxidase and is known to participate in Fe uptake. RNAi analysis using a portion of Fox1 resulted in greatly reduced transcript for Fox1 and synthesis of Fox1p. However, high affinity Fe transport was reduced by only ca. 50%. In addition, a membrane protein was identified that was synthesized de novo under Fe deficiency and showed distinct sequence homology to Fe(III)-chelate reductases (e.g. Fro2 and FRE1). Although the mechanism of Fe uptake at the plasma membrane of Chlamydomonas resembles Saccharomyces, there are also likely other high affinity transport systems present.

6.2.6. Channelrhodopsin, a hybrid light sensor in green algae

P. Hegemann[1], S. Kateriya[1], P. Berthold[1], G. Nagel[2], D. Gradmann[3];
[1]Humboldt-Universität zu Berlin, Berlin, Germany, [2]Universität Würzburg, Würzburg, Germany, [3]Universität Göttingen, Göttingen, Germany.

The green alga *Chlamydomonas reinhardtii* contains two mammalian type rhodopsins with so far unknown function and 5 microbial type rhodopsins. Two of the latter, Channelrhodopsin-1 (ChR1) and Channelrhodopsin-2 (ChR2), exhibit light-gated ion channel activity after expression in *Xenopus oocytes* (1,2). ChR1 is highly selective for H^+ whereas ChR2 conducts H^+, Na^+, K^+ and Ca^{2+}. Upon stimulation with light pulses, the photocurrents of both channelrhodopsins partially inactivate before a stationary current is observed, very similar as observed for photocurrents recorded from *Chlamydomonas* eyes. Recovery in the dark is slow but accelerates at negative membrane voltage and low extracellular pH. We have developed a complete model that quantitatively explains light dependence and kinetics of both rhodopsins. Due to the extremely fast activation of the conductance we have proposed that both channelrhodopsins are mediating phobic responses. This conclusion was supported by action spectroscopy for fast photoreceptor currents in *C.reinhardtii* at neutral and alkaline pH and is compatible with electrical measurements on antisense transformants with reduced content of ChR1 (3). The contribution of both ChR1 and ChR2 to phototaxis, especially at low light is still unknown. The expression of the ChR1 and ChR2 is light dependent and possibly under circadian control. Recently, we have found three more microbial rhodopsin sequences in the Genbank of *C.reinhardtii*, which we named Cop5, Cop6, Cop7. All three are coupled to transducer sequences and might be part of a microbial type “two component signaling system”. These new rhodopsins are photoreceptor candidates for phototaxis at low light. 1. Nagel, et al. (2002) *Science* 296, 2395-2398, 2. Nagel, et al. (2003) PNAS 100, 13940-13945, 3. Sineshchekov et al. (2002) *PNAS* 99, 8689-8694.

6.2.7. Organelle interactions and possible degradation pathways in the green alga *Micrasterias* visualized by energy filtering transmission electron microscopy (EFTEM)

U. Lütz-Meindl, N. Aichinger, A. Oertel;
Plant Physiology Division, Cell Biology Department, University of Salzburg, Austria.

Organelle and vesicle interactions are essential for both anabolic and catabolic pathways in plant cells. In this study we investigate structural details of different organelle-organelle, organelle-vesicle and organelle-membrane interactions in *Micrasterias denticulata* cells of different age, by use of high pressure freeze fixation and energy filtering transmission electron microscopy (EFTEM). Contacts between organelles are achieved by formation of a cone-shaped protuberance by one of the compartments which penetrates into its fusion partner. In the same way lytic compartments contact organelles and vesicles by extending their contents into the respective compartment. Detached portions of organelles are found inside lytic compartments as a consequence of such interactions. Fusions between different populations of mucilage vesicles may represent a fast excretion machinery. Partial disintegration of mitochondria upon contact with the plasma membrane point towards a release of these organelles. All organelle, vesicle and membrane contacts observed, occur independently from cytoskeleton function as demonstrated by use of inhibitors.

6.3.1. Root growth, nutrients, soil organisms and soil structure

M. Watt[1], W. K. Silk[2], J. B. Passioura[1];
[1]CSIRO Plant Industry, Canberra, Australia, [2]University of California, Davis, CA, United States.

Roots acquire nutrients from soil and return nutrients to soil as exudates, sloughed cells and decomposing tissue. These processes involve close interaction between roots and rhizospheres, from arrival of a root in a soil volume to its death and decay. Interactions rely on kinematics, soil structure, including the propensity of roots to grow where others have grown before, and dynamics of soil organisms. They have substantial agronomic implications. Here we use wheat to illustrate the principles. Root apices extend rapidly for nutrients or water unless hindered by soil structure or temperature. Extension rates affect root hairs and branches, and rhizosphere microbes via exudates. Remnant roots and rhizospheres provide pathways and inocula that help or hinder new roots. Wheat genotypes vary in growth rates, exudates, and responses to the structure and microflora of unploughed soils. Those adapted grow roots quickly and host less deleterious bacteria and fungi, due in part to residence time on root caps. We use fluorescence *in situ* hybridization of microorganisms on field roots, *in situ* elemental analyses, and time-lapse imaging to quantify these interactions.

6.3.2. Variations in developmental pattern of lateral roots induced by environmental factors: the response to mechanical stress induced by slope.

D. Chiatante[1], G. S. Scippa[2], A. Di Iorio[1], B. Lasserre[2], M. Di Michele[2];
[1]Università dell'Insubria, Como, Italy, [2]Università del Molise, Isernia, Italy.

We show that modifications of root architecture induced by the mechanical stress acting on slope cannot be explained only with the simple reiteration of an intrinsic pattern of lateral root formation which is independent from root-category and -function. Therefore we suggests that in an adult root system, the development of new lateral roots might follow also a different pattern in response to specific environmental signals perceived by the plant. Our findings show that pericycle cells cannot be the only source of initials for lateral root primordial morphogenesis and propose that new ray initials from the cambium might be engaged to provide the source for new root meristem initials. The contemporaneous activity of these two developmental patterns explains why it is impossible to determine in the root system of adult plants the existence of growth units analogous to the phytomers responsible for stem development.

6.3.3. Role of ABA in root growth maintenance under water deficits: prevention of high levels of reactive oxygen species

R. E. Sharp;
University of Missouri, Columbia, MO, United States.

Accumulation of abscisic acid (ABA) is required for root growth maintenance under water deficits in maize seedlings (Sharp 2002, Plant Cell Environ 25: 211-22). To investigate the hypothesis that ABA functions in regulating the antioxidant system to maintain reactive oxygen species (ROS) at non-damaging levels, effects of ABA deficiency in the root growth zone are being studied using the vp14 mutant, fluorescent imaging of ROS levels, high resolution kinematic analysis of elongation rate profiles (van der Weele et al., 2003, Plant Physiol 132: 1138-48), and microarray analysis of gene expression. Under water deficits, ROS levels increase slightly in wild-type roots and dramatically in vp14. The effect of ABA-deficiency is specific to the apical 1-3 mm where cell elongation is normally maintained under water deficits but is inhibited by ABA deficiency. Loss of membrane integrity occurs in the same region of the ABA-deficient roots. Time course experiments indicate that increase in ROS precedes and causes the loss of membrane integrity. Broader implications for the role of ABA in stressed plants will also be discussed. NSF Plant Genome Program, DBI-0211842.

6.3.4. Longitudinal pattern of lateral root initiation: predictable or not predictable? A case study of *Arabidopsis*

J. G. Dubrovsky, A. Hernandez-Barrera, G. A. Gambetta, I. González;
Universidad Nacional Autónoma de México, Instituto de Biotecnología, Cuernavaca, Mor., Mexico.

Lateral root (LR) initiation is considered to occur in an acropetal pattern. We analyzed the longitudinal pattern of LR primordium (LRP) initiation along the primary root in Arabidopsis using two approaches. First, we estimated the density of LRs as a ratio between the number of LRs and the length of the LR-bearing root portion. This approach permitted the evaluation of how LR density is related to the average number of cells between LRPs. We found that in younger roots, the LRP density was similar to the LR density in the region of the root bearing LRs and that in older roots, the LRP density in this zone decreased. The dilemma of delayed or de novo LRP development will be discussed. Second, we estimated the inter-primordial distance expressed in units of length and in the number of pericycle cells. Our data apparently indicate that LRP initiation obeys a pattern of regular spatial distribution, possibly established by inhibition via signals produced by already initiated primordium. This demonstrates that the developmental principle of lateral inhibition may operate during LRP initiation. Acknowledgements: DGAPA, IN 210202 (UNAM), FOSEMARNAT-2004-01-80.

6.3.5. Rhizosphere nitrogen and root development in *Arabidopsis*

P. Walch-Liu, Y. Gan, S. Filleur, **B. G. Forde**;
Dept. of Biological Sciences, Lancaster University, Lancaster, United Kingdom.

Like the rest of the plant, the root system has no pre-defined body plan, rather its development is continuously modified by interactions with environmental factors, including nutrients. We have been studying the role of nitrate in regulating root branching. A MADS box transcription factor (ANR1) is known to be required for the stimulation by nitrate of meristematic activity in the lateral root tip. Current studies are focussed on understanding how ANR1 acts and identifying its downstream targets. We have recently obtained evidence that roots are also capable of sensing and responding to the presence of organic nitrogen in the soil. Arabidopsis root growth was found to be highly sensitive to the presence of external glutamate, but not to the majority of other amino acids. The ability to sense glutamate appears to reside in the root tip itself and is common to both primary and lateral roots. We will discuss our current understanding of the genetic and physiological basis of this phenomenon and its possible relationship to the existence of a family of glutamate receptor genes in plants.

6.3.6. Cytokinin regulates root development and gravitropism

R. Aloni[1], M. Langhans[2], E. Aloni[1], C. I. Ullrich[2];
[1]Tel Aviv University, Tel Aviv, Israel, [2]Darmstadt University of Technology, Darmstadt, Germany.

In roots, cytokinin is mainly produced in the cap. From there, cytokinin is exported upward through the xylem and accumulates in young shoot organs with highest transpiration. Cytokinin has a negative regulatory role in root growth and might function as an inhibitor of tropistic root elongation during early phase of gravity response. In vertically growing Arabidopsis roots the cytokinin in the cap is distributed symmetrically. When roots are turned to a horizontal position, free cytokinin is transported laterally within less than 30 min and becomes concentrated at the new lower side of the cap, where it locally retards elongation of the lower side and promotes elongation of the upper root side. This asymmetrical activation pattern causes the initiation of a downward gravitropic root bending near the root apex. Exogenous application of cytokinin to vertical roots induced bending toward the site of application, indicating that cytokinin has an inhibitory effect in root gravitropism. Our results suggest that early root graviresponse is controlled by cytokinin. We conclude that both, cytokinin and auxin are key hormonal signals which regulate root gravitropism.

6.4.1. Can the geographical distribution help to understand the function of growth forms?

E. J. Jäger;
Institute of Geobotany, Halle (Saale), Germany.

There are different functional approaches of growth forms:
First, the study of the plants in the plant community and succession, e. g. the space conquering (phalanx and guerilla), the competitive ability (c, r, s strategy), the relation to herbivory, and ressource partitioning. Second, to investigate the relation to local site conditions. Here, statistics show the adaption e. g. of runners to sandy or wet soil, of taproots to deep, dry soil. Finally, it is also possible to study the worldwide distribution of growth form characters. The distribution patterns are either connected with the geographical distribution of site conditions (e. g.: root sprouting on bare, eroded, often dry soil; pseudo-annuals in the dark taiga with rare light spots) or with the regional climate, especially with the length and the conditions of the growth period. There are some published examples (stem succulents, thorny cushions, lianas). Some others will be discussed in detail: bulbs ant tubers, rosulate/erosulate and monopodial/sympodial growth. This “Raunkiaerian approach” reveals evolutionary advantages of the special character beyond mere speculations on the function.

6.4.2. Bud morphology and shoot growth dynamics in two species of Mediterranean sub-shrubs co-existing in gypsum outcrops.

S. Palacio, R. Milla, G. Montserrat-Martí;
Instituto Pirenaico de Ecología (C.S.I.C.), Zaragoza, Spain.

Understanding the effects of the environment on the morphology and shoot growth activities of plants is crucial to identify plant ecological strategy. This study analysed the bud morphology, bud activity, shoot growth dynamics and shoot water content at full hydration (WC_h) of two species of Mediterranean sub-shrubs, *Lepidium subulatum* and *Linum suffruticosum*, co-existing in gypsum outcrops in NE Spain. Both species bore naked buds and displayed discontinuous seasonal patterns of shoot growth, leaf primordia formation and WC_h as a result of the strong seasonality of Mediterranean climate in gypsum outcrops. The number of leaf primordia in the bud peaked before the beginning of shoot expansion. In both species, organogenesis and expansion were uncoupled throughout the year. The time lapse between these two processes varied throughout the year, and was greatest for those elements differentiated in autumn. The beginning of the spring period of expansion of long branches coincided with maximum values of WC_h, while the rest period of summer matched minimum values. These results support the hypothesis that the growth of long branches and WC_h are strongly related.

6.4.3. Finding the Center of a Phyllotactic Pattern

S. G. Hotton;
University of California - Merced, Merced, CA, United States.

An important quantity characterizing a phyllotactic pattern is the divergence angle, i.e. the angle between primordial that form consecutively. This angle often varies only slightly about some particular value as the plant develops. The calculation of divergence angles between primordia in shoot apical meristems (SAMs) depends on the point used as the center of the SAM. The field of phyllotaxis has been challenged by the diversity of shapes that SAMs can have. In mathematically ideal phyllotactic patterns, the center is well defined but there has not been a precise definition for the center of naturally occurring phyllotactic patterns. A few techniques have been proposed for estimating the location of the center but without a precise definition for the center the accuracy of these methods cannot be analysed. In this talk I will present a precise definition that can be used as the center of a phyllotactic pattern and anumerical method which can accurately find this point. This helps lay the groundwork to objectively compare theory against experiment for a more general class of phyllotactic patterns.

6.4.4. Plant architecture of Gentians - a source for taxonomy and evolutionary biology

G. Karrer, N. Davitashvili;
Institute of Botany, Department of Integrative Biology, University of Natural Resources and Applied Life Sciences, Vienna, Austria.

The genus *Gentiana* L. is rich in species and in different growth forms as well. Although some authors already stressed the relevance of detailed growth form characters for the taxonomy of Gentians, such traits are not yet fully implemented in the common taxonomical concepts. Even in the newly published worldwide revision of the genus *Gentiana* the authors did not utilise this character set with its full accuracy of discrimination. Despite of the low number of well dissected specimens in herbariums and the low availability of fresh material in many taxa, we provide an overview on crucial growth form characters that should be used to achieve a better resolution of the subgeneric classification of Gentians. Besides the already accepted value of basic architectural traits like monopodial or sympodial branching we emphasise the taxonomical power of further morphological characters (i.e. leaf dimensions, longevity and longitudinal dispersion; root system) for inter and intrasectional classification and evolution processes in *Gentiana*.

6.4.5. The rare and valuable species of the sort of Gentiana L. and the methods of their preservation

N. Y. Yavorska[1], V. P. Yevtukh[2], N. Y. Yavorska[1];
[1]the Ivan Franko Lviv National University, Lviv, Ukraine, [2]the Danylo Halytskyi Lviv State Medical University, Lviv, Ukraine.

As a result of worsening ecological situation, increasing of anthropogenic influence the area of the rare, valuable species of plants has been much narrowed that caused to the threat of their disappearing. The reintroduction is one of the methods of preservation of these species in nature. During 1998-2000 in the Botanical Gardens of the Ivan Franko Lviv National University carried out investigations of the rhythm of growth and development of Gentiana lutea, Gentiana cruciata, Gentiana punctata. As a result of investigations was estimated that these species have the stable rhythm of development in the conditions of introduction. The last is evidence of the good adaptation of these species. Reproduction is going on the generative or vegetative ways. The optimal date of the seminal sowing are October, planting - August-September. Sowing seeds in spring it is necessary to make stratification during 60-90 days.There is perspective the reproduction of these species of the sort of Gentiana under the conditions in vitro because they are micorysmus and characterized by longtime generative cycle.

6.5.1. Shoots and leaves, an evo-devo perspective

N. R. Sinha, C. Champagne, K. Chung, B. Townsley, H. Garces, S. Seiki, D. Kelley;
University of California, Davis, Davis, CA, United States.

The Class I Knotted-like homeobox (KNOX 1) genes are highly expressed in the shoot apical meristem but not expressed in the emerging leaf primordium in tobacco, maize, or *Arabidopsis*. We have analyzed compound leaf producing shoot apices in clades with independently derived compound leaves and shown that with one exception (a derived clade in the Fabaceae) compound leaves always show expression of KNOX genes (Bharathan et al., 2002). In the derived pea clade the LFY/FLO gene regulates this function of generating leaf complexity. We have explored the function of LFY in the basal and derived clades in the Fabaceae. In addition, we find that other genes like PHANTASTICA might play a role in determining the form of the compound leaf generated. Global gene expression differences between simple and compound leaves are also being analyzed using *Neobeckia aquatica* RNA on the *Arabidopsis* gene chip. In addition, we are exploring the evolution of KNOX genes and their role in shoot morphology across Angiosperms. This research is funded by the National Science Foundation.

6.5.2. Evolution of morphological flexibility in Lentibulariaceae

R. W. Jobson;
Department of Ecology and Evolutionary Biology, University of Michigan, 830 North University, Ann Arbor, MI, United States.

The Lentibulariaceae (Lamiales) is the largest carnivorous plant family
and has undergone an extraordinary degree of adaptive radiation, with
unprecedented morphological and ecological diversity. The bladderwort lineage (*Utricularia* and *Genlisea*) is substantially more species-rich, phenotypically divergent, and variable in molecular evolutionary rates than its sister lineage, the butterworts (*Pinguicula*). Bladderworts have a relaxed body plan, characterized by apparent rootlessness and indistinct leaf/shoot organogenesis, that has permitted the evolution of terrestrial, epiphytic, lithophytic, and highly varied aquatic forms that capture prey in intricately-designed suction bladders or corkscrew-shaped lobster-pot traps. In contrast, the flypaper-trapping butterworts maintain vegetative structures more typical of angiosperms. The underlying evolutionary mechanisms responsible for the extreme developmental flexibility found in the bladderwort lineage remains elusive. However, future developmental-genetic approaches that target hormonal regulatory pathways, may provide some answers.

6.5.3. Investigations into the genetics and evolution of unusual growth forms in phyllomorphic *Streptocarpus*

A. Spada[1], R. Mantegazza[1], J. Harrison[2], **M. Moeller**[3];
[1]Università degli Studi di Milano, Dip. Biologia Sez. Bot. Gen 3A, Via Celoria 26, 20133 Milan, Italy, [2]Department of Plant Sciences, University of Oxford, South Parks Road, Oxford OX1 3RB, United Kingdom, [3]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

The genus *Streptocarpus* is morphologically highly labile and some species exhibit a drastically reduced plant body. While species belonging to subgenus *Streptocarpella* possess a 'traditional' shoot apical meristem (SAM) and ordinary serial phytomer development, species of subgenus *Streptocarpus* include predominantly unifoliate and rosulate taxa and lack a conventional SAM. Unifoliate taxa possess a single 'phyllomorph' made up of a petiolode, lamina and basal serial inflorescences. Rosulate taxa possess several phyllomorphs. The switch between unifoliate and rosulate morphologies occurred several times in the evolution of the genus. We demonstrate the involvement of developmental genes such as SHOOTMERISTEMLESS (STM) in generating the phenotype of these different growth forms. Moreover, we use gene expression patterns to understand the origin and development of meristems in this complex phyllomorph system.

6.5.4. Unusual organogenesis of *Monophyllaea* and *Guarea* from view point of developmental genetics on leaf morphogenesis of *Arabidopsis thaliana*

H. Tsukaya[1,2,3];
[1]National Institute for Basic Biology, Okazaki, Japan, [2]Graduate University for Advanced Studies, Hayama, Kanagawa, Japan, [3]Graduate School of Science, Kyoto University, Kyoto, Japan.

Guarea spp. and *Monophyllaea spp.* are unusual in having indeterminate leaves. *Guarea* species of Meliaceae have a shoot-apical-meristem (SAM)-like apical meristem (LAM) on the tip of their compound leaves. We found that *Guarea* LAM expresses high level of mRNA of *LEAFY* homolog as much as in the SAM, while primordia of leaflets do not, suggesting that LAM has a part of natures of SAM. On the other hand, the indeterminate leaf of *Monophyllaea* species of Gesneriaceae, called "phyllomorph", is composed of a single leaf lamina and a petiole. A phyllomorph continues to expand the existing leaf lamina by a special meristem in the basal part of the leaf lamina. In dicots, cell proliferating activity is gradually diminished from the apical part of leaf primordia and later stages of leaf expansion are supported by the cell proliferation in the basal part of the leaf lamina. Thus, a phyllomorph can be regarded as a leaf primordia with a prolonged leaf expansion. In *Arabidopsis thaliana,* we found that *bop1* mutant does not cease the cell proliferation in the basal part of the leaf lamina. *BOP1* homolog of *Monophyllaea* may be a key to understand the genetic basis of the phyllomorph.

6.5.5. Did giants evolve from dwarfs? Developmental morphology of *Gunnera herteri*.

L. Wanntorp[1,2], R. Rutishauser[3];
[1]Department of Botany, Stockholm University, Stockholm, Sweden, [2]Department of Systematic Botany, Ludwig Maximilians Institute, Munich, Germany, [3]Institute of Systematic Botany, University of Zurich, Zurich, Switzerland.

The genus Gunnera, mainly distributed in the Southern Hemisphere, includes herbs varying in size, from a few centimetres to several metres. Recently, phylogenetic studies based on molecular and morphological data highlighted the relationship among the species. One of the best-supported results regarded the position of Gunnera herteri at the base of the tree as sister to the rest of the genus. While the other species of Gunnera are rhizomatous or stoloniferous perennials, G. herteri is a tiny annual, differing in these and many other traits from the other species of Gunnera. Rare and with a restricted distribution in Uruguay and Brazil, G. herteri has been seldom collected and its developmental and flower morphology have been poorly known.
Here, we summarize our studies on G. herteri and discuss whether the peculiarities of this plant are autapomorphies connected to the annual habit, or if the ancestral species of Gunnera were actually dwarfs that developed into giants.

6.5.6. Saltational loss of root-shoot bauplan in *Dalzellia zeylanica* (Podostemaceae) with crustose vegetative shoot, compared to closely related *Indotristicha ramosissima* with roots and shoots

R. Imaichi;
Faculty of Science, Tokyo, Japan.

The Podostemaceae are aquatic rheophytes with remarkably specialized morphology. Saltational evolution amplifies the diversity of their morphology as seen in species pairs with distinctly different morphologies. *Dalzellia zeylanica* lacks a root while its shoot is foliose and adheres to rock surfaces. A unique complex meristem at the shoot margin is involved in the coenosomic shoot structure. By contrast, *Indotristicha ramosissima*, sister to *D. zeylanica*, has subcylindrical roots and root-borne, branched shoots. Seedlings of *D. zeylanica* have no obvious primary shoot

and no root; one of two shoots formed in the axils of two cotyledons grows into a secondary shoot. Seedlings of *I. ramosissima* have secondary roots arising from the hypocotyl. The saltational evolution of the *D. zeylanica* bauplan may be due to drastic early ontogenetic changes, such as appearance of secondary shoots in the epicotylar region and loss of the root, as well to modifications, such as flattening and adherence of the shoot compensating functionally for loss of the root.

6.5.7. Concluding statements: Classical plant morphology in the context of dynamic morphology*

C. R. Lacroix[1], R. Rutishauser[2];
[1]University of Prince Edward Island, Charlottetown, PE, Canada,
[2]Institute of Systematic Botany, Zurich, Switzerland.

Classical plant morphology and dynamic morphology represent two theoretical frameworks used to describe and understand the bauplan of vascular plants, especially flowering plants. Generally, plants are interpreted in terms of three mutually exclusive structural categories: stem, leaf, and root. Stem and leaf together constitute a shoot which usually shows axillary branching. According to the classical approach, organ identity can be predicted by its relative position within the plant's bauplan. This model applies to many but not all flowering plants. There are groups with forms that do not clearly fit into the classical model. In these cases, a dynamic morphological perspective may serve as a more encompassing model. It accepts developmental mosaics between stem, leaf, and root. This continuum model was revived during the pre 'EVO-DEVO' period by Agnes Arber, Rolf Sattler, and others. Some of the ideas of this dynamic approach are compatible with results obtained by evolutionary developmental plant biologists. * dynamic morphology = continuum morphology

6.6.1. Late Paleocene floras of North Dakota, USA: New sites and new insights

K. B. Pigg[1], M. L. DeVore[2];
[1]Arizona State University, Tempe, AZ, United States, [2]Georgia College & State University, Milledgeville, GA, United States.

A recently recognized Late Paleocene flora at Beicegal Creek, western North Dakota, USA provides new information about floristic elements known from the classic Almont flora. Whereas the original Almont site yields silicified shale that shows a combination of external morphology and some of the only known anatomical detail for Paleocene plants, the new site offers permineralized remains more similar to the silicified "bog" floras of the Eocene Princeton chert and Miocene Yakima Canyon. In contrast to the surface occurrence at Almont, fossils from Beicegal Creek are found in place and can provide details about depositional environment and stratigraphic relationships. Even outcrops in close vicinity to one another show heterogeneity in both floristic composition and preservation Newly recognized floristic elements occur at this locality, including ferns and an aquatic monocot, and some plants currently known from Almont occur in greater numbers e.g. (Spiromatospermum, Musaceae). The higher level of resolution also allows for greater taxonomic comparison in currently known taxa (e.g., Amersinia, Cornaceae; Paleomyrtinaea, Myrtaceae).

6.6.2. Fossil woods from the Paleogene of Russian far east

N. I. Blokhina;
Institute of Biology and Soil Science FEB RAS, Vladivostok, Russian Federation.

Additional information about plant biodiversity in Russian Far East (RFE) during the Paleogene has been obtained due to the study of fossil woods collected from several sites in Kamchatka, Sakhalin, the Lesser Kuril Islands, Primory'e and Khabarovsk Territory. As a result of the study 30 species assigned to genera: *Podocarpoxylon* (Podocarpaceae), *Abietoxylon*, *Cedus*, *Keteleerioxylon*, *Laricioxylon*, *Piceoxylon*, *Pinuxylon* (Pinaceae), *Metasequoia*, *Sequoioxylon* (Taxodiaceae), *Cupressinoxylon* (Cupressaceae), *Alnus* (Betulaceae), *Engelhardioxylon* (Juglandaceae) were identified; among them 19 species have been described as new ones. Fossil woods studied show mostly a mixing of anatomical features of the extant species growing in Siberia, RFE, Korea, China, Japan or western North America. Fossil woods of the Engelhardioideae and *Cedrus* were found in Russia for the first time, *Alnus* and *Keteleeria* - for the first time in RFE. The Sikhote-Aline has been proposed to consider as a second center of species formation in the *Larix* during the Late Oligocene. The work was supported by the Presidium of Russian Academy of Sciences (grants 05-1-P12-022, 05-1-P25-078).

6.6.3. Origin of early Paleogene deciduous flora in the Pacific Sector of Arctic

M. G. Moiseeva, A. B. Herman;
Russian Academy of Sciences, Moscow, Russian Federation.

The late Maastrichtian age of the Koryak Flora (NE Russia) is established based on correlation of plant-bearing and marine deposits. The Sagwon Flora (North Alaska) is dated as the Paleocene by palynological data. The Koryak Flora has much in common with the Sagwon Flora. Dominant components in both floras are dicots and conifers. The Sagwon Flora of a lower taxonomic diversity includes almost all taxa known in the Koryak Flora. Absence of characteristic Cretaceous taxa indicates a younger age of the Sagwon Flora. The close similarity of these two floras evidences against a hypothesis of a global catastrophic event at the Cretaceous-Paleogene boundary. Development of floras was likely controlled here by climatic fluctuations, evolution and migration of plants. Presumable consequences of meteoritic impacts are recorded in the middle-latitude North America only and have not been global in scale. Floristically and physiognomically the Koryak flora has much in common with Early Tertiary floras of North-eastern Asia and North America. Probably, it was the Koryak flora that gave rise to the Early Tertiary deciduous floras of the Arctic and adjacent regions.

6.6.4. The phytogeographic history of Rhizophoraceae*

J. JIN;
School of Life Sciences, Sun Yat-sen University, Guangzhou, China.

The fossils of 4 genera of Rhizophoraceae, *Rhizophora*, *Kandelia*, *Ceriops* and *Bruguiera*, distributed in the strata of Tertiary to Quaternary in Asia, Europe, Africa, Oceania and America. The fossil record of Rhizophoraceae indicated (1) Rhizophoraceae was highly probable originated in the Tethys seacoast from Paleocene through Early Eocene, and rapidly dispersed to Asia, Europe, Africa, Oceania and America during Middle Eocene; (2) during Oligocene Rhizophoraceae continued to spread in Asia, Europe, Africa, Oceania and America, but it became extinct in Europe since Oligocene; (3) during Miocene Rhizophoraceae became a characteristic taxon across tropical-subtropical seacoast of Asia, Africa, Oceania and America; (4) from Pliocene through Pleistocene Rhizophoraceae reduced markedly, and then began to flourish in Holocene. The distribution pattern and phytogeographic evolution of Rhizophoraceae distribution closely correlated to the continental drift, Quaternary glaciation and global climates changed.
***** The Project Supported by NSFC (No.40342013) and the Foundation of Sun Yat-sen University Advanced Research Centre (No.05A1)

6.6.5. A soboliferous acaulescent palm from the deccan intertrappean beds of India

S. D. Bonde;
Agharkar Research Institute, Pune, India.

A permineralized matured soboliferous acaulescent palm from the Deccan Intertrappean bed exposed at Umaria, District Mandla, M.P., India has been reported. The specimen exhibits a large tuberous mother plant having stem covered with sheathing leaf bases, some of them enclosing axillary peduncles. The young plant arises monopodially. Some of the leaf bases of the young plant also enclose peduncles in their axils. The stem apex is crowned with spirally arranged young leaves. The stem of the mother plant and also the stem of the young plant exhibit vascular bundles typical to Palmae. The inflorescence axis is woody, elongated in cross section at the base and becoming circular towards the distal part is covered with the spathes. Anatomically it shows a compact arrangement of fibrovascular bundles along with trace, diminutive and fusion bundles. The spathe covering the peduncle shows parallel arrangement of the vascular bundles in the mesophyll tissue. The morpho-anatomical characters suggest the affinity with the soboliferous acaulescent palms probably belonging to subfamily Coryphoideae and tribe Phoeniceae.

6.6.6. Novel applications of confocal laser scanning microscopy: examining fossil plants

S. A. Little, S. Y. Smith, R. A. Stockey;
University of Alberta, Edmonton, AB, Canada.

Confocal laser scanning microscopy (CLSM) has been in common use for about 20 years. However, the application of confocal microscopy in paleontological research has been largely limited to microfossils and mammal dentistry. This study presents some of the first uses of confocal microscopy for research on plant fossils. CLSM allows for the excitation of autofluorescent plant tissues and compounds such as phenolics. Some lauraceous material from the Middle Eocene Princeton Chert has previously been noted for its autofluorescent characteristics. We demonstrate the utility of confocal techniques in examining permineralized fossil fruits, seeds, pollen, and vegetative organs. In particular structures with complex secondary compounds are prime candidates for this technique. Use of the CLSM results in dramatically increased image resolution, and also allows for the production of three dimensional reconstructions using computer software.

6.7.1. Introduction: A perspective on species radiation - the New Zealand story

P. J. Lockhart[1,2];
[1]Allan Wilson Centre, Palmerston North, New Zealand, [2]Massey University, Palmerston North, New Zealand.

This talk will provide a perspective on the contribution that studies on the New Zealand flora are making to understanding the phenomenon of species radiation. As such it will act as an introduction to subsequent talks of the symposium. It will also consider the problems that species radiation pose for phylogenetic reconstruction. One aim of the talk is to explain the motivation for some newer methods of phylogenetic analysis that may facilitate biological interpretation of plant species relationships. Methods such as neighbornet, consensus networks, split decomposition and supernetworks are expected to be most helpful when species relationships are non-bifurcating, and when gene trees are incongruent, due to hybridisation, lineage sorting and/or phylogenetic error. To illustrate how different features and properties of sequence data may be identified and distinguished using phylogenetic networks, my presentation will include observations on angiosperm radiation, as well as observations on the radiation of alpine plants in New Zealand.

6.7.2. New Zealand as a model system for investigating plant biodiversity: a comparison with volcanic island archipelagos.

C. E. C. Gemmill;
Centre for Biodiversity and Ecology Research, University of Waikato, Hamilton, New Zealand.

Oceanic islands have long served as the paradigm for studying evolutionary processes such as species radiations. These model systems provide outstanding opportunities to study such microevolutionary processes due to their extreme isolation and comparatively straightforward geological and geographic histories. Islands that are vestiges of Gondwana, such as New Zealand, with highly complex yet well understood geographical and geological histories can also offer much to the study of evolution. In this paper I will describe the geological and climatic features unique to each of these systems and how they act to promote species radiations. Examples from the floras of the Hawaiian Archipelago and New Zealand will illustrate how the physical characteristics of these diverse systems have shaped the plant biodiversity. I will conclude with a discussion of how the study of New Zealand's plant biodiversity can further our understanding of plant evolution particularly within insular systems.

6.7.3. Significance of long-distance dispersal in the evolution of the New Zealand flora

S. J. Wagstaff[1], D. Glenny[1], R. C. Winkworth[2], P. J. Lockhart[3];
[1]Allan Herbarium, Landcare Research, Lincoln, New Zealand, [2]Dept. of Ecology and Evolutionary Biology, Yale University, New Haven, CT, United States, [3]The Allan Wilson Centre for Molecular Ecology and Evolution, Massey University, Palmerston North, New Zealand.

The New Zealand archipelago has a unique prehistory - originally part of the Gondwanan supercontinent, New Zealand has been isolated and oceanic in character for much of the last 80 million years. Furthermore, since the mid to late Tertiary tectonism, volcanism, eustatic sea-level change, and glaciation have dramatically modified the landscape. This highly dynamic prehistory has profoundly influenced the composition of the contemporary flora. New Zealand's extensive fossil record documents the extinction of many plant groups and suggests that many plant lineages have only arrived since its isolation from the other Southern Hemisphere landmasses. Recently, molecular phylogenies and age estimates have provided important new insights. We review molecular evidence for the importance of long-distance dispersal in shaping the modern New Zealand flora. More specifically that progenitors of many plant groups have arrived by long-distance dispersal since the mid Tertiary. We also describe examples in which New Zealand plants have colonized habitats in Australia, New Guinea, and South America.

6.7.4. Morphological diversity of New Zealand plants: species radiation and convergence on an oceanic island group

I. Breitwieser[1], J. M. Ward[2];
[1]Allan Herbarium, Landcare Research, Lincoln, New Zealand, [2]School of Biological Sciences, University of Canterbury, Christchurch, New Zealand.

A distinctive feature of the New Zealand oceanic island flora is species radiation into a variety of forms and habitats, for which examples are presented. An increasing number of these radiations, including those of gnaphalioid Asteraceae, Brachyglottis, Ranunculus, and Myosotis, have been shown to have very little genetic divergence compared with their morphological and ecological differentiation. This contrast implies rapid species radiation, which is consistent with the extensive geological and climatic changes in New Zealand in the Pliocene and Pleistocene. There is a link between these explosive radiations and other distinctive features of the New Zealand flora such as divaricating habit, heteroblasty, white or inconspicuous flowers, cushion habit and mobile scree plants, because radiated species groups often contribute members to these convergences. One result of this is that similar forms often belong to a range of unrelated families. We present the example of plants of mobile screes.

6.7.5. Hybridisation and polyploidy in the New Zealand angiosperm flora

P. J. Garnock-Jones;
Victoria University of Wellington, Wellington, New Zealand.

Hybridisation is often advanced as an explanation for taxonomic difficulty in New Zealand angiosperm groups, especially where extensive hybridisation occurs in cultivation, e.g., *Veronica*. Until recently there has been little empirical support for extensive introgression, although some interspecific and intergeneric F1 hybrids have been well documented. Several recent studies have demonstrated polyploid hybrid speciation (e.g., *Ranunculus*, *Thelymitra*). However, the possible role of diploid hybrid speciation has not yet been widely examined. Many large genera have speciated at one level of ploidy (often hexaploid) in New Zealand, but some (e.g., *Leptinella*, *Veronica*) show extensive polyploidy and aneuploidy. Poor phylogenetic signals from ITS sequence data have been assumed to indicate rapid and recent diversification in the flora. However in some cases incongruence of cpDNA and ITS gene trees might be evidence of extensive hybridisation over a longer time period. I will present some New Zealand examples that use a novel analytical approach based on gene tree incongruence for the recognition of hybridisation in a phylogenetic context.

6.7.6. Plant mating strategies and their role in adaptive radiation

L. K. Jesson;
Victoria University of Wellington, Wellington, New Zealand.

Plant mating strategies govern genetic transmission across generations and can both drive and limit species radiations. While mating systems such as dioecy are associated with lower species number, others such as self-fertilisation can enforce reproductive isolation. The New Zealand flora is characterised by radially symmetric, white flowers pollinated by an unspecialised insect fauna. Moreover, greater than 10% of the native species are dioecious and over 20% are predominantly selfing. To investigate the link between mating systems and species radiation in New Zealand I used published phylogenies to compare species richness and breeding system of monophyletic genera or subgenera in New Zealand with their overseas sister taxa. Most New Zealand taxa are less, or no more, speciose than their sister group. However, there are a few cases of striking species radiations in New Zealand (e.g. *Veronica*, *Myosotis*, and *Aciphylla*). Most New Zealand groups examined had smaller, less specialised flowers than their sister taxa, irrespective of their species richness. In New Zealand breeding system may limit, rather than drive, species radiations.

6.7.7. *Pachycladon* (Brassicaceae) as a model plant in the study of species radiation

P. B. Heenan[1], M. A. Lysak[2], K. McBreen[3], P. J. Lockhart[3];
[1]Allan Herbarium, Landcare Research, Lincoln, New Zealand, [2]Royal Botanic Gardens, Kew, London, United Kingdom, [3]Allan Wilson Centre for Molecular Ecology and Evolution, Massey University, Palmerston North, New Zealand.

Model plants are a powerful tool to understand evolutionary processes and to investigate the genetics underlying morphological and ecological diversity. The New Zealand *Pachycladon* are a monophyletic group closely related to the model plant *Arabidopsis thaliana*. They are similar to this species in terms of sequence divergence and chromosome synteny. Species of *Pachycladon* differ in growth habit, leaf and rosette morphology, the number of times they flower, and seed morphology. There are nine *Pachycladon* species indigenous to the Southern Alps of New Zealand and these are considered to represent a recent and rapid radiation. The geological and climatic framework in which *Pachycladon* has evolved is well understood, providing the opportunity to investigate genetic and also environmental drivers of species radiation. Utilising the genetic and molecular resources developed for *Arabidopsis*, we report on the potential of *Pachycladon* as a model plant for investigating the genetics underlying morphological and ecological diversification during species radiation.

6.8.1. Phylogeny and evolution of Rosaceae

C. S. Campbell[1], R. C. Evans[2], D. Potter[3], T. Eriksson[4], D. R. Morgan[5];
[1]University of Maine, Orono, ME, United States, [2]Acadia University, Wolfville, NS, Canada, [3]University of California, Davis, CA, United States, [4]Botaniska institutionen, Bergianska stiftelsen, Stockholm, Sweden, [5]Western Washington University, Bellingham, WA, United States.

Rosaceae are systematically challenging from subfamilial to species levels. Molecular data strongly support as monophyletic the two largest traditional subfamilies, Maloideae and Rosoideae, although with somewhat altered composition. Neither of the other two traditional subfamilies, Amygdaloideae and Spiraeoideae, is monophyletic, and instead their genera plus some cast-offs from Rosoideae fall into about eight lineages, each with a few genera. Molecular analyses have so far failed to resolve fully and strongly relationships among these clades, hinting at the possibility of a rapid radiation of the family early in its history. Most of these clades are heterogeneous for carpel and fruit characters, suggesting complex patterns of morphological evolution. Hybridization has been inferred in the ancestry of the Maloideae and within and among numerous genera of Rosaceae. The interplay of hybridization, polyploidy, and agamospermy has created numerous agamic complexes in the Maloideae and Rosoideae. Intricate evolutionary relationships in these complexes have made consistent application of any species concept extremely difficult.

6.8.2. Rosaceae in Neotropical montane forests and paramos

K. Romoleroux;
Pontificia Universidad Catolica, Quito, Ecuador.

The family Rosaceae is economically and ecologically important in the Neotropical region, several native species are used for wood, food, and also as medicinal plants; however, there are relatively few studies of the Rosaceae in this region. In the Neotropics occur 17 genera of Rosaceae with about 220 native species, 50% of these genera are endemic from Central and South America, such as Hesperomeles, Lachemilla and Polylepis. Other genera probably migrated from the northern hemisphere such as Prunus and Rubus, although those have several native Neotropical species. The Rosaceae in the Neotropics are mainly distributed at high elevations in the montane forests and páramos, between 2000 and 5000 m. Lachemilla is one of the most diverse genera of Rosaceae in the Neotropics with approximately 80 species distributed in the western Neotropical mountains, about 60% of the species are found from Venezuela to Bolivia, above 3000 m, which suggests that the elevation of the Andes was important for the evolution and diversification of this genus. First molecular analyses have confirmed a close relationship of Lachemilla to Alchemilla and Aphanes.

6.8.3. Major clades in the evolution of Rosoideae

T. Eriksson[1], J. E. E. Smedmark[1], M. S. Kerr[2], L. A. Alice[3], R. C. Evans[4], C. S. Campbell[5];
[1]Bergius Foundation, Stockholm, Sweden, [2]University of Maryland, College Park, MD, United States, [3]Western Kentucky University, Bowling Green, KY, United States, [4]Acadia University, Wolfville, NS, Canada, [5]University of Maine, Orono, ME, United States.

Recent phylogenetic analyses of Rosoideae based on chloroplasts and the nuclear DNA sequence data mostly agree on six well supported clades: Filipendula (10 spp.), Rubus (c. 700 spp.), Colurieae (c. 70 spp.), Sanguisorbeae (c. 275 spp.), Rosa (c. 100 spp.), and Potentilleae (500+ spp.). The three latter comprise the Roperculina clade. As delimited since the landmark contribution by Morgan et al. (1994), Filipendula is sister to the remainder of Rosoideae. Separate analyses of chloroplast and nuclear data have shown different relationships among the remaining clades, particularly in the position of Rubus. Ribosomal ITS data favour Rubus + Colurieae, while noncoding chloroplast data favour Rubus + Roperculina, but not in all cases. Analyses of GBSSI (waxy) exon data do not show a consistent pattern with current sampling, when the two loci present in Rosaceae are compared. Analyses of the sequence data using model-based approaches may shed light on these relationships, as well as the position of Rosoideae within Rosaceae.

6.8.4. Evolution of Maloideae with a focus on *Crataegus*

T. A. Dickinson[1,2], E. Lo[2,1], N. Talent[2,1];
[1]Royal Ontario Museum, Toronto, ON, Canada, [2]Botany Dept. - University of Toronto, Toronto, ON, Canada.

The last 10 years have seen progress not only in deducing generic relationships within Rosaceae subfamily Maloideae, but also in obtaining novel evidence for relationships between species in some of the larger genera. *Malus* and *Pyrus* have been the subject of studies aimed at discovering relationships between wild and cultivated genotypes. Data from molecular markers have also corroborated earlier inferences from cytology and morphology about the origins of *Sorbus* hybrids. In *Crataegus* a major breakthrough has been the ability to determine ploidy level by means of flow cytometry. This makes it possible to concentrate on diploid taxa initially, and to predict the number of gene copies to be expected when adding triploids and tetraploids to the sample. Molecular data support the view that morphological variation in *Crataegus* encompasses that seen in *Mespilus*. Other genera such as *Amelanchier* and *Aronia* have been studied up to now only in North America. *Cotoneaster* remains as a major challenge for future work.

6.8.5. Molecular Evolution in the Rosaceae.

R. C. Evans[1], C. S. Campbell[2], D. R. Morgan[3], T. Eriksson[4], T. A. Dickinson[5];
[1]Acadia University, Wolfville, NS, Canada, [2]University of Maine, Orono, ME, United States, [3]University of California, Davis, CA, United States, [4]Botaniska Institutionen, Bergianska Stiftelsen, Stockholm, Sweden, [5]Centre for Biodiversity and Conservation Biology, Royal Ontario Museum, Toronto, ON, Canada.

During the past decade molecular systematic studies have refined our understanding of relationships within Rosaceae and helped resolve a long-standing evolutionary question. Our first insight into Rosaceae molecular systematics came from analyses of *rbc*L sequences by Morgan et al. (1994) who demonstrated that chromosome number was more representative of relationships than fruit type, and Maloideae may have originated from Spiraeoid progenitors. The first study of nuclear DNA sequence variation used *nr*ITS (Campbell et al. 1995) and identified a close affinity between traditional Spiraeoid genera and Maloideae as well as small clades within Maloideae. Both were jumping off points for numerous studies, with the most recent using sequence from the multi-copy, nuclear-encoded GBSSI gene. The presence of multiple copies of GBSSI genes has provided a powerful tool for recent molecular studies (Evans et al. 2000, Evans and Campbell 2002, Smedmark et al. 2003). Collectively these analyses have used multiple copies of GBSSI to demonstrate the importance of hybridization in Rosoideae genera, as well as the North American origin of Maloideae.

6.8.6. Evolution of gametophytic self-incompatibility in the Rosaceae

O. Raspé[1], J. R. Kohn[2];
[1]National Botanic Garden of Belgium, Meise, Belgium, [2]University of California, San Diego, CA, United States.

In the Rosaceae, the control of self-incompatibility is gametophytic, which means that the rejection reaction is conditioned by the genotype of the male gametophyte. RNases are the stylar product of the gametophytic self-incompatibility locus in three families: the Rosaceae, Scrophulariaceae, and Solanaceae. Most studies on the evolution of RNase-based self-incompatibility undertaken so far have dealt with the Solanaceae and have revealed extensive sequence divergence and transspecific evolution (closely related alleles are found in different species or even genera). Both extensive sequence divergence and transspecific evolution result from the negative frequency-dependent selection acting on the locus. The Rosaceae, however, have shown some striking differences compared to the Solanaceae. In paticular, sequence divergence is much lower and, although extensive transspecific evolution has been observed within subfamilies Maloideae and Amygdaloideae, no overlap has been observed between those subfamilies. Various equilibrium and nonequilibrium scenarios may be considered to account for the observed differences.

6.8.7. Hybridization as an evolutionary factor in *Rosoideae* with a focus on *Rosa*.

V. Wissemann, C. M. Ritz;
Friedrich-Schiller-University, 07743 Jena, Germany.

Hybridization is recognized as a major mode of evolution in plants. However, the distribution and frequency of this evolutionary factor is uneven among plants. Within Rosaceae, subfamily *Rosoideae* is subject to intensive reticulation processes. One of the most remarkable genera within *Rosoideae* with respect to systematic biology is the genus *Rosa*. The realization of multiple reproductive strategies from apogamy to reticulation, matroclinal character inheritance, auto- and allopolyploidy, concert between environmental dependent and independent speciation and intensive networked genome evolution in the genus limit concepts of diversification, radiation, speciation and subsequent taxonomy. An analysis of the evolutionary patterns and processes in *Rosa* gives on one hand clear evidence for the stochastical character of this specific evolutionary scenario. On the other hand certain results are comparable to evolutionary strategies in other polymorphic taxa and shed light on general patterns and processes of reticulate evolution in polyploid plants.

6.9.1. Aspects of fern radiations

H. Schneider;
Albrecht-von-Haller Institut für Pflanzenwissenschaften, Göttingen, Germany.

Leptosporangiate ferns exists as a separate lineage at least since the early Carboniferous. They underwent several major diversification and extinction events that shaped their extant diversity. Recently, it was shown that the most divers lineage of leptosporangiate ferns, the polypods, diversified not earlier than the Cretaceous. Thus, at least 80% of extant fern diversity evolved after the appearance of the angiosperms. In this presentation, major questions concerning the global pattern of fern radiations are addresses with the focus on events in the last 100 million years. Putative factors triggering radiations of ferns are discussed based on selected lineages such as asplenioid and polygrammoid ferns. Various factors are considered such as climatic change, colonization of new habitats, and morphological/physiological key-innovations. Several radiations respectively diversifications of fern lineages are explored using phylogenetic evidence with and without estimation of divergence times. Finally, current evidence about patterns of fern radiations are compared with theories concerning the process of diversification or radiation.

6.9.2. Dating the diversification of pleurocarpous mosses

A. E. Newton[1], **N. Wikström**[2], N. Bell[1], L. L. Forrest[3], M. S. Ignatov[4];
[1]Natural History Museum, London, United Kingdom, [2]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala, Sweden, [3]Southern Illinois Univeristy, Carbondale, IL, United States, [4]Main Botanical Garden of Russian Academy of Sciences, Moscow, Russian Federation.

Molecular phylogenetic analysis of pleurocarpous mosses shows the presence of very short internal branches in the base of the pleurocarpous "bush", indicating the possibility that they diversified rapidly over a (geologically) short period of time. However, the absence of a good fossil record of mosses in general, and pleurocarpous mosses in particular, has hindered attempts to determine when this group evolved and the processes implicated. In particular, the idea that the evolution of pleurocarpous mosses was associated with the appearance of angiosperm forests has been untestable. Here we explore the patterns of diversification of the pleurocarpous mosses and other bryophytes using sequence divergence based methods and estimate possible dates for their origins. The appearance of pleurocarpy was dated at 161-194 mya, but the majority of pleurocarp lineages appear about 131-165 mya. This latter event potentially coincides with the origin of angiosperms in the Early Cretaceous, but clearly predates the appearance of complex angiosperm forests in the early Cenozoic. The hypothesis that pleurocarpous mosses evolved to exploit the angiosperm forests needs to be modified - instead, it is suggested that pleurocarpous mosses diversified in parallel with the early angiosperms, contributing to the development of the complex modern ecosystems.

6.9.3. Fast and slow filmy ferns: molecular rate heterogeneity a chloroplast-wide phenomenon in the Hymenophyllaceae.

S. Hennequin[1], K. M. Pryer[2], E. Schuettpelz[2], J. Dubuisson[1];
[1]Universite Pierre et Marie Curie, Paris, France, [2]Duke University, Durham, NC, United States.

The Hymenophyllaceae is the largest family of basal leptosporangiate ferns, comprising more than 650 species in two large sister genera (*Trichomanes* and *Hymenophyllum*). Although these two genera are equally rich in species number, they are quite different in terms of ecological diversity; *Trichomanes* exhibits five ecological modes (terrestrial, climbing, hemi-epiphytic, lianescent, and epiphytic), whereas *Hymenophyllum* is exclusively epiphytic. Recent *rbcL* studies have revealed striking differences in the rate of molecular evolution between *Trichomanes* and *Hymenophyllum*, with *Hymenophyllum* showing a significant rate deceleration. Here, using a taxonomic sampling of 25 species for each genus, we show that this same pattern is present in two additional regions of the plastid genome, and is therefore likely a chloroplast-wide phenomenon. Molecular divergence time estimates also confirm that *Hymenophyllum* diversified much more recently than *Trichomanes*. Possible explanations for the observed molecular rate differences are examined in the context of what is known about the ecology and life history patterns of these ferns.

6.9.4. Diversification of heterosporous ferns: Kovach and Batten revisited

R. A. Lupia[1], H. Schneider[2], N. Nagalingum[3], M. Nowak[3], K. Pryer[3];
[1]University of Oklahoma, Norman, OK, United States, [2]Albrecht-von-Haller Institute of Plant Sciences, Goettingen, Germany, [3]Duke University, Durham, NC, United States.

Heterosporous ferns (Salviniales) are the most recent evolutionary experiment with heterospory and are one of many taxa, along with angiosperms and polypodiaceous ferns, that transformed terrestrial ecosystems during the Cretaceous and Paleogene. Extant families Salviniaceae and Marsileaceae form a monophyletic clade, but are morphologically distinct from each other, limiting our ability to test hypotheses about morphological tranformations. However, heterosporous ferns and their relatives (inferred from megaspores) possess an extensive fossil record from the Cretaceous through to the Recent. Our morphological phylogenetic analysis including fossil and extant taxa supports the inclusion of Balmeisporites and Ghoshispora in crown group Salviniales, and previous conclusions about a marsileaceous affinity for Arcellites and inclusion of Glomerisporites and Parazolla in Salviniaceae. By combining new discoveries and phylogenetically-based spore affinites with an expanded data base of occurrences, we update the work of Kovach and Batten (1993) who first described quantitatively heterosporous fern diversification.

6.9.5. The diversification of epiphytic ferns: evidence for a radiation on angiosperms

E. Schuettpelz;
Duke University, Durham, NC, United States.

The epiphytic habit has clearly been of paramount importance in the evolutionary history of ferns, with epiphytes accounting for more than 30% of extant fern species. Nonetheless, remarkably little is known about the diversification of these plants, and critical questions concerning the timing and patterns of epiphyte evolution remain unanswered. Recent analyses of fossil and molecular data have revealed that the bulk of extant fern diversity arose subsequent to the rise of angiosperms in the Cretaceous, perhaps as an opportunistic response to the development of more complex angiosperm-dominated habitats. The latest Cretaceous and earliest Tertiary establishment of multistratal, angiosperm-dominated, everwet tropical forests provides a reasonable stimulus for the diversification of epiphytic ferns. Here, this hypothesis is evaluated by estimating the timing and patterns of diversification for both epiphytic and terrestrial fern lineages, within a broad phylogenetic framework.

6.9.6. Diversification of Hawaiian Ferns

J. M. O. Geiger[1], T. A. Ranker[2];
[1]Carroll College, Helena, MT, United States, [2]University of Colorado at Boulder, Boulder, CO, United States.

The native Hawaiian fern flora is composed of approximately 140 species, classified in 67 genera. We and several of our colleagues have conducted evolutionary studies of various groups of Hawaiian ferns. The combined results across groups are helping us discern several patterns of speciation and diversification. 1) Multiple/repeated colonizations of single, widespread species that have not undergone speciation post-colonization; e.g. *Asplenium adiantum-nigrum* and possibly such species as *Sphenomeris chinensis*, *Dicranopteris linearis*, and others. 2) Small radiations of species in relatively specialized habitats (e.g. epiphytes in wet forest), presumably from similar specialized species/colonizers; e.g. Grammitidaceae. 3) Small radiations of species with apparent more generalist ecological adaptation from ecologically similar, but relatively narrowly distributed non-Hawaiian colonizers; e.g. some of the groups of *Dryopteris*. 4) Single endemics diverging from widespread species but not radiating into more species rich endemic groups; e.g. *Asplenium hobdyi* and *Dryopteris subbipinnata*.

6.9.7. Exploring the radiation of asplenioid ferns using phylogenetic and population genetic approaches

J. C. Vogel[1], H. Hunt[1], C. Duraes[1], S. Russell[1], M. Grundmann[1], F. Rumsey[1], I. Pinter[2], M. Gibby[3], J. Barrett[4], H. Schneider[5];
[1]Natural History Museum, London, United Kingdom, [2]Eoetvoes Lorand University, Budapest, Hungary, [3]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom, [4]Department of Genetics, Cambridge, United Kingdom, [5]Albrecht-von-Haller Institut of Plant Sciences, Goetingen, Germany.

Phylogenetic studies of *Asplenium* on a global scale have allowed us to date historic radiations in this species rich genus. We are comparing these results with population genetic and biosystematic investigations into European taxa in order to infer general patterns and processes of evolution and radiation.

With more than 50 taxa *Asplenium* is the most species rich fern genus in Europe. Climate fluctuation and habitat disturbance during Pleistocene glaciation cycles has led to range contractions and expansions in many plant species. Contact and hybrid zones were formed, resulting in repeated polyploid formation. Minority cytotype exclusion prevented the mixing of the different cytotypes and supported the establishment of distinct cytotype ranges. We use the rock fern genus Asplenium to explore the dynamics of speciation and extinction in relation to environmental change.

6.10.1. The origin and early diversification of eudicots

P. R. Crane[1], K. R. Pedersen[2], E. M. Friis[3];
[1]Royal Botanic Gardens, Kew, Surrey, United Kingdom, [2]Department of Geology, University of Aarhus, Arhus, Denmark, [3]Department of Palaeobotany, Swedish Museum of Natural History, Stockholm, Sweden.

Eudicots comprise the bulk of extant angiosperm species, and much of the broad phylogenetic structure within the group has now been clarified through the application of phylogenetic techniques based on molecular sequence data. In the fossil record eudicots are first recognised in rocks slightly younger than those containing the earliest evidence of angiosperms. In the first palynofloras and mesofloras in which eudicots can be recognised they are subservient to putative monocots and magnoliids (sensu lato) in both diversity and abundance. Subsequently, they quickly become important and early fossils include forms related to extant *Platanus*, Buxaceae and perhaps Trochodendraceae. Eudicots then diversify rapidly through the mid-Cretaceous. There is further rapid diversification through the late Cretaceous and into the Cainozoic. A steadily increasing number of extant lineages can be recognised through the Cretaceous and early Cainozoic in a pattern that is broadly consistent with that predicted by phylogenetic analyses of extant taxa.

6.10.2. Basal eudicots from the mid-Cretaceous of Euroasia

J. Kvacek[1], R. Zetter[2], L. B. Golovneva[3];
[1]National Museum, Prague, Czech Republic, [2]University of Vienna, Vienna, Austria, [3]Institute of Botany, Russian Academy of Sciences, St. Petersburg, Russian Federation.

Fossil plant assemblages comprising reproductive structures, pollen and leaves have been studied in Central Europe, Kazakhstan and Western Siberia. Two major groups of basal eudicots, platanoids and trochodendroids, have been recognized. Platanoids are represented by the staminate globular inflorescences, *Sarbaya,* which has tetramerous flowers, and *Platananthus*, which has pentamerous flowers. Both genera show massive stamens with peltate apical parts of connectives. Trochodendroids in Western Siberia are characterised by the reproductive structure, *Nordenskioeldia*, and leaves of *Zizyphoides* type. In Central Europe, they are represented by unequivocal pollen grains. Eudicots in Euroasia are further represented by the intriguing pistilate reproductive structure, *Cathiaria.* It consists of a main axis with helically arranged, flattened lateral axes bearing adaxially unilocular sessile fruits. The associated staminate racemose inflorescence, *Freyantha,* is characterized by bracteate flowers bearing tricolpate, reticulate pollen. In all known Euroasian localities *Cathiaria* co-occurs with the compound biternate leaves *Liriodendropsis*.

6.10.3. The Cretaceous and early tertiary history of primitive eudicots in North America

G. R. Upchurch[1], J. A. Wolfe[2];
[1]Texas State University, San Marcos, TX, United States, [2]University of Arizona, Tucson, AR, United States.

Eudicots migrated from the tropics to North America by early Aptian. Representatives include tricolpate pollen-characteristic of all eudicots-and *Vitiphyllum*, an herbaceous plant with leaf architecture suggestive of Ranunculales. By the late Albian at least three of the four major clades of primitive eudicots were present. Proteales were a major component of the angiosperm record; they include *Nelumbites*, a primitive relative of Nelumbonaceae, and the *Sapindopsis*/platanoid complex, which has features that link it to Platanaceae and Proteaceae. During the latest Albian and Cenomanian platanoids underwent a major adaptive radiation. During the Late Cretaceous Platanaceae and Trochodendrales/Cercidiphyllales were an important component of high-latitude deciduous vegetation, while Platanceae and Menispermaceae were minor components of lower-latitude evergreen vegetation. During the Paleocene Platanaceae and Trochodendrales were common components of mid-latitude deciduous forests. During the Eocene modern genera of Menispermaceae were a diverse component of thermophilic rainforests, which were widespread at middle northern latitudes.

6.10.4. The timing of eudicot early diversification

S. A. Magallon;
Universidad Nacional Autonoma de Mexico, Mexico City, Mexico.

The onset of eudicot diversification gave rise to a number of lineages with distinct morphologies, some of which may represent the baseline condition for characters possibly associated with the diversification of core eudicots. We investigate the initial phases of eudicot diversification to address the timing of origin of major early eudicot lineages and the age of their crown groups, the diversification dynamics of species-poor and diverse clades, and the rates of molecular evolution associated with the origin of early eudicot lineages. Dates and molecular rates were estimated by applying penalized likelihood to a parametric hypothesis of phylogeny constrained with ages derived from fossils. Our results suggest the rapid differentiation of major eudicot lineages soon after the origin of eudicots, and, in many cases, a substantial temporal gap until the origin of their crown groups. Distinct species diversification patterns seem to characterize differentially diverse early eudicot clades: whereas some lineages are presently depauperate survivors of formerly diverse clades, at least one species-rich clade resulted from a recent rapid radiation.

6.10.5. Biogeography of the early eudicots

S. B. Hoot;
University of Wisconsin, Milwaukee, WI, United States.

The early eudicots, consisting of the Ranunculales and several other lineages (e.g., Proteales, Buxales, Sabiales), contain taxa with geographic distributions throughout the world. Various vicariant/dispersal hypotheses are proposed to explain the patterns of distribution found within this diverse group, concentrating on those taxa with distributions in the Southern Hemisphere. In the Ranunculales, geographic patterns found in some groups (e.g., *Anemone* and *Caltha*, Ranunculaceae) strongly suggest a former Gondwanan distribution. Other families (e.g., Menispermaceae) may have a Gondwanan origin but, due to more recent dispersal events, the pattern is less evident. In the non-ranunculean lower eudicots, several lineages (e.g., Proteaceae) also suggest a Gondwanan distribution. To test the roles of vicariance and dispersal in selected taxa, the following lines of evidence will be explored: 1) paleogeographic reconstructions using parsimony-based tree fitting to identify concordant geographic patterns, 2) the fossil evidence, and 3) the congruence of the dates for various geologic events with the latest time-calibrated lower eudicot trees.

6.10.6. Floral structure and evolution in Proteales and Buxales

M. von Balthazar;
Department of Palaeobotany, Swedish Museum of Natural History, Stockholm, Sweden.

Buxales (Buxaceae, Didymelaceae) and Proteales (Nelumbonaceae, Platanaceae, Proteaceae) belong to the partly unresolved grade of early diverging eudicots situated between Ranunculales and core eudicots. Early diverging eudicots are characterized by a high evolutionary plasticity in floral organ differentiation and flower organization. This is in contrast to the rather fixed conditions within the core eudicots. With the exception of Proteaceae and Nelumbonaceae, perianth organs are often more or less bract-like and undifferentiated. Floral organs are arranged in whorls in all members of Buxales and Proteales, except for Nelumbonaceae and female flowers of Buxaceae, which both have spiral phyllotaxis. Within a whorl, organs may either be initiated simultaneously or successively. Most often are the floral organs organized in a dimerous decussate pattern. Trimery and pentamery are occasionally found in the flowers of fossil and extant Platanaceae, and the uppermost perianth organs of female flowers in Buxaceae tend towards a pentamerous arrangement. Developmental studies of extant Platanaceae indicate a high variability of floral organ merosity.

6.10.7. Patterns of MADS-box gene duplication and the evolution of the ABC program in the lower eudicots.

E. M. Kramer;
Harvard University, Cambridge, MA, United States.

The elucidation of the genetic program controlling floral organ identity has created opportunities for understanding the evolution of floral morphology. In particular, it appears that aspects of floral diversity could have been generated through simple shifts in the functional domains of the homeotic organ identity genes. Members of the lower eudicot family Ranunculaceae are well suited for testing this hypothesis due to their wide array of perianth types. In many genera, two whorls of morphologically distinct petals are present in the flower, indicating that two separate petal identity programs may be functioning. The genus Aquilegia is very useful in the study of this phenomenon due to its small diploid genome and the availability of many floral homeotic mutants. We have identified homologs of all the major Arabidopsis floral organ identity genes in Aquilegia, and have begun to characterize their expression patterns and protein interactions. It appears that gene duplications which occurred in the APETALA3 lineage before the diversification of the Ranunculaceae have facilitated the evolution of multiple forms of petaloid organs in this new model species.

6.11.1. Evolution of the Compositae: the big picture.

V. A. Funk[1], R. J. Bayer[2], L. Watson[3], B. Gemeinholzer[4], C. Oberprieler[5], N. Garcia-Jacas[6], A. Susanna[7];
[1]Smithsonian Institution, Washington, DC, United States, [2]Australian National Herbarium CSIRO, Canberra, Australia, [3]Miami University, Oxford, OH, United States, [4]Botanischer Garten und Botanisches Museum Berlin-Dahlem, Berlin, Germany, [5]Universitat Regensburg, Regensburg, Germany, [6]Botanic Institute of Barcelona (CSIC), Barcelona, Spain, [7]Botanic Institute Barcelona (CSIC), Barcelona, Spain.

One of every 10 flowering plant species is in the Compositae. Although monophyletic, there is much diversity among the members. Ideas about classification and diversification remained largely unchanged from Bentham through Cronquist. The results of molecular studies were used to produce a meta-supertree formed by the grafting of the tribal trees onto a base supermatrix tree. Examination of the distribution of terminal taxa indicates that the origin of extant members of the Compositae was in southern South America. A subsequent radiation in Africa gave rise to most extant tribes. The African radiation contains clades from Asia, Eurasia and Australia. There was a North American origin and diversification of the Heliantheae *s. l.* The pattern might suggest a Gondwanan origin for the family but data indicate a more recent origin. A monotypic North American genus is between the South American and African radiations. The sister-group to the western hemisphere clade Heliantheae *s. l.* is a small tribe from tropical Africa. A global picture of the Compositae provides a framework for studies in morphology, evolution, and diversification and highlights areas in need of work.

6.11.2. Phylogeny and biogeography of Barnadesioideae, the most ancient subfamily

E. Urtubey[1], T. F. Stuessy[2];
[1]Seccion Plantas Vasculares, Museo Nacional de Historia Natural, La Plata, Argentina, [2]Systematic and Evolutionary Botany, Institute of Botany, Vienna, Austria.

Barnadesioideae, with 91 species in nine genera, represent the most ancient lineage of Compositae. This small complex is confined to South America, with a concentration in the Southern Cone and with extensions along the Andes north into Colombia. Morphologically the group contains much variation, ranging from small herbs (such as in *Doniophyton*) to trees 20 m tall (in *Dasyphyllum*). Recent cladistic analyses based on separate morphological and molecular data have shown different patterns of intergeneric relationships. New analyses of selected corolla characters support patterns based on molecular data, in which *Barnadesia* and *Huarpea* are ancestral within the group (as opposed to *Schlechtendalia*, hypothesized previously). Implications for early biogeography of the subfamily are explored, with data suggesting origin and diversification in southern South America followed by subsequent radiation southward into Patagonia and also northward into the Andean chain. This second lineage, accompanied by selection for hummingbird pollination, resulted in a wide range of different morphological forms.

6.11.3. Molecular phylogeny of Cardueae: the complete picture

A. Susanna, N. Garcia-Jacas;
Botanic Institute of Barcelona, Barcelona, Spain.

The classification of Compositae has changed dramatically in recent years. The new outline of relationships in basal branches confirms that the sister group to the large tribe Cardueae are not Mutisieae, but only a small group of African genera of this tribe that are now classified as tribe Tarchonantheae. This change implies that our outgroup selection in previous molecular studies was not suitable, and monophyly of Cardueae must be reassessed on a molecular basis. Moreover, new collections in recent years allow us to extend our sampling to 70 of the 74 genera of the tribe. We performed a new molecular study of the tribe using one nuclear region (ITS) and two chloroplastic ones (*trn*L-*trn*F and *mat*K) and a more appropriate outgroup. Our results confirm that Cardueae are a natural group but indicate some changes in subtribal delineation: a new subtribe Cardopatiinae is recognized and some genera are moved to other subtribes (*Myopordon*, *Nikitinia*, *Syreitschikovia* and the *Xeranthemum* group). A recapitulation of a number of interesting questions that remain unresolved in the classification of some large genera is presented.

6.11.4. Phylogeny and subtribal delimitation of the *Cichorieae* (Asteraceae)

B. Gemeinholzer, N. Kilian;
Botanic Garden and Botanical Museum Berlin-Dahlem (FU-Berlin), Berlin, Germany.

Subtribal delimitations within the Asteraceae-Cichorieae (c. 100 genera and over 1550 species) are often controversially discussed as delimiting morphological features are scarce. Analyzing DNA sequences of ITS and *mat*K of a broad representation of the family and combining molecular and morphological data, we discovered robust support for 10 monophyletic subtribes: (1) Scolyminae including *Catananche*, (2) Scorzonerinae, (3) Cichoriinae comprising *Cichorium, Tolpis* and *Arnoseris*, (4) a primarily North American clade comprising the Microseridinae, Malacothricinae, and Steophanomeridinae, (5) Hieraciinae sensu stricto, (6) Lactucinae sensu stricto, (7) Chondrillinae including *Urospermum* and *Phitosia*, (8) Crepidinae including *Nabalus* and *Rhagadiolus*, (9) Sonchinae including *Hyoseris* and *Dendroseris*, (10) Hypochaeridinae sensu stricto but including *Prenanthes* sensu typo. Our phylogeny confirms an origin of the tribe in Eurasia. General history and distribution of the tribe are discussed.

6.11.5. Small tribes, but a large challenge: clades and grades of Arctotideae and Liabeae

P. Karis[1], V. Funk[2], R. Chan[3], R. McKenzie[4], N. Barker[4];
[1]Stockholm University, Stockholm, Sweden, [2]US National Herbarium, Smithsonian Institution, Washington, DC, United States, [3]University of Hawaii at Manoa, Honolulu, HI, United States, [4]Rhodes University, Grahamstown, South Africa.

The primarily Andean Liabeae with c. 180 spp. contains two monophyletic and one paraphyletic subtribes. Within this opposite-rosulate-trinerved-leaved clade, the fate of its largest, paraphyletic genus Munnozia of the Munnoziinae, is of key interest. The systematic position of the southern African genera Hoplophyllum, Eremothamnus, Heterolepis, and Platycarpha remains uncertain, although they most likely are closely related to the Arctotideae (with c. 220 spp.), distributed in the same phytogeographical area. Arctotoid disc floret styles is the only putative morphological synapomorphy for this tribe and the molecular support is rather weak. In contrast, both subtribes are diagnosed by morphological synapomorhies, such as anthers with an obsolete filament collar, radial endothecium, and soft apical appendage (Arctotidinae), and connate phyllaries, 4-lobed rays, and sclerified disc floret lobes (Gorteriinae). In the Arctotidinae, Arctotis and Haplocarpha are paraphyletic, but a large portion of species of Arctotis form a clade. A parallel situation is found in the Gorteriinae, where both Hirpicium and Berkheya are paraphyletic.

6.11.6. Progress in understanding Vernonieae evolution

H. R. Robinson[1], S. Keeley[2], R. Chan[3];
[1]Smithsonian, Washington, DC, United States, [2]University of Hawaii, Honolulu, HI, United States, [3]Singapore General Hospital, Singapore, Singapore.

The combined tmLc-F + ndhF + ITS results of Keeley, Forsman and Chan (2004) are compared with taxonomic, geographic, chemical, palynological, and other aspects of the Vernonieae. Vernonia s.s. is mostly North American taxa. Recent concepts of the paleotropical Gymnanthemum, and the Neotropical Critoniopsis seem too broad. Paleotropical ancestry of the tribe is confirmed. The yellow-flowered, trinervate-leaved Distephanus is basal. Centrapalinae and typical Gymnantheminae are near basal. The paleotropical Erlangiinae I and II are most advanced, group I with mostly sublophate Type A pollen and 5-methyl-coumarins, group II with Type A and triporate pollen and eremanolides. Neotropical taxa have all pollen types, sublophate often obviously derived. Elephantopinae, with dilactones, and Manyonia reached the paleotropics with some evolved differences. Paleotropical Centratherum and Struchium were introduced by humans. Some paleotropical taxa relate to the Eremosis group. More limited trnL DNA show strictly Neotropical relationships for Acilepidopsis with separate origin of triporate pollen.

6.11.7. An updated outline of the tribe Mutisieae s.l. (Asteraceae)

L. Katinas[1], S. Ortiz[2];
[1]Museo de La Plata, La Plata, Argentina, [2]Laboratorio de Botanica, Universidade de Santiago, Spain.

The tribe Mutisieae s. l. (Asteraceae), with 85 genera and ca. 960, species is extremely diverse morphologically. Its basal position enhances the tribe's value as a key for understanding the systematics, evolution, and biogeography of the whole family. Since the elevation of Barnadesiinae to subfamily status, the Mutisieae is constituted by 3 subtribes: Mutisiinae, Gochnatiinae, and Nassauviinae. The first two were joined in Mutisiinae s. l. Nassauviinae is monophyletic but Mutisiinae is taxonomically complex, constituted by generic groups, isolated genera, and taxa of dubious position. Molecular phylogenies exclude Ainsliaea and relatives, Dicoma and relatives, Gochnatia and relatives, Brachylaena and Tarchonanthus, Hesperomannia, Oldenburgia, and Hecastocleis from Mutisieae s. str. but a final resolution of the tribe taxonomy has not been achieved. The last morphological studies of Mutisieae s. l. agree with the exclusion of many of these taxa, but not with the exclusion of Gochnatia and relatives, Ainsliaea and relatives, Oldenburgia, and Hecastocleis. The value of the style and pollen morphology in the classification of Mutisieae is emphasized.

6.12.1. Soil seed banks in Europe: What do we know?

K. Thompson;
Department of Animal and Plant Sciences, The University of Sheffield, Sheffield, United Kingdom.

Even in Northern Europe, little is known about seed banks of species that occur outside the farmed landscape, or about rare species in general. Seed bank data are also of extremely variable quality, and the seed bank of an individual species cannot be confidently classified on the basis of fewer than five independent records. This picture is changing only slowly. Most new data concern species whose behaviour is already well-known. Data for new species occur only rarely and it will be a very long time before we have good empirical data for most European species. Prediction of persistence from seed traits has been only moderately successful. Physiological seed dormancy and persistence in soil are scarcely related. Seed size and shape are related to persistence in the soil, but the relationship cannot predict the behaviour of individual species. Defence against pathogens is linked to long-term persistence in the soil, but the variety of defence chemicals involved, and the difficulties of analysis, mean that this will never be a practical predictor of persistence. Here I review research on European seed banks and reflect on the likely future progress of this research.

6.12.2. Long-term investigation of seed dispersion on a sandy grassland in a Kiskunsági National Park

I. Kincsek, Z. Aranyi, N. Bracsok, K. Bulik;
Dep. of Biology, Szeged, Hungary.

We have analysed the species diversity in seed rain investigations in the mosaic complex of the grass conozis that were taken over 20 years. The dominant species of the vegetation were Festuca vaginata ,Festuca pseudovina,Plantago indica, Crepis capillata, Silene otites, Dactylis glomerta, Koeleria glauca , Poa angustifolia, Chrysopogon gryllus, Secale silvestre, Crepis rhoeadifolia, Silene longiflora, Dianthus serotinus, Stellaria graminea, Poa bulbosa, Calamagrostis epigeios, Molinia coerulea, Cynodon dactylon, Medicago minima, Seseli osseum, Polygonum arenarium, Prunella laciniata We have classified the seeds that were taken from 60 places based on similarities in quality and quantity. The factors that affected the groups were irrigation, isolatiun, chemical fertilization and the removal of the plant species. The temporary forms that represent the secondary succession stages of the plant communities can determined based on the seed samples.

6.12.3. Common, but not forgotten: population biology of *Trachymene incisa* (Apiaceae)

G. M. Wardle;
The University of Sydney, Sydney, NSW, Australia.

Population studies frequently focus on threatened species and overlook the common but ecologically interesting plants that make up the diversity of the Australian bush. Our studies of *Trachymene incisa* have revealed that this herbaceous perennial plant has a complex life cycle which includes seeds, rosette plants, and dormant adult tap-roots. These components of the population ensure that *T. incisa* is capable of multiple responses to disturbances such as fire. Plants may either resprout from a tap root or seeds may germinate from a seed bank. Interestingly, there are two forms of seed bank in these populations; a transient aerial seed bank and a long-lived soil seed bank. These complex life history attributes are incorporated into a stage-based matrix population model. This enables us to evaluate the relative contributions of the two seed banks and the adult dormancy to the population growth rate. The demography of two populations of *T. incisa*, one of which had recently been burnt, are compared and the consequences of the seed bank for population persistence are presented.

6.12.4. Seed germination strategies investigated using computer simulations.

D. Lafferty, **L. R. Landrum**;
Arizona State University, Tempe, AZ, United States.

In the Sonoran Desert environment of the Phoenix area, rainfall is irregular and unpredictable in quantity and frequency. Some plants survive dry periods by existing as seeds during unfavorable periods. Approximately one half of the native plant biodiversity near Phoenix consists of these ephemeral plants that exist mainly as seeds in a seed bank. A desert ephemeral whose seeds all germinated on first exposure to moisture might quickly become extinct. A better strategy might be to germinate only a fraction of its seeds in a particular growing season, thus hedging the risk. A computer simulation program has been developed that models various climates and plant characteristics to suggest strategies that might be effective under different conditions. The results of these simulation experiments indicate that the best strategies for ephemeral plants in a Sonoran desert environment seem to match some of the observed germination characteristics of actual desert plants, e.g. Pectocarya recurvata (Boraginaceae).

6.12.5. Germination and establishment of snowbed plant species of the North-Eastern Calcareous Alps

K. Bardy, N. Martinek, S. Dullinger, K. Hülber, G. Grabherr;
Department of Conservation Biology, Vegetation and Landscape Ecology, Vienna, Austria.

The template of suitable habitats will shift upwards for most alpine species due to climate change. Area loss and fragmentation will especially concern species restricted to small and well-defined habitat patches such as snowbeds. Germination and successful establishment of seedlings are assumed to be rare in alpine regions but data on germination and establishment rates are still lacking for most alpine species. This study focuses on ten selected snowbed species of the North-Eastern Calcareous Alps, Austria. Germination experiments with different stratification treatments were carried out in a climate chamber. The seedlings of the four most successfully germinating species were transplanted to a snowbed on Mt. Rax and monitored throughout one vegetation period. Germination rates for these latter species ranged from 75 to 93 %. Among treatments stratification with gibberellic acid shortened time to germination but enhanced seedling mortality. Mortality of transplanted seedlings was generally low (5 - 14 %). We conclude that a considerable part of alpine plants may successfully recruit from seeds at surprisingly high rates under favourable conditions.

6.12.6. Genetic structure of experimental populations and reproductive fitness in a heterocarpic plant *Atriplex tatarica*

B. Mandák[1], K. Bimova[1,2];
[1]Institute of Botany, Pruhonice, Czech Republic, [2]Institute of Applied Ecology, Czech Agricultural University, Kostelec nad Cernymi lesy, Czech Republic.

Atriplex tatarica L. is a heterocarpic species of man-made habitats with a mixed mating system and wide geographic distribution. Seeds of *Atriplex tatarica* do not germinate immediately after shedding, but may remain in a dormant but viable state indefinitely. We investigated the influence of genotype and fruit type of *Atriplex tatarica* on germination and establishment rates. We asked whether there were genetic and fitness differences between plants derived from seeds of the different fruit types that germinate (a) early versus late, and (b) under different ecological conditions (temperature and salinity). We found that the allozyme allele frequencies varied significantly with both fruit type and germination time under temperature and salinity treatments. When single locus heterozygosity was taken into account, we found significant differences only for germination time under temperature treatment and for fruit type under salinity treatment. Moreover, fitness components, i.e. the amount of generative and vegetative biomass, of particular plants within experimental populations increased with their increasing heterozygosity.

6.13.1. Mosses and alternative adaptation to life on land

M. C. F. Proctor;
Department of Biological Sciences, University of Exeter, Exeter, United Kingdom.

Bryophytes represent optimal adaptation to land life at a scale two orders of magnitude smaller than vascular plants. At this scale surface tension is a major force, gravity is trivial, and bryophytes often lie largely or wholly within the laminar boundary layer of the air; the contrast is comparable to that between insect and mammalian physiology. Most of the cell physiology of bryophytes is essentially the same as vascular plants, but water storage and movement are largely external, and mosses generally deal with intermittent availability of water by tolerance of desiccation rather than by regulating water loss. Photosynthesis by moss shoots tends be limited by CO_2 diffusion at high irradiance (when photoprotection becomes important); few show light-saturation levels above 1000 µmol $m^{-2}s^{-1}$ PAR. This diffusion limitation is escaped by Polytrichales and Marchantiales which have evolved ventilated photosynthetic systems analogous to vascular-plant leaves; these structures relate to enhancing CO_2 uptake rather than conserving water.

6.13.2. Desiccation tolerance in the liverwort *Jamesoniella colorata.*

C. A. M. Hooijmaijers, K. S. Gould;
University of Auckland, Auckland, New Zealand.

The leafy liverwort *Jamesoniella colorata*, has two distinct colour morphs; red-brown and green. In higher plants the functional significance of these (red) accessory pigments has been ascribed to reducing cell damage. One of these proposed protective roles involves desiccation tolerance. The susceptibility of *J. colorata* to desiccation and subsequent rehydration was studied.

When gametophytes were desiccated chlorophyll fluorescence parameters only changed at the onset of turgor loss. After rewetting, the recovery of photosynthesis was more complete in the red gametophytes than in the green. The results suggest that non-radiative energy dissipation is an important factor in recovery from desiccation. Changes in stress indicators, such as increase in lipid peroxidation and decrease in ascorbate content, could only be detected after rehydration. Chlorophylls and carotenoids only decreased upon remoistening the samples in low light. The data indicate that accessory pigmentation shields the photosynthetic apparatus from excessive radiation at vulnerable stages and thereby enhances tolerance to adverse climatic conditions.

6.13.3. An integrated model of bryophyte canopy water and carbon dynamics.

S. K. Rice;
Union College, Schenectady, NY, United States.

In bryophytes, canopy structure controls light attenuation thereby affecting photosynthetic rates and also the duration of photosynthetic activity by governing water loss. Canopies may not optimize light capture and water retention simultaneously, leading to potential physiological tradeoffs. To explore these tradeoffs, a two-component model of canopy carbon and water exchange was constructed. For the photosynthesis component, the canopy was stratified into 5 mm layers. For each layer, shoot area, light and photosynthetic light response curves were combined to calculate carbon exchange rates. Light attenuation and shoot area were modeled as a function of surface roughness (L_r), a structural parameter. The water exchange component employed a boundary-layer model that relates conductance to L_r. Increased L_r led to greater light penetration and higher whole-plant photosynthetic rates. In contrast, increased L_r caused greater rates of water loss, reducing photosynthetically active time. The model predicts that bryophytes occupying mesic habitats would benefit from high L_r, whereas under xeric conditions, low L_r should enhance carbon gain.

6.13.4. Acclimation to within-canopy light gradient in four moss species of contrasting architecture

M. Tobias, Ü. Niinemets;
Department of Plant Physiology, University of Tartu, Tartu, Estonia.

Although bryophytes typically grow in deep shade, they seldom grow as individual shoots, but form tightly packed cushions with strong vertical light gradients. We studied light acclimation of photosynthetic activity along the moss canopy light gradients in branching (*Pleurozium schreberi*, *Scleropodium purum*) and non-branching (*Polytrichum commune*, *Tortula ruralis*) species to test the hypotheses that light gradients strongly modify moss physiological activity and that light gradients are stronger in branching mosses. We studied the rate of photosynthetic electron transport ($J_{\max}$), nitrogen (N_M) and chlorophyll (Chl_M) and estimated moss LAI and light interception in one cm intervals along the canopies. Mosses intercepted 95-99% of incident irradiance, implying extensive light gradients in the canopies. Branching mosses intercepted more light than non-branching species. N_M decreased from the top to the bottom of plant canopies by 1.5-3-fold, while Chl_M decreased by 5-20-fold. These changes were accompanied by 2-3-fold changes in $J_{\max}$, demonstrating major light-dependent physiological modifications.

6.13.5. Effects of an altitude-dependent natural gradient of UV-B radiation on the physiology of sun and shade populations of an aquatic liverwort

M. Arróniz-Crespo, E. Núñez-Olivera, J. Martínez-Abaigar, R. Tomás, N. Beaucourt, S. Otero;
Universidad de La Rioja, Logroño (La Rioja), Spain.

We report the effects of a 676-m altitudinal gradient of UV-B radiation on the physiology of the aquatic liverwort *Jungermannia exsertifolia* subsp. *cordifolia* coming from mountain streams in northern Spain. Photosynthetic pigment composition, photosynthesis and respiration rates, some variables of chlorophyll fluorescence, UV-absorbing compounds (UVAC), protein concentration and sclerophylly were measured in 11 sun populations and 7 shade ones. In sun plants, UVAC levels, $\mathrm{ETR}_{\max}$ and $\mathrm{NPQ}_{\max}$ increased with increasing altitude, whereas photoinhibition percentage decreased. These characteristics may confer tolerance to high UV-B levels. The concrete UVACs whose concentration increased with increasing altitude were chemically identified. Shade plants did not show such congruent response to altitude, probably because the UV-B gradient was scarce for these plants. A Principal Components Analysis summarized the influence of both altitude and procedence of the samples (sun *vs.* shade) on the physiology of *J. cordifolia*. Globally, this liverwort showed highly plastic physiological features in response to UV-B radiation.

6.13.6. Seasonal variations in storage substances and sensitivity to predators in the moss *Grimmia pulvinata*

B. Estébanez Pérez[1], A. Costa[2], C. Alfayate Casañas[3];
[1]Universidad Autónoma de Madrid, Madrid, Spain, [2]Real Jardín Botánico de Madrid, CSIC, Madrid, Spain, [3]Universidad de La Laguna, La Laguna, Tenerife, Spain.

Mosses are generally resistant to herbivory, with some exceptions that often include young sporophytes. Although they produce substances of nutritional value, some secondary metabolites have been suggested to play a deterrent role. In *Grimmia pulvinata*, we have observed predation, mainly by slugs, affecting only immature capsules. In this research, the content of storage substances (sugars, starch and lipids) has been analysed during a complete annual cycle. Qualitative observations have been obtained using histochemical techniques. Enzymatic detection and MS spectroscopy were performed for quantitative analysis. These substances are subjected to seasonal variations. The lipidic fraction includes mainly fatty acids and aliphatic alcohols, together with biologically active compounds such as vitamin E, sterols, and triterpenes. Starch and sugars are detected especially in structures growing actively. Among them, the gametophyte tissues and capsules after sporogenesis show a high lipidic content, probably making them resistant to predators. In turn, young capsules, with a reduced lipidic fraction, would remain unprotected.

6.14.1. From source to shelf or an introduction to the supply chain of medicinal and aromatic plants

D. Lange;
Institute of Biology, Landau, Germany.

At least every fourth flowering plant is a medicinal and aromatic plant (MAP) in use. The high demand in MAP for domestic and commercial use results in a huge trade from local to international level. Not less than 400,000 t worth US $ 1.2 billion are traded internationally each year, unknown are those volumes produced and consumed within the countries. The international trade is dominated by only few Asian and European countries. Until now, the production of botanicals relies to a large degree on wild-collection, which is not necessarily detrimental in itself, but, the increasing commercial collection, largely unmonitored trade, and habitat loss have lead to an unsustainable pressure on plant populations in the wild. World-wide an estimated 4,000 MAP are threatened. Possible ways to address the threat to the future supply of MAP and their habitats range from resource management, cultivation, shifting value-adding in source countries, species conservation to trade restrictions. As the majority of MAP will continue to come from wild-collection in the foreseeable future, MAP are of high conservation priority to secure their supply for local healthcare and trade.

6.14.2. Sustainable wild collection of medicinal and aromatic plants: Development of an international standard

D. J. Leaman[1], S. Salvador[2];
[1]Medicinal Plant Specialist Group, Species Survival Commission, IUCN - The World Conservation Union, Ottawa, ON, Canada, [2]Forestry Consultant, Bonn, Germany.

Between 40,000 and 50,000 plant species are known to be used in traditional and modern medicine systems throughout the world. Uncounted additional species are used in the growing cosmetics and botanicals industries. The great majority of these materials is provided by collection from wild resources. Notwithstanding growing interest in cultivation, wild collection is likely to continue as the principal source for most species of medicinal and aromatic plants, in most parts of the world, based on biological, economic, and social factors. Building on successes in the development of sustainable harvest and resource stewardship standards in other sectors such as timber, non-wood forest products, organic agriculture, and marine aquarium fish, an initiative has recently been launched to develop an international standard and criteria for good practice in the sustainable wild collection of medicinal and aromatic plants. This paper summarizes the current status of work to develop this standard, supported by the German Federal Agency for Nature Conservation, WWF/TRAFFIC Germany, IUCN Canada, and the IUCN Medicinal Plant Specialist Group.

6.14.3. The role of associations in sustainable sourcing - perspectives from collectors and processors

C. Lombard[1], G. Le Breton[2];
[1]PhytoTrade Africa, London, United Kingdom, [2]PhytoTrade Africa, Harare, Zimbabwe.

The paper presents the views of Southern African producers and processors (all of whom are members of PhytoTrade Africa - The Southern African Natural Products Trade Association) on sustainable sourcing of MAP. It notes that producers accept the need for independent verification of sustainability, but are concerned that certification procedures carry realistic transaction costs and do not become barriers to trade. The paper emphasizes the need for contextually appropriate indicators of sustainability, and highlights the steps that can, and cannot, be taken by associations to promote efficiency in the adoption of certification systems. Examples are given of how existing certification systems actually inhibit moves towards sustainability, tend to favour wealthy organised commercial farmers over wild-harvesting rural poor, and the practical steps that PhytoTrade Africa has taken to promote sustainable production amongst its membership. The paper concludes by urging pragmatism in the development of standards and criteria for sustainable sourcing.

6.14.4. Collectors training: basis for trade promotion

F. Staubli Asobayire;
Swiss Import Promotion Program, Zurich, Switzerland.

SIPPO (Swiss Import Promotion Programme) supports private businesses in emerging markets and markets in transition that are endeavouring to access the Swiss and European market. In Bosnia Herzegovina SIPPO promotes companies which collect medicinal and aromatic plants in a sustainable way. SIPPO therefore trains companies and collectors and has developed together with an organic certifier a manual for good collection practices and monographs with practical information for the most collected plants in this area. This training and the documentation coming out of the certification helps companies to sell their products in the European market and gives them the possibility to trace their products back to the area of collection and the collector.

This is a niche market in the commerce of MAPs and the agents and retailers are prepared to pay a higher price for these added value products. Important in this setting is the constant training and checking of the collectors in order to ensure the sustainability of medicinal and aromatic plants.

6.14.5. Bio trade: implementation of conservation and sustainable use practices along the value chain

R. Kutsch Lojenga, M. T. Becerra;
UNCTAD, Geneva, Switzerland.

The BioTrade Initiative of the United Nations Conference for Trade and Development (UNCTAD) supports developing countries to promote trade in products and services derived from biodiversity with the aim of contributing to sustainable development. BioTrade programmes in Latin America, together with national and international partners from private and public sector, have been providing support to enterprises and their providers along the whole value chain. The latter need to comply with an increasing number of compulsory or voluntary guidelines that assure sustainability of their sourcing practices. Assistance on conservation and sustainable use practices is therefore provided, taking into account market requirements, local legislation, voluntary guidelines and BioTrade principles and criteria. The implementation of such practices involves the development of protocols and training programmes, which are elaborated together with enterprises in each country. Experience shows the importance of promoting integrated approaches that support different actors along the whole value chain, involving the private sector and providing market incentives.

6.14.6. Certification of wild products - an important tool for sustainable crop management

R. C. Bächi;
IMO Institut für Marktökologie, Weinfelden, Switzerland.

Exploitation of natural flora has become a major threat to biodiversity in many regions. While collection of wild plants is for millions of people the sole source of income, a global market drains the resources and promotes unnecessary product loss by low quality and deterioration. Certification is based on standards. The set up of standards for sustainable collection practises is the starting point of a certification system. Such standards should contain as many relevant criteria as possible, but to start with simple standards is better than not to start at all; standards can and should always be improved with increasing knowledge of the specific situation of the ecosystem. Standards are also an important tool to train the collectors as in many regions collecting is done by immigrants with no traditional knowledge of ecology and the ecosystem. In addition, post-harvest handling should be included in the standards and need to be monitored and verified by the inspection procedures in order to increase the percentage of high quality output. And - of course - certification goes hand in hand with a traceability system which is a precondition for a global market approach.

6.15.1. Soil community feedbacks and plant community dynamics

J. D. Bever;
Indiana University, Bloomington, IN, United States.

While the direct effects of soil microorganisms on plant growth are known to be profound, evaluation of the importance of soil organisms on plant community processes has been technically difficult. I outline an approach to evaluating the role of soil organisms in plant community dynamics that involves testing the feedback on plant growth through host-induced changes in the composition of the soil community. I use this approach to test the importance of soil organisms in the coexistence of competing grasses and forbs and generally find that the composition of the soil community changes in a manner that decreases the growth rate of their host species relative to that of a second plant species. These negative feedbacks on host growth result from accumulation of host-specific soil pathogens, and from shifts in the composition of mutualistic arbuscular mycorrhizal fungi and rhizosphere bacteria. The negative feedbacks can allow coexistence of strong competitors, with the long-term dynamics being inferred from general community models.

6.15.2. Root secondary metabolites: pure chemical defence or negative feedback to facilitate soil microfungi coexistence

F. Hadacek;
Department of Chemical Ecology and Ecosystem Research, Faculty of Life Sciences, University of Vienna, Vienna, Austria.

An important function that is attributed to the so-called secondary plant metabolites is chemical defence that guarantees survival in the ecosystem in contrast to primary metabolites that are essential for life sustenance. However, recent developments of hypotheses that focus biotic interactions, and especially such occurring belowground, as important factors structuring plant communities, challenge this view especially in regarding negative feedbacks as favourable for species coexistence. Bottom up regulated microbes are well known to produce antibiotic secondary metabolites that have shown the contribute to the coexistence of strains in a way resembling the computer game rock-paper-scissor. I propose to extend this view to secondary metabolites which are often accumulated in huge amounts in plant roots and present a major constraint to microbial decomposers, the majority of them soil fungi showing high species and strain diversity.

6.15.3. Plant-soil feedbacks and exotic invasions

R. M. Callaway[1], **K. O. Reinhart**[2];
[1]Division of Biological Sciences, The University of Montana, Missola, MT, United States, [2]Department of Biology, Indiana University, Bloomington, IN, United States.

Evidence is increasing for the important role of soil biota in exotic invasions. Invaders may escape inhibitory biota, encounter facilitative biota, or alter soil microbial processes in invaded ecosystems. We find that plant-soil feedback processes shed light on exotic invasions in both Europe and North America. *Centaurea maculosa*, a European invader of North America, and *Prunus serotina*, an American invader of Europe, participate in different plant-soil feedback processes at home compared with their home ranges. In native soils, these invaders cultivate soil biota with increasingly negative effects on their growth, possibly leading to their control. But in soils from invaded ranges, *Centaurea* and *Prunus* cultivate soil biota with increasingly positive effects on themselves, which may contribute to the dramatic increase in ecological success that these species experience in their new ranges. We attribute these biogeographic differences to pathogen-plant relationships that are more host-specific than mutualist-plant relationships. In sum, the feedback loops that develop between soil biota and an invasive plant depend on the biogeographical source of the microbes.

6.15.4. Shrub facilitation and feedback with soil fungi contribute to succession in a chaparral-oak forest Mediterranean ecosystem

F. Richard[1,2], M. Selosse[3], M. Gardes[1];
[1]Laboratory Evolution & Diversité Biologique, Toulouse, France, [2]Office National des Forêts, Corte, France, [3]CEFE, Montpellier, France.

Quercus ilex L., the holm oak, is widely distributed around the Mediterranean basin. In mature forests of Corsica, recruitment is very low in despite significant acorn production. However, this evergreen species establishes well in chaparrals dominated by Arbutus unedo L. (the Strawberry tree). We investigated whether microbe-mediated interactions are driving forces in the chaparral-forest transition. Acorns were introduced in plots protected against animal predation, and their growth and survival rates were monitored during one year. Plant-soil feedbacks were investigated through a manipulation of microbial communities using (i) a reciprocal soil transfer between the chaparral and the oak forest and (ii) a soil fumigation approach. We also examined the ectomycorrhizal colonization of the seedlings, and we identified the fungal symbionts using molecular methods. We found greater survivorship and ectomycorrhizal colonization of oak seedlings beneath the canopies of A. unedo shrubs, (ii) soil-related effects on establishment of seedlings, and (iii) a significant effect of the fungicide on seedling survival in forest soils.

6.15.5. Response of an arid woodland to N fertilization: contrasting ecto- and arbuscular mycorrhizal conifers

M. F. Allen;
University of California, Riverside, Riverside, CA, United States.

Nitrogen deposition is escalating from urbanization and agriculture in arid regions. I applied 100kg N/y in a pinyon pine-juniper woodland in New Mexico, USA from 1997 to 2004. Mixed EM Pinyon and AM juniper woodlands cover 20million ha. Soil NO3- and NH4+ increased with fertilization but soil C declined. Isotope data indicate that turnover is increasing in soils beneath pinyon but stable C is increasing under juniper. Root length, and % and total mycorrhizae did not change, although both varied with changing rainfall. Based on ŭ15N of EM sporocarps and pinyon, 60 to 80% of leaf N was provided by EM fungi, likely as organic N. Juniper appeared to use soil inorganic N. Leaf %N increased in pinyon (2%) but decreased 11% in juniper. ŭ15N increased by 0.8o/oo in pinyon but only 0.3o/oo in juniper. Leaf production increased in 50% in juniper, and 33% in pinyon. However, pinyon began to suffer from mortality from drought in the fertilized plots (40% versus none in the controls), whereas juniper thrived. These data indicate that EM conifers may be especially sensitive to N deposition whereas AM conifers may be adapted to the higher inorganic soil N.

6.15.6. Symbiont diversity as a driver of plant diversity and ecosystem functioning

M. G. A. van der Heijden;
Institute of Ecological Sciences, Vrije Universiteit, Amsterdam, The Netherlands.

Symbiotic interactions between plants and micro-organisms are widespread and very abundant in nature. About 150,000 plant species associate with arbuscular mycorrhizal fungi (AMF) and more than 15,000 species of legumes form intimate relationships with nitrogen fixing rhizobia bacteria. In this talk, evidence will be presented showing that both AMF and rhizobia play a key role in ecosystems. These microbes contribute to plant diversity and ecosystem productivity by stimulating growth and nutrition of their host plants. AMF and rhizobia also can act as support systems for seedling establishment in nutrient poor grassland. Interestingly, many legumes form tripartite symbiotic associations with both rhizobia and AMF, and several legumes appear to rely on both symbionts to flourish in natural communities. The fact that specific AMF communities are found to be associated with the roots of nitrogen fixing legumes suggests that synergistic interactions may exist of which previously has not been thought.

6.15.7. Plant-soil feedback: from black box to multitrophic interactions

W. H. Van der Putten;
Netherlands Institute of Ecology, Heteren, The Netherlands.

Plant-soil feedback has become a powerful concept for understanding influences of communities of soil organisms on plant community and vegetation development. However, in order to really understand consequences of feedback effects between plants and soil organisms for the performance of individual plant species and the result for vegetation development, it is necessary to further explore interactions below ground. Here I will propose how to apply the concept of multitrophic interactions in improving our understanding of plant community processes as influenced by feedback effects from the soil community. I will use plant defence approaches developed for aboveground interactions between plants, herbivores and carnivores and show how different plant defence strategies may result in succession, plant species diversity and plant invasions. Then, I will show that individual plant species may exhibit more than one defence strategy at the same time using results of the EU-EcoTrain project on mulitrophic interactions between plants, root-feeding nematodes and natural antagonists in the root zone of a natural dune grass (Marram grass; *Ammophila arenaria*).

6.16.1. Vascular plants as indicators of overall species richness

M. Sætersdal;
Norwegian Forest Research Institute, 5244 Fana, Norway.

The selection of sites for management of biodiversity is a difficult task. A detailed inventory of all species is practically impossible. Therefore, one is forced to use some form of surrogates or indicators of overall species richness. Basic requirements for a successful use of vascular plants as a surrogate species group are discussed. A selection strategy based on species richness hotspots requires that hotspots for vascular plants are hotspots for the target species groups as well. Whereas a selection strategy based on complementarity requires that target species groups respond to the same major environmental gradients as vascular plants. It is concluded that vascular plants may be a useful indicator species group, especially in a complementary site selection. In addition to common gradients with several other species groups, vascular plants are well-known, they are easily identified in the field, and their gradient relationships (vegetation types) are well-studied.

6.16.2. The relationship between landscape disturbance and biodiversity using ecological indicators and a site comparison index

A. J. Krzysik[1], **H. E. Balbach**[2], D. A. Kovacic[3], J. H. Graham[4], M. P. Wallace[3], J. J. Duda[5], J. C. Zak[6], D. C. Freeman[7], J. M. Emlen[5];
[1]Prescott College, Prescott, AZ, United States, [2]U.S. Army Research Laboratory, Champaign, IL, United States, [3]University of Illinois, Urbana, IL, United States, [4]Berry College, Mount Berry, GA, United States, [5]U.S.G.S. WFRC, Seattle, WA, United States, [6]Texas Tech University, Lubbock, TX, United States, [7]Wayne State University, Detroit, MI, United States.

The relationship between habitat disturbance and biodiversity has strong implications for both ecological theory and land conservation strategies. Research to identify ecological indicators of landscape disturbance was conducted in the complex Fall-Line Sandhills physiographic ecotone of southeastern USA (Fort Benning, Georgia). Forty sites were selected representing the full range of military training disturbance and upland vegetation communities. Seven ecological indicators were analytically identified, standardized, and weighed by statistical criteria to develop a composite Site Comparison Index (SCI). SCI transect scores were grouped into five ordinal disturbance classes. Within this disturbance gradient, 33 metrics of biological diversity were statistically evaluated (16 for ground cover, 9 for trees, and 8 for ants). Diversity metrics included: species richness, abundance, dominance, and Simpson, Shannon, Brillouin diversity and evenness indices. The effect of disturbance on biodiversity varied dramatically with the metric employed. A number of patterns substantiated the intermediate disturbance hypothesis.

6.16.3. Searching for indicators of epiphytic crustose lichen diversity: Macrolichens, forest variables and climatic variables

A. Bergamini, S. Stofer, C. Scheidegger;
Swiss Federal Research Institute WSL, 8903 Birmensdorf, Switzerland.

Species richness is a fundamental measure of biodiversity, and global trends of declining species richness are a major ecological concern. However, gathering data on species richness is expensive and time-consuming. Consequently, cost-effective methods have to be developed. Our focus is on indicators for crustose lichen diversity. Crustose lichens are a very species rich group, but they are laborious to sample and identify and, thus, are often neglected. In a large scale study, we found significant relationships between species richness of crustose lichens and the easily assessible macrolichens (R2: 0.38 - 0.70, depending on substrate group). Currently, we are searching for better models for epiphytic crustose lichens by adding different sets of variables (forest stand variables and climatic conditions) to the epiphytic macrolichen data. If easy-to-measure forest stand variables sufficiently improve the models, epiphytic crustose lichen richness could cost-efficiently be predicted. Moreover, for designing efficient forest reserve networks, we are studying the complementarity between both epiphytic macrolichens and crustose lichens.

6.16.4. An approach for the identification of indicators for biodiversity

I. Schmidt[1], S. Zerbe[1], J. Betzin[2];
[1]Technical University Berlin, Institute for Landscape and Environmental Planning, Berlin, Germany, [2]Technical University Berlin, Statistics and Mathematical Economics Group, Berlin, Germany.

The identification of indicators for biodiversity is of essential importance with regard to science as well as practical purposes. In the presented study, we focus on forest biodiversity and analyze published vegetation data of Scots pine (*Pinus sylvestris*), Norway spruce (*Picea abies*), and European beech (*Fagus sylvatica*) forests on acidic soils in the lowland and mountain ranges of Germany. For different plant groups, such as bryophytes or Red List species, we investigate species numbers as a parameter of biodiversity. Species numbers are differentiated into three classes to describe low to high diversity. Our approach focuses on the probability of being in a defined range of species numbers, i.e. class, if a certain indicator species occurs. Only few indicators can be found for the low ranges of species numbers. In addition, there are only a few species groups and stand types having indicators for all three classes. Various species have multiple indicator functions, e.g. with regard to the investigated species groups. The catalogue of indicators resulting from the investigation can help to facilitate and accelerate biodiversity evaluations of forest stands.

6.16.5. Besides plants, soil organisms provide added value as indicators for conservation and restoration success

P. Kardol[1], M. Bezemer[2,3], W. van der Putten[1,3], A. van der Wal[1];
[1]Netherlands Institute of Ecology (NIOO-KNAW), Heteren, The Netherlands, [2]Laboratory of Entomology, Wageningen University and Research Centre, Wageningen, The Netherlands, [3]Laboratory of Nematology, Wageningen University and Research Centre, Wageningen, The Netherlands.

Conversion of arable land into semi-natural grassland or heath land is a major practice for restoring and conserving plant diversity, but little is known about the restoration of taxonomic and functional diversity in the soil. In a chronosequence of abandoned fields we determined how plant and soil communities develop along a secondary succession gradient. Plant community development proceeded according to a clear succession towards the theoretical plant associations *Galio hercynici-Festucetum ovinae* and *Genisto anglicae-callunetum*. However, succession of the nematode community was less well predictable. For nematodes, theoretical references are far less well developed than for plants, but similarity with a theoretical community indicative of arable land significantly declined with time since abandonment. Moreover, regarding similarity to natural reference sites, our results show that plant and soil nematode communities have individual trajectories of secondary succession after land abandonment. Therefore we argue that besides plants soil organisms provide added value as indicators for conservation and restoration success.

6.16.6. When two is better than one: a global analysis of complementarity patterns in flowering plant families

N. Brummitt[1], E. Nic Lughadha[1], J. Mutke[2];
[1]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [2]Nees Institute for Biodiversity of Plants, Bonn, Germany.

An important focus of current conservation biology is the use of indicator taxa for rapid biodiversity assessments. However, an understanding of the efficacy of indicator taxa for biodiversity conservation is hampered by a lack of information on the distribution of biodiversity as a whole. Without this information, it is difficult to know whether patterns in the diversity of indicator taxa truly mirror such patterns in all of biodiversity. We used a unique database, developed and maintained at the Royal Botanic Gardens, Kew, which records presence or absence of all 14274 vascular plant genera across 52 major regions of the world to establish whether some plant families are more representative of global diversity patterns than are other families. Patterns of complementarity between large, widely-distributed families of flowering plants result in remarkably high correlations between global distributions of certain pairs or triplets of plant families and total genus-level flowering plant diversity across the regions studied. Conservation inventories focusing on these few families might therefore accurately reflect the total biodiversity of the region.

6.16.7. Life history characters and phylogeny are correlated with rarity in the australian angiosperms.

C. L. Gross, A. Sjostrom;
University of New England, Armidale, NSW, Australia.

An exploration of four life-history traits (habit, life span, sexual system, fruit type) in the Australian flora (18 822 spp.) was undertaken to determine whether patterns can be extracted from our recently extinct and endangered species. Within the 31 extinct species we detected a significant departure from the expected values only for habit. There are significantly fewer trees on the extinct list than expected, reflecting perhaps the resilience of trees to extinction processes. Within the 450 endangered species we found significant differences within sex systems and fruit types. There are more monoecious species than expected by chance among the trees listed as endangered but fewer in the herbs and endangered herbaceous species are less likely to have dry-indehiscent fruit types. A supertree analysis and character tracing showed that rarity was non-randomly clustered and occurs in some genera more often than expected by chance. This indicates that phylogeny is also an important component of rarity. We suggest that specific life history traits could be used in conservation planning and as an early warning sign for detecting vulnerability in lists of species.

6.17.1. Tropical ethnobotany

A. C. Hamilton;
Plantlife International, Salisbury, United Kingdom.

Ethnobotany, the science of ‘the botany of the people’, explores the knowledge of people about plants - their types and how they are seen to be related, their uses and other properties, and how they live and can be managed. In principle, ethnobotany as carried out in the tropics is no different from ethnobotany carried out anywhere else, but the tropics tend to have certain features which make the subject especially apposite: the richness of the flora, a wealth of related folk knowledge of plants, the close dependency of many rural people on a diversity of local plants, both wild and cultivated, and the paucity of scientific knowledge of plants, giving added value to other traditions of botanical knowledge. Ethnobotany is emerging as a key subject for conservation and sustainable development in the tropics. This is leading to a more problem-centred and participatory approach to research, with local people and ethnobotanists working together to define the research questions, gather and analyse data, and explore the practical implications of the results. Applied ethnobotany is continuing to actively evolve. Some examples are given from the People and Plants Initiative.

6.17.2. Variation of traditional knowledge of the plant element among Zapotecs of three municipalities at t he Sierra Madre del Sur, Oaxaca

A. L. Luna-José[1], **B. Rendón**[2];
[1]Colegio de Postgraduados México, Texcoco, Mexico, [2]Universidad Autónoma Metropolitana, México, Mexico.

Traditional knowledge is the result of perception and interpretation of natural environment. Different expresions reflect the way native cultures develop traditional knowledge. One of this expressions correponds to the folk nomenclature applied to natural elements like plants and animals. Zapotec group represents one of the most important ethnic group at the Sierra Madre del Sur, state of Oaxaca. As a consequence of thousand of years of interaction with local environment and, throughout a process of oral transmition, Zapotec people has developed a complicated folk system of the plant element. We interviewed 200 persons from three municipalities with different levels of aculturation, to know how many plants they know, Zapotec names, uses, where are they obtained and what part of the plant they use. We obtained 649 plant records, 10 plant communities and 11 plant life-forms. Levels of acculturation determined the variety of Zapotec names applied to plant life-form, vegetation types, number of plants species they recognized and uses they have. Keystone plant species were also those prominent species of the different ecosystems were people obtain plant species.

6.17.3. Naga home gardens & traditional knowledge of biodiversity conservation, Nagaland, India.

A. Godbole, J. Sarnaik;
Applied Environmental Research Foundation, Pune, India.

Nagaland is one of north eastern states of India with wide range of cultural as well as biological diversity. Nagas have elaborated tradition of maintaining home gardens. These home gardens have been responsible for conserving valuable biodiversity. It is important to know the role of these traditional systems in conservation. In depth analysis of home gardens of Angami and Konyak Nagas and their relationship with higher biodiversity is presented in the paper.

Angami and Konyak Naga home gardens have many similar features as well as differences. It is attempted to define the linkages of these features and number of species that are cultivated and maintained through the indigenous knowledge of communities. Various functions of the home gardens, diversity within and among the home gardens, role of home gardens in domestication of wild species and development of varieties has been discussed in details.

Finally the role of home gardens research as a tool to develop methodologies for application of traditional knowledge in conservation and community development is discussed.

6.17.4. An ethnobotanical study in Wechiau community Hippopotamus Sanctuary in Ghana

A. Asase[1], A. A. Oteng-Yeboah[2];
[1]Department of Botany, University of Ghana, Legon, Accra, Ghana,
[2]Council for Scientific and Reserach (CSIR) Ghana, Accra, Ghana.

An ethnobotanical survey was conducted on the communities living within and round the Wechiau Community Hippopotamus Sanctuary in the Upper West Region of Ghana to understand and document the human uses of plants in the sanctuary. The study was conducted through direct interviews, questionnaires and personal observations. Seventy-six species of plants were identified as sources of food, medicines, fuel wood, animal feed, construction material, crafts and tools, as objects of culture and religion, and for other miscellaneous uses. in order of percentage use respectively, more plants were used for medicine (61.8 %), fuel wood (36.8 %), construction material (26.3 %) and crafts and tools (23.7 %). The sanctuary has therefore been identified as an excellent repository of Non-Timber Forest Products (NTFPs) whose conservation and suistainable uses will provide for the livelihood of the people in the locality.

6.17.5. Prioritizing conservation of medicinal plants in Sub-Saharan African forests

G. Chekuimo;
TRAFCAM, Yaounde, Cameroon.

The demand for traditional herbal medicine is increasing rapidly in Sub-Sahara countries mainly because of harmful effects of synthetic chemical drugs. However, the future of African medicinal plants lies on enhancing people’s participation in the utilization and conservation of its forests. Worldwide a total of at least 35000 plants species are used for medicinal purposes. The subcontinent has a rich floral diversity, totalling about 24 000 species, with 4 000 species used in traditional medicine. Their use and conservation are across sectoral concerns that embrace not only the health care, but also nature conservation, biodiversity, economic assistance, trade and legal aspects. Today, unsustainable forest management is causing biodiversity loss and massive soil erosion, as well as negatively affecting the economic future of many communities around the globe, especially in the Sub-Saharan tropics. Programme activities need to be supported to reduce the rate of deforestation of the African tropical forests and conserve the biodiversity contained within them.

7.1.1. Transcriptional regulation of root hair development in arabidopsis and its conservation among the land plants

L. Dolan;
John Innes Centre, Norwich, United Kingdom.

Root hairs are required for the uptake of minerals and water from soil. Hairs elongate by a mechanism known as tip growth, where cell expansion is focussed to a restricted region of the cell surface. Similar cell types are found throughout the land plants. A cascade of transcription factors regulates the development of root hairs in the model angiosperm arabidopsis. Early acting transcription factors control the fate of cells in the root epidermis - epidermal cells may be hair-bearing or hairless. We have evidence that the early acting genes also control the expression of a suite of transcription factors that are required for late stages of root hair differentiation, when hair outgrowth occurs. One of these genes, *RHD6,* is only expressed in the root hair cell where it promotes the transcription of three other related genes which are also required for root hair cell differentiation. Evidence will be presented that defines the regulatory interactions between these genes in arabidopsis and we will demonstrate that *RHD6* and *RHD6-LIKE* genes are part of an ancient mechanism that controls the differentiation of tip-growing cells in plants.

7.1.2. Stem cell specification and cell polarity in *Arabidopsis* roots

V. Willemsen, C. Galinha, M. Wildwater, M. Aida, D. Beis, I. Blilou, R. Heidstra, B. Scheres;
Utrecht University, Utrecht, The Netherlands.

Mutants in auxin transport and response indicate that distribution of this hormone is required for patterning distal stem cell populations and control of cell division. Recent data suggest that transport-dependent auxin maxima are used not only in the root but also during embryogenesis and in shoot-derived organs. It becomes an important question how auxin as a patterning cue induces specific downstream pathways to mediate diverse effects. The *PLETHORA1* and *2* genes encode transcription factors required for stem cell specification and can ectopically induce root identity. *PLT* expression is auxin-inducible, depends on the auxin response factors MP and NPH4 and follows the basal auxin accumulation pattern during embryogenesis and in post-embryonic root development. *PLT* genes translate auxin accumulation into region- and cell type specification patterns, and interact with the SHR-SCR pathway that plays a role in patterning the root stem cells. The *PLT* genes regulate expression of the PIN facilitators of polar auxin transport and this contributes to a specific auxin transport route to maintain stem cells at the appropriate position within the root meristem.

7.1.3. Deciphering the transcriptional network for root radial patterning in *Arabidopsis*

T. Vernoux, P. N. Benfey;
Duke University, Durham, NC, United States.

The simple symmetrical organization of the Arabidopsis root makes it an excellent system to analyze the molecular mechanisms regulating patterning during organ development. The root has a rotational symmetry along its longitudinal axis, generated through asymmetric cell divisions that take place in the root meristem. The transcription factor SHORT-ROOT (SHR) regulates the asymmetric cell division that generates the two sub-epidermal layers and is a key-component in the root radial patterning pathway. SHR was used as an entry point to reconstruct the transcriptional network controlling root radial patterning. We designed a genomic approach to identify the direct and secondary targets of SHR. We used a statistical analysis to combine information across 4 different microarray expression analyses, based on perturbation of SHR expression or activity. New insights into the mechanisms regulating root radial patterning will be discussed.

7.1.4. Genetic analysis of phloem development and differentiation in *Arabidiopsis*

A. Carlsbecker, M. Bonke, A. Honkanen, O. Lindgren, S. Tähtihärju, S. Tithamadee, Y. Helariutta;
Institute of Biotechnology, University of Helsinki, Finland.

We have shown that phloem development in the Arabidopsis root is established by a set of specific periclinal cell divisions. Resulting cell lineages differentiate into sieve element and companion cells. The recessive mutant *altered phloem development* (*apl*) lacks these divisions and the phloem-pole cells differentiate xylem characteristics instead of phloem (Bonke et al., 2003, Nature 426:181). *APL* encodes a MYB transcription factor active specifically in phloem cells. Ectopic *APL* expression results in inhibition of xylem development but not ectopic phloem development, indicating that APL is necessary but not sufficient for phloem differentiation. To identify additional factors in phloem development we performed a genetic screen of an EMS-mutagenized companion cell-specific marker line. This resulted in the identification of a set of novel mutants with patterning and/or cell proliferation defects specific to the stele. We present the characterization of these mutants. In combination with a forward genetic approach we aim at identify factors acting up and down-stream of *APL* in the regulation of phloem development and differentiation in Arabidopsis.

7.1.5. Exploiting natural genetic variation in *Arabidopsis* to identify novel regulators of quantitative aspects of root development

C. F. Mouchel[1,2], G. C. Briggs[1,2], **C. S. Hardtke**[1,2];
[1]University of Lausanne, Lausanne, Switzerland, [2]McGill University, Montreal, PQ, Canada.

To isolate novel modulators of root growth, we exploited natural genetic variation in Arabidopsis. Two accessions with slow growing primary roots were investigated in detail. Through (back)crosses to control accessions, we mendelized the major QTLs responsible for slow growth. So far, we isolated one of the two loci, named BREVIS RADIX (BRX), by positional cloning. This locus is responsible for ca. 80% of the variance of root length between the short-rooted and the control line, by controlling cell proliferation and elongation in the root tip. BRX belongs to the highly conserved plant-specific BRX gene family. Analyses of multiple mutants suggest that BRX is the only gene of this family with a role in root growth. This lack of redundancy results from differential activity of BRX-like proteins as well as differential expression. BRX is nuclear localized, activates transcription in yeast and contains two highly conserved domains of unknown function. One domain mediates protein-protein interaction with another family of transcription factors. Thus the data indicate a role for BRX family proteins in transcriptional regulation. Further details will be reported.

7.1.6. Genetic analysis of root development in *Oryza sativa*

W. Park, I. Hwang, S. Jung;
Department of Molecular Biology/ Institute of Nanosensor and Biotechnology, Dankook University, Seoul 140-714, Republic of Korea.

Rice (*Oryza sativa*) root system at the seedling stages consists of a primary-, several crown- and many lateral roots. Although the importance of the root system for the maintenance of plant function has been well recognized, almost of the genetic and molecular biological bases of rice root morphogenesis remain still unknown. Recently genetic studies to verify the mechanisms of rice root development were started, and several root-type specific mutants were reported. However, the rice root mutants with a relevant tag that can be utilized for the isolation of the gene are still very rare. Therefore, we established a mutant screening system with *Ds*-tagged populations to dissect the root developmental mechanisms and to analyze the function of the genes in rice. As a result, mutant candidates showing root type-specific aberrations were selected. In this report, we introduce the phenotypes of the selected lines and discuss the implicated developmental mechanisms. This research was supported by a grant (CG1515) from Crop Functional Genomics Center of the 21st Century Frontier Research Program funded by the Ministry of Science and Technology of Republic of Korea

7.2.1. Adaptive evolution of flowering responses to environmental cues in *Arabidopsis thaliana*

J. Schmitt[1], T. Korves[1], J. Stinchcombe[1], M. Purugganan[2];
[1]Brown University, Providence, RI, United States, [2]North Carolina State University, Raleigh, NC, United States.

The transition to flowering is regulated by diverse environmental cues such as photoperiod, vernalization, and ambient temperature, which mediate several different signaling pathways. Plants must integrate information from all of these pathways in order to flower at the appropriate time under dynamic real-world conditions. Both the environmental signals and the ecological factors that exert selection on the resulting phenotypes vary in space and time, so the optimal flowering response may vary geographically or across seasons. *Arabidopsis thaliana* is an ideal model system for investigating the functional and evolutionary significance of natural variation in the converging signaling pathways regulating reproductive timing. Ecotypes of *A. thaliana* from diverse climates exhibit considerable natural variation in developmental timing and its sensitivity to different environmental signals. Natural molecular polymorphisms at several key flowering time genes are associated with natural variation in developmental timing, as well as fitness under field conditions, and display geographic patterns suggesting adaptation to climate.

7.2.2. Chaperone Hsp90 as a molecular mechanism of genetic and environmental canalization

T. A. Sangster[1], C. McLellan[2], N. Salathia[2], K. Schellenberg[2], S. Lindquist[3], **C. Queitsch**[2];
[1]University of Chicago, Whitehead Institute for Biomedical Research, Chicago, Cambridge, MA, United States, [2]Harvard University, Cambridge, MA, United States, [3]Whitehead Institute for Biomedical Research, Cambridge, MA, United States.

The molecular chaperone Hsp90 plays a central role in the unfolding of genotype to phenotype. Manipulation of Hsp90 function yields a wide array of altered morphological phenotypes in plants and flies, which depend on underlying genetic variation. In *Arabidopsis*, manipulation of Hsp90 influenced phenotypic responses to environmental cues and buffered normal development from the destabilizing effects of stochastic processes. The multiple Hsp90 isoforms may be required to accomplish specific responses to the various external signals that plants must react to appropriately. To address the role of Hsp90 in the interplay of genotype and environment, we assembled a comprehensive set of Arabidopsis lines reduced in different HSP90 isoforms via T-DNA insertion and RNAi approaches. We have used a combination of gene expression analysis, molecular and phenotypic assays to characterize novel phenotypes of adult Hsp90-reduced plant lines. These phenotypes suggest that Hsp90 plays an important role in organismic responses to biotic and abiotic environmental challenges and may facilitate the integration of signaling pathways, resulting in a canalized response.

7.2.3. A trade-off between root responses to waterlogging and nutrient patchiness - a general trend with *Rumex palustris* as an expection

C. Jansen, **H. de Kroon**;
Inst. for Wetland and Water Research, Nijmegen, The Netherlands.

Roots are extremely responsive to changing soil environments, but it is yet unclear how responses to different soil factors are correlated. In a comparative study with 8 herbaceous species we examined whether selective root placement in nutrient hotspots and survival under water by adventitious root formation can be combined. Amongst 7 species there was a significant negative correlation among these responses, suggesting an ecological trade-off that may partly explain the distribution of the species in flooding gradients. One species (*Rumex palustris*) was an exception, with the highest propensity to explore enriched soil patches and the largest root system under water, indicating that the operation of these different root responses by a single plant is not physiologically constrained. Our results suggest that evolution has moulded the root responses of these species, depending on the specific dynamics of the soil environment.

7.2.4. Root to shoot signalling and the regulation of shoot growth and functioning in droughted plants

W. J. Davies[1], W. Jia[2];
[1]Lancaster University, Lancaster, United Kingdom, [2]China Agricultural University, Beijing, China.

Interactions between roots and drying soil generate chemical signals which move through the transpiration stream to shoots to regulate growth and functioning. Mild soil drying (and other edaphic variables) can modify the pH of the xylem sap and the shoot apoplast, thereby affecting the partitioning of the hormone abscisic acid (ABA) in the leaf to exert control on stomatal behaviour and growth. ABA-based control of these variables can be enhanced by sap alkalinisation, even when the delivery of ABA to shoots is not enhanced by soil drying. Apoplastic pH can also be modified by climatic conditions such that this signalling catena can allow the plant to integrate edaphic and climatic influences such that stomata can respond appropriately to a range of environmental cues. More severe soil drying can influence the delivery of hormonal signals to the shoots and we highlight changes in the ABA and ethylene balance of shoots as soil drying intensifies. In this paper we show how each component of a signalling cascade from soil, through roots and stems to the leaves can influence the information content of the signal which arrives in the shoot.

7.2.5. The multifaceted implications of internal and environmental signals

A. Novoplansky;
Ben-Gurion University of the Negev, Midreshet Ben-Gurion, Israel.

Plastic development necessitates that a plant coordinates its responses according to the detected conditions in the immediate environment. Recent evidence suggests that in many cases the very same mechanisms are responsible for mediating both the internal interactions between different tissues and organs of the same plant and the interactions of the plant with its external environment. Avoidance of inanimate obstacles by roots, self/nonself discrimination in roots and directional red/far-red sensitivity in shoots exemplify the multifaceted role of morphogenetical controls in plants. In all of these cases the very same physiological mechanisms are used to coordinate growth and development among different parts of the same individual plant and facilitate the perception and the adaptive responses to external stresses. It is suggested that the multifaceted role of some morphogenetical mechanisms evolved by "hitchhiking" of secondary adaptations on primary functions of the plant.

7.2.6. Shoot plasticity in respons to neighbours; integrating light and hormone signaling

R. Pierik, L. A. C. Voesenek;
Utrecht University, Utrecht, The Netherlands.

Plants growing in dense vegetations respond to neighbour plants through shade avoidance responses that include upward leaf movement and increased shoot elongation, thereby enhancing light capture. These responses are traditionally interpreted as phytochrome-mediated responses to reduced red : far-red (R:FR) light ratios of the canopy light.

We show here that several plant hormones, including gibberellins and the gas ethylene, are required to regulate shade avoidance. Ethylene-insensitive tobacco plants are weak competitors for light due to a reduced plasticity to neighbours. This is, however, not entirely related to R:FR signaling as these plants respond well to low R:FR. Interestingly, blue light photon fluence rates are also reduced in canopies and this induces shade avoidance responses in wild-type, but not at all in ethylene-insensitive plants. Furthermore, ethylene could accumulate in canopies to levels that induce shade avoidance responses. We conclude that plant neighbour detection is a complex interplay between different light signals that interact with different hormones, resulting in coordinated plasticity in respons to neighbours.

7.2.7. What must a branch say to the plant?

T. Sachs;
Hebrew University, Jerusalem, Israel.

Branch removal leads to varied developmental modifications, and it follows that an intact branch signals its presence. Both an experimental system of two shoot plants and comparative observations suggest that quantitative information about the local environment of the branch, its size and its developmental rate is carried by the hormone auxin. Information about both the environment and internal developmental relations is thus integrated by being translated to a joint molecular signal.

Auxin and presumably other information coming from a branch elicit responses throughout the plant. These include the oriented differentiation of vascular tissues, along the flux of auxin from its sources in a developing branch. By means of this differentiation the various branches compete, their genetic identity not withstanding. This competition is a component in the self organization of plant form. Branches also compete for light, which influences auxin formation, again demonstrating that there need not be a separation between internal and environmental information in determining the relations between organs and overall plant form.

7.3.1. Floral syndromes: Empiricism versus typology

S. P. Vogel;
Faculty Center for Botany, Vienna, Austria.

The typological concept of floral syndromes classifies flowers ecologically and naturally according to their pollination agents. Among zoophilous syndromes, generalism and seven specialized (euphilic) flower types are distinguished, characterized by sets of loosely combined attributes. They represent the most superficial and evolutionarily most labile organizational level of the flower, usually recognizable in the living condition only. Determining a syndrome results from an interplay of character analysis and critical field observation. Assignments may be falsified by field data, and these may be misinterpreted by rigorous empiricism. Euphilic syndromes coevolved diffusely with pollinator guilds, resulting in adaptive radiation and world-wide convergences. The present state of classification and the taxonomical distribution of syndromes are reviewed. Although the syndrome concept has a high predictive power and has proved reliable in characterizing taxa, analysing communities, and tracing evolutionary trends, it has not been unanimously accepted. Objections raised, from merely semantic to fundamental, are discussed.

7.3.2. Stamens and mimic stamens as components of floral colour patterns

K. Lunau;
AG Sinnesökologie, Düsseldorf, Germany.

Stamens of zoophilous plants are multifunctional floral organs which protect pollen, attach pollen to the pollinators body surface, provide pollen as a reward for flower visitors, and attract potential pollinators. Pollen eating flower visitors such as syrphid flies and pollen collecting flower visitors such as bees innately respond to stamen and pollen signals prior to individual experience. Flowering plants signalling with conspicuous stamens and pollen to attract pollinators have numerous costs associated with visual exposure of pollen in a way that prevents protection against solar radiation, and against pollen losses caused by wind, rain, and illegitimate flower visitors. Many flowers use mimic stamens (e.g. staminodes, plastic false stamens, yellow floral guides in the size and shape of anthers) and overcome the disadvantages of attracting and rewarding flower visitors with pollen. Several study cases focus on the benefits of signalling with mimic stamens. The aim of this presentation is to illustrate the various cases in which flowering plants may benefit by attracting flower visitors by means of mimic stamens.

7.3.3. Fruit like flowers and pollinators like frugivores: a unique pollination mechanism in *Cullenia exarillata*

M. S. Devy, T. Ganesh;
Ashoka Trust for Research in Ecology and the Environment,
Bangalore, India.

Cullenia exarillata (Bombacaceae) is a dominant tree in south Western Ghats, India. Flowers of *Cullenia* attract the entire contingent of arboreal frugivore community in site, which contribute to its pollination. *Cullenia* showed adaptations to capture their visitors at 3 levels: 1. at individual flower level, they act as fruits and does not have free flowing nectar as it is embedded in the tissues of the sepals, whereas petals are distinctly absent. The visitors remove the sepals and chew it to get the nectar. On many occasions the sepals come out easily as sleeves leaving the reproductive parts intact. 2. The flowers are densely clustered around the lateral branches and exhibit cauliflory. This facilitates elaborate display to attract arboreal mammals. These branches can bear the weight of mammals, which walk on them and help in pollen transfer. 3. Finally, they flower during times of fruit scarcity in the forest that leads to convergence of the entire frugivore community to *Cullenia*. We explore multiple selective factors that could have led to the evolution of this unique pollination system that appears to be between non-flying mammal and bat pollination syndromes.

7.3.4. The evolution of ant pollination systems

A. J. Beattie;
Macquarie University, Sydney, Australia.

The Hymenoptera are among the most important pollinators worldwide but ants, although abundant in most terrestrial ecosystems, and frequent flower visitors, are rarely involved. I review the evidence for the scarcity of ant pollination and the few cases in which ant pollination has been documented. Two very different systems have evolved: The first, limited to two orchid species with highly specialized interactions involving complex floral traits and insect behaviour, occur only in S. and E. Australia. By contrast, the second kind involves a variety of widely distributed plant families, is relatively unspecialized, with easily accessibly floral rewards that ants share with a variety of small winged insects. These systems occur chiefly in harsh habitats where selection for plants with low growth forms favours visits by ants. In the future, more plant species with varying levels of dependence on ants for seed set are likely to be found and the apprently unspecialized systems may yet reveal ant traits that predispose particulart species for pollination.

7.3.5. The chiropterophily syndrome: an analysis of the Neotropical species

I. C. Machado, A. V. Lopes;
Federal University of Pernambuco - Brazil, Recife - PE, Brazil.

Since the revision published by Dobat and Peikert-Holle, in 1985, various other cases of bat pollinated flowers were described. Currently, it is estimated the occurrence of chiropterophily, in the Neotropical Region, in ca. 50 families (among the 65 which have chiropterophilous taxa), 192 genera, and more than 600 species. From these families, 22 are referred to have chiropterophilous taxa only in the Neotropics. In this study we present a revision of published data with chiropterophilous neotropical species, and an analysis of the state of the art of chiropterophily in relation to families/genera and species, with respective floral traits. The syndrome occurs in basal, but also in derived families as Orchidaceae and Fabaceae. Results evidenced case histories with chiropterophilous species hardly confirming the floral traits referred to the syndrome, with high frequencies of species with white, cream-greenish flowers, of the gullet, brush or bell-funnel types. Recent studies added some features to the syndrome. (Financial support: CNPq).

7.3.6. Chiropterophily in the Cuban Flora

J. Gutierrez[1], C. U. Koch[2], O. von Helversen[2];
[1]Cuban Botanic Garden, Havanna City, Cuba, [2]Institute of Zoology, Erlangen University, Germany.

Cuba, the largest island in the Caribbean, consists of a big variety of landscapes and subsoils. Together with the geographical position and the influence of tropical climate, these factors contribute to the very diverse Cuban vegetation. With more than 6350 species of angiosperms, half of them are endemic.

Among the Cuban bats there are four species of flower visiting bats. Only one, *Monophyllus redmani*, belongs to the subfamily Glossophaginae, the other three species (*Phyllonycteris poeyi*, *Brachyphylla nana* and *Erophylla sezekorni*) belong to the Phyllonycterinae, a group with a distribution restricted to the Antillean islands.

On the base of an extensive revision of the Cuban flora, we are able to present for the first time a summarizing overview of the potential chiropterophilous plant species of the island. Direct field observations and IR video records, as well as an analysis of the characteristics of floral morphology and phenology of these plants, will be discussed with respect to the syndrome of chiropterophily in general and to potential adaptations to the two different groups of flower visiting bats in the island.

7.3.7. Characteristics associated with wind pollination in the southern heaths (Epacridaceae) - a sub group of the Ericaceae.

P. G. Ladd;
Murdoch University, Murdoch, Western Australia, Australia.

Wind pollination is associated with particular groups including conifers, some monocots and flowering tree species. However sporadically (but frequently) it has evolved in lineages that are predominantly biotically pollinated. Factors which may have forced the change are often associated with extreme environmental conditions that could limit pollinator attention to the flowers of the species. The Epacridaceae has been considered exclusively biotically pollinated, with insects the predominant visitors and vertebrates much less important. However at least three species of *Richea* have a number of characteristics which point towards wind as the main pollen vector. This study outlines some of the characteristics of selected species and evaluates the likelihood that wind pollination has evolved in *R. sprengelioides, R. procera,* both in Tasmania and *R. victoriana* in Victoria, Australia. The genus seems to have exaptations, for example the “operculum type” of corolla, which would facilitate development of wind pollination from an animal pollinated ancestor. A number of other floral characteristics of the species conform to the syndrome of wind pollination.

7.4.1. The evolution of anisogamy: an overview

G. A. Parker;
University of Liverpool, Liverpool, United Kingdom.

Anisogamy underlies the important evolutionary processes in sex ratio and sexual selection. Our theory (hereafter PBS) proposed that anisogamy arose through a form of disruptive selection in an ancestral isogamous external-fertilising ancestor, with gamete production under a size/number trade-off. Small gametes (proto-sperm producers) benefit because they can produce many more gametes, parasitically gaining most fusions with the important large gametes (from proto-ovum producers) with a high survival advantage (zygote survival was an increasing function of size). Selective fusions were proposed to have evolved later. Subsequent PBS versions assumed non-random fusions between two mating types. New theories are that: (i) anisogamy is a mechanism for controlling cytoplasmic inheritance of parasitic replicators, and (ii) eggs became larger to increase sperm encounter rates. PBS has been wrongly claimed to require an unusual relationship between zygote size and fitness. A new analysis of PBS shows more clearly the conditions under which the ESS is for isogamy or two sexes: isogamy is most likely in protists, and anisogamy in higher organisms.

7.4.2. Density dependent sexual selection in external fertilizers

D. R. Levitan;
Florida State University, Tallahassee, FL, United States.

The evolutionary transition from isogamy to anisogamy likely occurred among organisms with external fertilization. While theory offer explanations for this transition, there is little data on sexual selection and whether gamete traits can influence reproductive success in external fertilizers. Using sea urchins and molecular markers, I estimate reproductive success, the variance in reproductive success and the intensity and nature of sexual selection for both males and females under natural conditions in the sea. These measurements are made across a gradient from sperm limited to sperm competitive conditions. The results indicate that (1) gender differences in the intensity of sexual selection is dependent on population density, (2) differences in population density can select for differences in gamete traits that are better adapted to either sperm limited or sperm competitive environments, and (3) there are sex differences in the costs associated with variation in spawning behavior. The nature of sexual selection in external fertilizers is dependent on population density and the targets of selection are gametes and spawning behavior.

7.4.3. Evolutionary origins of anisogamy in marine green algae

T. Togashi[1,2], J. L. Bartelt[2], P. A. Cox[2];
[1]Marine Biosystems Research Center, Chiba University, Amatsu-Kominato, Japan, [2]National Tropical Botanical Garden, Kalaheo, HI, United States.

In marine green algae, isogamous or slightly anisogamous species are taxonomically widespread. They produce positively phototactic gametes in both sexes. We developed a new numerical simulation of gamete behavior in C++ to elucidate potential advantages of gamete behavior, with input parameters based on experimental data. Each gamete swimming in a virtual rectangular test tank was tracked and the distances between the centers of nearby male and female were measured at each step to detect collisions. These numerical experiments elucidated the roles of gamete behavior and the mechanisms of the evolution of anisogamy and more derived forms of sexual dimorphism. We found that gametes with positive phototaxis were favored, particularly in shallow water, because they could search for potential mates on the two-dimensional water surface rather than randomly in three dimensions. We also found evidence that sperm limitation is not the dominant selective force in the evolution of isogamous or slightly anisogamous marine green algae; gamete behaviors appropriate to the microhabitat and gamete density appear to be far more important.

7.4.4. Adaptive significance of egg size variation of aquatic animals: referring to mesoscale features of aquatic environments.

K. Nishimura[1], N. Hoshino[2];
[1]Hokkaido University, Hakodate, Japan, [2]Hokkaido Fish Hatchery, Eniwa, Japan.

Zygosis rule of megagamete and microgame for initiating ontogenesis of diplophase organisms that is ubiquitous in animals and plants has bee a fascinating phenomenon for evolutionary biologists. Anisogamy would be a common resolution for maximizing the chance of making a zygosis and the success of the zygote. Since megagamete (eggs) totally takes on the responsibility of the success of the zygote in anisogamy, we can expect adaptive significance of egg size variation on various environmental conditions. We review egg size variation of various types of fish species inhabiting throughout freshwater habitats and ocean pelagic and demersal habitats by focusing common features of life history in aquatic environment. We further present a theory to understand the adaptive significance of egg size variation of the aquatic animals by focusing the common mesoscale features of aquatic environments, e.g., current, transportation, and environmental gradients.

7.4.5. Why are equally-sized gametes so rare? The instability of isogamy and the cost of anisogamy

H. Matsuda[1], P. A. Abrams[2];
[1]Yokohama National University, Yokohama, Japan, [2]University of Toronto, Toronto, ON, Canada.

The aim of this study was to determine the circumstances in which isogamy can be maintained in a population that has already evolved mating types. We analysed the evolutionary dynamics of gamete sizes when there are two mating types. The models and conclusions differ depending on: (1) whether size-determining loci are linked to loci-determining mating types or not; (2) whether gamete size affects gamete success or not; and (3) whether viable mutations with large effects on size are possible or not. In all cases, the reproductive success of a zygote depends on the sum of the sizes of the two uniting gametes, and the number of gametes produced is inversely proportional to gamete size. When size is not closely linked to mating type, it is possible for isogamy to be likely stable, particularly when mutations of large effect are deleterious. However, when size is linked to mating type, isogamy can only be stable when there are significant direct effects of size on gamete survival and mating success. The cost of anisogamy is generally less than two-fold.

7.5.1. Reconstruction of the landscape unit relate to the roof-shale level from the Quitéria Outcrop - Rio Bonito formation, Paraná Basin, Rio Grande do Sul State, Brazil - Lower Permian - Gondwana.

A. Jasper[1], M. Guerra-Sommer[2], M. Cazzulo-Klepzig[2], R. Menegat[2], J. Spellmeier[1], I. C. Osterkamp[1], J. Salvi[1], E. d. Santos[1];
[1]UNIVATES, Lajeado, Brazil, [2]UFRGS, Porto Alegre, Brazil.

The Quitéria Outcrop is an isolated portion of the Rio Bonito Formation, Paraná Basin - Lower Permian of the Rio Grande do Sul State, Brazil. The present study is an attempt to establish a landscape model from a specific level of this Outcrop. This level is characterized as a roof-shale flora, a singular registry in Gondwana, developed in coastal lagoon depositional system protected by a barrier, composed by abundant autochthonous cormophytic bases of arborescent lycophytes (*Brasilodendron pedroanum*). Also, occur, associated to the autochthonous elements, parautochthonous forms, represented by fronds (*Botrychiopsis valida*, rodheopterideous fronds), conifer shoots with adpressed leaves as well as fertile shoots presenting cones in organic connection (*Coricladus quiteriensis*), associated to herbaceous lycophyte fertile shoots (*Lycopodites ?* sp.) allowed establishing the presence of canopy forms and understory, representing groundcover and shrub-like vegetation. The study of the floristically components and the Stratigraphic elements are important to reconstruct the landscape unity and to compose an artistically representation presented here.

7.5.2. Permian-Triassic vegetation in Antarctica: Floral turnover in relation to changes in paleolatitude and paleoclimate

E. L. Taylor;
University of Kansas, Lawrence, KS, United States.

Like the rest of Gondwana, Antarctica experienced a floral turnover at the end of the Permian--from a low diversity *Glossopteris* flora to more diverse assemblages, eventually dominated by corystosperm seed ferns. Floral change occurred throughout the Triassic, reflecting a general climatic warming. The P-T boundary in Antarctica has traditionally been defined by floral change, but evidence of Triassic *Glossopteris* elsewhere in Gondwana calls this definition into question. The best floral records come from the central Transantarctic Mountains (CTM) and Prince Charles Mountains (PCM). In the PCM, mega- and palynofloras show the disappearance of glossopterids and cordaiteans, followed by the appearance of peltasperms and lycophytes, with corystosperms, conifers and ferns occurring later. In the CTM, the Early Triassic fossil record is poor; palynomorphs indicate the presence of lycophytes, but no corresponding megafossils are known. Floral changes near the boundary will be discussed, along with the increase in floral diversity and abundance from the Early to Late Triassic.

7.5.3. Floristic turnover at the Permian-Triassic boundary in Australia and East Antarctica

S. McLoughlin[1], S. Lindström[2];
[1]School of Natural Resource Sciences, Queensland University of Technology, Brisbane, Australia, [2]Department of Geology, Geobiosphere Science Centre, Lund University, Lund, Sweden.

The P-Tr boundary records global devastation of gymnosperm forests in a short transition zone. In Australia and Antarctica this is expressed by collapse in glossopterid abundance and rise in *Lunatisporites pellucidus* pollen, locally synchronous with peaks of the fungal/algal palynomorph *Reduviasporonites*. Glossopterid decline is abrupt but other palynofloral changes across the boundary are more gradual. The Early Triassic saw the rise of other gymnosperms, notably peltasperms, voltzialean conifers and corystosperms, many of which were already sparse components of latest Permian floras. This phase is typically associated with a rise in lycophyte spores and/or acritarchs. This floristic transition in Australia-Antarctica is associated with abrupt termination of coal deposition at the P-Tr boundary, sharp decline in carbonaceous shales through the transition zone, and extensive redbeds in the Early Triassic. Complex corystosperm-dominated floras and coal deposition reach a post-extinction peak around Carnian-Norian times. The P-Tr and K-Pg events show similar patterns of plant turnover but the Triassic floristic recovery was more protracted.

7.5.4. Vegetational changes in India during the K/T boundary

R. C. Mehrotra;
Birbal Sahni Institute of Palaeobotany, Lucknow, India.

The position of India in the past especially during the Cretaceous-Tertiary was very important as the sub-continent had performed a remarkable northward journey after being separated from other Gondwanaland continents. It would be interesting to know the floral changes taking place on this island continent during the period. During the greater part of the Cretaceous the flora was dominated by the gymnosperms, with few reports of angiospermous fossils of uncertain affinities. The entry of the flowering plants into India might have been late as compared to their appearance on other continents. The definite records of angiosperm fossils started appearing in India from the Lameta beds which are Maastrichtian in age. The successive eruptions of lava flows called the Deccan Traps started in India during the upper Maastrichtian and continued till the Danian with quiescent intervals in between. The sedimentary beds deposited during these intervals are very rich in the plant fossils that reveal a drastic change in the flora during the period. The gymnosperms declined in number whereas the angiosperms which had been poorly represented earlier, suddenly became dominant.

7.5.5. Short-term collapse of vegetation at the Cretaceous-Paleogene boundary in New Zealand - cause for extinction of polar dinosaurs?

V. Vajda;
GeoBiosphere Science Centre, Lund, Sweden.

High-resolution palynological investigations of sediments spanning the Cretaceous-Paleogene boundary in New Zealand reveal a sudden turnover in the flora most strikingly expressed by a thin layer of fungal spores coincident with an iridium anomaly of 4ppb. Pioneer recovery vegetation, following the end-Cretaceous catastrophe is represented initially by *Laevigatosporites ovatus* spores succeeded by *Gleicheniidites*, both representatives of ground ferns (Blechnaceae and Gleicheniaceae). Younger assemblages are dominated by spores of tree ferns eg. *Cyathidites* and *Cibotiidites*. Following an interval of fern dominance, gymnosperms and later angiosperms return to the palynological record. Extinction levels of plants do not exceed 15%. The absence of vascular plant spores and pollen and the abundance of fungal spores at the boundary is evidence of wholesale dieback of photosynthetic vegetation due to reduced insolation following the Chicxulub meteorite impact. The period with low light levels is estimated to have lasted less than a year but vegetation dieback had dramatic consequences for the terrestrial food web and on large herbivores in particular.

7.5.6. Floristic changes in the Cretaceous to Cenozoic vegetation of Antarctica

D. J. Cantrill[1,2], **I. Poole**[3,4];
[1]Department of Palaeobotany, Stockholm, Sweden, [2]Swedish Museum of Natural History, Stockholm, Sweden, [3]Wood Anatomy Section, Utrecht, The Netherlands, [4]National Herbarium of the Netherlands, University of Utrecht Branch, Utrecht, The Netherlands.

Recent investigations of patterns of taxonomic turnover and wood abundance reveal little impact of the K-T mass extinction event in Antarctica. This supports previous work on palynofloras that indicate a gradual transition and continued turnover both prior to and after the event. Four stages of forest development are recognized through the Cretaceous and Cenozoic. Aptian to Albian Conifer dominated wood floras are replaced by conifer dominated but with a presumed minor angiosperm component in the Cenomanian to Turonian. By the Coniacian to Santonian these conifer-dominated forests are replaced by a diverse mixed angiosperm forest. The Campanian to Maastrichtian is characterized by the expansion of Nothofagaceae at the expense of many older taxa. This continues through the Cenozoic till the final extinction in the Neogene. The patterns of vegetation change appear to be strongly linked to climatic fluctuations.

7.5.7. Changes in Cretaceous/Paleogene Angiosperm floras of Southern South America

M. A. Gandolfo[1], M. C. Zamaloa[2];
[1]L. H. Bailey Hortorium, Ithaca, NY, United States, [2]Laboratorio de Paleobotánica y Palinología, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires., Buenos Aires, Argentina.

It is well known that, while the disintegration of Gondwanaland started during the Mesozoic, the Cenozoic was period of significant geologic activity. Major geological events affected the climate of Antarctica and South America in general, and therefore it affected the distribution and migration of the biota. Here, we re-analyze data gathered from palynology and megafossils in the light of the new evidence and we present examples of how changes in the climate are reflected in the paleofloras. Data collected provides evidence that during the Campanian-Maastrichtian, the angiosperms were dominants in number of taxa but they still were not the dominants in the ecosystems. A remarkable change is observed during the Paleocene-Eocene when the angiosperms are dominant in number of taxa and became the principal component of the ecosystems. Paleofloras of Southern South America had the greatest influence from Antarctica at least until the Eocene, and after that, that influence decreased.

7.6.1. Compositree - where do we go from here?

C. Oberprieler;
Institut of Botany, Regensburg, Germany.

Besides the discussion of the state-of-the-art and the way ahead towards the Tree-of-Life for the Compositae within the framework of The International Compositae Alliance (TICA), the presentation will concentrate on a demonstration of potential applications of phylogenetic tree information on groups of this family in the fields of biogeography, evolutionary biology and ecology. Using the Peri-Mediterranean clade of Compositae-Anthemideae as an example, the reconstruction of temporal and spatial aspects of the biogeographical history of this plant group based on a combination of dispersal-vicariance analysis (DIVA) and molecular clock dating of a calibrated, rate-smoothed nrDNA ITS maximum-likelihood tree is demonstrated, along with the employment of phylogenetic information in tests on the relationship between life history trait evolution (e.g. life-form, dispersal structures) and ecological niche differentiation (e.g. growth habit, ecoclimatic conditions).

7.6.2. Molecular phylogeny of the Astereae: Generic relationships among the Daisies, tribe Astereae

L. E. Urbatsch[1], **T. Lowrey**[2], L. Brouillet[3], C. Quinn[4];
[1]Louisiana State University, Baton Rouge, LA, United States,
[2]University of New Mexico, Albuquerque, NM, United States,
[3]Universite De Montreal, Montreal, PQ, Canada, [4]Royal Botanic Gardens, Sydney, Australia.

Tribe Astereae with just over 200 genera and 3000+ species are especially well represented in arid temperate, tropical and subtropical habitats with centers of diversity in North and South America, Africa, and Australasia. Unlike the tribe's stable circumscription, subtribal and generic treatments are often paraphyletic and polyphyletic. Many traditionally recognized genera have been shown to be polyphletic including *Aster, Chrysothamnus, Ericameria, Erigeron, Haplopappus, Olearia, Tetramolopium, Vittadinia,* etc. Based on the supertree by V. Funk and colleagues, Astereae is relatively derived and sister to Anthemideae. It appears to have originated in the southern hemisphere, probably in southern Africa or a combination of southern continents, and expanded from there. In conjunction with The International Compositae Alliance, the Astereae Working Group (AGW) was organized to develop a more complete understanding of relationships among Astereae. Initial focus for this effort is to generate a comprehensive, molecular based phylogeny. Information about AWG is given on the website hosted by the New Mexico Museum of Southwestern Biology Herbarium.

7.6.3. Diversification and tribal revision of Helianthoideae

J. L. Panero[1], B. G. Baldwin[2];
[1]University of Texas, Austin, TX, United States, [2]University of California, Berkeley, CA, United States.

Molecular studies of subfamily Helianthoideae (Cass.) Lindl. based on several genes of cpDNA reveal 13 lineages we recognize as tribes. The subfamily is primarily characterized by presence of phytomelanin in the cypselae. All lineages of the subfamily have their origin in North America, except for the basalmost lineage, the mostly African tribe Athroismeae. We hypothesize that the evolution of Helianthoideae in America is the result of a long distance dispersal event from Africa. The Helenieae, characterized by cypselae with large crystals and without phytomelanin, is reminiscent of Inuleae and represents the basalmost lineage of the subfamily in the Americas. The next lineage to split is Coreopsideae. The remaining tribes of Helianthoideae are grouped into two main clades. One clade contains Neurolaeneae, followed by Tageteae, and Chaenactideae sister to Bahieae. The other clade contains Polymnieae as sister to two clades, one containing Heliantheae and the other Millerieae sister to Madieae, Perityleae, and Eupatorieae. The present classification scheme is based on the desirability of recognizing monophyletic tribes, including Eupatorieae.

7.6.4. A global molecular phylogeny of the Gnaphalieae (Asteraceae).

M. Unwin[1], R. Bayer[1], J. Ward[2], I. Breitwieser[3], M. Koekemoer[4];
[1]CSIRO, Plant Industry, Canberra, Australia, [2]University of Canterbury, Christchurch, New Zealand, [3]Landcare Research, Lincoln, New Zealand, [4]South African National Biodiversity Institute, National Herbarium, Pretoria, South Africa.

The Gnaphalieae are a tribe of 187 genera (1250 species) of Asteraceae that have their greatest diversity in the southern hemisphere. The objective of this ongoing study is to reconstruct a global phylogeny of the tribe using sequence data from two non-coding chloroplast DNA sequences, the *trnL* intron and *trnL/trnF* intergenic spacer, as well as the *matK* coding region. Included in this investigation are the genera of the Gnaphalieae from the African basal groups, and members of all recognized subtribes. Results indicate that the Relhaniinae, which are restricted to Africa, are not a monophyletic group as presently circumscribed, nor are the South African members of *Helichrysum*, the Cassiniinae and Gnaphaliinae. Also the, primarily Australian, subtribes Angianthinae and Cassiniinae are non-monophyletic as currently circumscribed. In most trees the Relhaniinae s. str. and some of the basal taxa comprise a clade that is sister to the remainder of the tribe Gnaphalieae and furthermore several genera that are currently in the Gnaphalieae, including *Printzia, Isoetopsis, Denekia*, and *Callilepis*, should be excluded from the tribe.

7.6.5. Origin and diversification of tribe Anthemideae (Asteraceae)

L. E. Watson[1], J. Valles[2], C. Oberpreiler[3];
[1]Miami University, Oxford, OH, United States, [2]Universitat de Barcelona, Barcelona, Spain, [3]Universitat Regensburg, Regensburg, Germany.

Tribe Anthemideae (Asteraceae) is composed of 111 genera and approximately 1750 species including many cultivars, such as chamomiles, daisies, and chrysanthemums, and ecologically important species, such as sagebrushes. Molecular phylogenies are largely incongruent with traditional classifications and morphological phylogenies, and instead resolve lineages strongly correlated with biogeographic distribution. The topology includes a grade of many South African genera that are basal to a large clade that is further resolved into two sister subclades. The subclades include 1) eastern Asian genera (including cosmopolitan *Artemisia* and allies) sister to South African genera, and 2) peri-mediterranean genera (including *Anthemis* and *Achillea*) sister to South African genera. Thus molecular phylogenies support a South African origin for the tribe itself evidenced by the placement of eastern Asian and western Eurasian lineages being deeply nested within and sister to South African genera. Correlations with morphology and karyology will also be discussed.

7.6.6. Reconstructing the evolutionary history of a giant: a preliminary ITS phylogeny of *Senecio* and tribe Senecioneae (Asteraceae)

P. B. Pelser[1,2], J. W. Kadereit[3], B. Nordenstam[4], I. Breitwieser[5], S. J. Wagstaff[5], L. E. Watson[1];
[1]Miami University, Department of Botany, Oxford, OH, United States, [2]Nationaal Herbarium Nederland, Leiden, The Netherlands, [3]Institut für Spezielle Botanik und Botanischer Garten, Johannes Gutenberg-Universität Mainz, Mainz, Germany, [4]Swedish Museum of Natural History, Department of Phanerogamic Botany, Stockholm, Sweden, [5]Allan Herbarium, Landcare Research, Lincoln, New Zealand.

Tribe Senecioneae (Asteraceae) includes *Senecio*, one of the largest genera of flowering plants composed of 1,000-3,000 species, which has a cosmopolitan distribution. This genus harbors remarkable diversity in morphology and life-history strategies. Systematic studies in *Senecio* have, however, always been frustrated by its enormous size. To better understand the underlying patterns of diversity and the evolutionary success of *Senecio,* we are inferring its evolutionary history within the broader context of Tribe Senecioneae using DNA sequence data of the ITS region of nrDNA. Preliminary results for over 600 species sequenced thus far support a polyphyletic nature of *Senecio*. Based on these results and morphological characters, we propose a new, monophyletic delimitation of *Senecio* and discuss several interesting global biogeographical patterns in Senecioneae. We are expanding our data set with sequences of several plastid regions and will include representatives of all 150 genera in the tribe and c. 125 sections of *Senecio* in our phylogenetic analyses.

7.6.7. Origin and diversification of tribe Eupatorieae

E. E. Schilling[1], J. L. Panero[2], D. Hind[3];
[1]University of Tennessee, Knoxville, TN, United States, [2]University of Texas, Austin, TX, United States, [3]Royal Botanic Gardens, Richmond, United Kingdom.

Eupatorieae is a species rich group that has long been recognized as a tribe. Thus it was a surprise when initial molecular analyses of the family placed it within Heliantheae s.l. Our estimates of relationships of the tribe, using a data set that has a broader sampling of both gene regions and taxa, shows tribe Perityleae as the sister group. The basalmost diverging lineage within Eupatorieae is formed by *Hofmeisteria*, which shares significant features with Perityleae. Basally diverging lineages of Eupatorieae share the high base chromosome number of x=18 or 19, indicating that the widespread numbers of x=9 or x=10 are derived. The latter numbers characterize a split within a derived clade of the tribe; the basalmost branches of the x=10 clade are formed by taxa such as *Brickelliastrum* and *Carminatia* that have often been included in *Brickellia*, which is x=9. Although there is decisive support from molecular data for the dismantling of traditional *Eupatorium*, preliminary results suggest that there will be the need for some adjustments of the subtribal taxonomy.

7.7.1. Multiple phylogeographic approaches to determine the post-glacial colonization history of *Hippophae rhamnoides* L. (Eleagnaceae) in Europe based on chalcone synthase intron (CHSI) sequence variation

I. V. Bartish[1], **H. P. Comes**[2], J. W. Kadereit[3];
[1]Swedish Museum of Natural History, Stockholm, Sweden, [2]Paris-Lodron-Universität, Salzburg, Austria, [3]Johannes Gutenberg-Universität, Mainz, Germany.

There are currently strong efforts in plant phylogeographic studies to obtain genealogical data from nuclear DNA gene sequences. Nuclear CHSI sequences were surveyed in populations of *Hippophae rhamnoides* from Europe, where pollen data suggest a post-glacial range expansion of the species into northern Europe from more southern localities. We tested whether sequence-based nuclear genealogies are useful in providing detailed insights into routes of colonization and population demographic changes in this early successional species. We used: mismatch analyses to make inferences about past population growth and the time of expansion; tests for neutral evolution (e.g. Fu's *Fs*) that can also be useful for assessing deviations from the null hypothesis of population equilibrium; and nested clade analysis. Ideally, one would want to find concordance among the inferences from these different methods, before feeling confident that populations of *Hippophae* have experienced a past history of population growth. However, our results indicate that inferences made from these different methods are not always congruent, possible reasons of which will be discussed.

7.7.2. Can the genetic structure of plant populations be predicted from species' life history traits?

J. S. Duminil[1], S. Fineschi[2], A. Hampe[3], P. Jordano[3], D. Salvini[4], G. G. Vendramin[5], R. J. Petit[1];
[1]INRA, Cestas, France, [2]CNR, Firenze, Italy, [3]CSIC, Sevilla, Spain, [4]Danish Centre for Forest, Landscape and Planning, Hørsholm, Denmark, [5]CNR, Sevilla, Spain.

Many studies have reported that the way genetic diversity is organised within and among plant populations is related with species' life history traits and geographic distribution. However, most analyses have neglected effects of shared ancestry between taxa although both life history traits and genetic diversity parameters tend to underlie strong phylogenetic inertia. Numerous studies have likewise neglected that many species traits are not mutually independent, which renders the interpretation of detected relationships difficult. Here, we use phylogenetically independent contrast and partial regression analyses to re-evaluate some widely acknowledged relationships between life history traits, geographic distribution and population genetic structure. We include measures of subdivision of diversity based on both maternally and biparentally inherited molecular markers. We conclude that the effect of life history traits on plant genetic structure has been overstated and that the geographical and historical contexts play a considerable role in shaping genetic structures of plant populations.

7.7.3. Biogeography and evolutionary history of *Abies alba* Mill. - a synthesis based on paleobotany and genetics

B. Ziegenhagen[1], R. Chedaddi[2], J. L. de Beaulieu[2], B. Fady[3], D. Gömöry[4], M. Konnert[5], T. Litt[6], R. Longauer[7], R. Terhürne-Berson[6], S. Liepelt[1];
[1]Philipps-University, Marburg, Germany, [2]Université, Marseille, France, [3]INRA, Avignon, France, [4]University, Zvolen, Slovakia, [5]Bayerisches Amt für forstliche Saat- und Pflanzenzucht, Teisendorf, Germany, [6]University, Bonn, Germany, [7]Forest Research Institute, Zvolen, Slovakia.

Silver fir (Abies alba Mill.) is characterized by a complex glacial and postglacial history, which since 30 years is controversially debated for locations of `effective´ refugia, postglacial migration routes, secondary contact and introgression zones. A synthesis based on the combination of data from different fossil signals, macro- and microfossil records, as well as from different genetic marker categories allowed us to clarify some of the debated uncertainties such as the presence of refugia in the Pyrenees, Western Alps and the Northern Apennine, respectively. We put forward a new hypothesis of a glacial refuge in the Western Balkans. The geographic distribution of genetic lineages together with the fossil records shaped large-scale migration routes. Suture and introgression zones were clearly visualised. An attempt is made to unravel evolutionary implications of a species biogeography as a history of migration and genetic diversity.

7.7.4. Phylogeography of European *Asplenium* (Pteridophyta)

H. Hunt[1], J. Vogel[1], C. Duraes[1], S. Russell[1], M. Grundmann[1], F. Rumsey[1], I. Pinter[2], M. Gibby[3], J. Barrett[4], H. Schneider[5];
[1]Natural History Museum, London, United Kingdom, [2]Eoetvoes Lorand University, Budapest, Hungary, [3]Royal Botanic Garden, Edinburgh, United Kingdom, [4]Department of Genetics, Cambridge, United Kingdom, [5]Albrecht-von-Haller Institut of Plant Sciences, Goettingen, Germany.

With more than 50 taxa *Asplenium* is the most species rich fern genus in Europe. Half of these rock ferns are diploid and they are ancestral to all European polyploids. Of these 50% are auto- or segmental allopolyploids and 50% are allotetraploids. Most European taxa have distinct distribution patterns and distinct habitat and substrate requirements. We use *Asplenium* as a model system to investigate European phylogeography for cryptogamic plants by exploring the discontinuities in ploidy levels, distribution patterns, breeding systems and genetic diversity in the genus. This paper will compare diploid and polyploid taxa from several polyploid complexes for which we have extensive allozyme and cpDNA data sets (e.g. A. adulterinum agg., A. ceterach agg., A. hemionitis, A. hispanicum agg., A. jahandiezii, A. majoricum agg., A. petrarchae agg., A. scolopendrium agg. & A. trichomanes s.l.) to infer long term glacial refugia and contribute to the debate on phylogeographic patterns in European and Macaronesian plants.

7.7.5. *Evolution of* zinc tolerance *in Arabidopsis halleri (*Brassicaceae*):* a phylogeographic approach using cpDNA

M. Pauwels[1], A. Babled[1], C. Godé[1], A. Holl[1], I. Bonnin[2], P. Saumitou-Laprade[1];
[1]Laboratoire de Génétique et Évolution des Populations Végétales
UMR CNRS 8016, FR CNRS 1818, Villeneuve d'Ascq, France, [2]Station de Génétique Végétale UMR CNRS-INRA-UPS-INAPG Ferme du Moulon, 91190 Gif/Yvette, France.

Using hydroponics, we evaluated Zn tolerance for 33 populations of *Arabidopis halleri*, a pseudometallophyte with metallicolous (M) populations. We showed species-wide tolerance with increased tolerance in M populations. We then used cpDNA variation to determine M population history. We revealed strong genetic structure. However, neither differentiation between edaphic types nor founder effects in M populations have been detected. Isolation by distance was greatly responsible for genetic structure. Moreover, we found genetic differentiation between assemblages north and south of the Alps. Zn tolerance should have appeared early in the species history and may be connected with speciation. M population foundation must have occurred several times and can not be related to population bottlenecks. Therefore, evolution towards increased tolerance should be regarded as convergent evolution in M populations. We suppose at least two glacial refuges for A. halleri, on both sides of the Alps. Populations might have survived in northern Europe during the Late Pleistocene and since have diverged from the southern ones.

7.7.6. Infraspecific differentiation, genomic constitution and modes of reproduction of North American genus *Boechera* (Brassicaceae) as deduced from nuclear microsatellite allelic variation

C. M. Dobes, M. A. Koch;
Heidelberg Institute of Plant Science, Heidelberg, Germany.

Genus *Boechera* (= *Arabis* p.p.) constitutes a monophyletic lineage of purely Greenlandic and North American distribution. Hybridization, polyploidisation and apomictic stabilization of new genotypes were shown to be the main factors underlying the high polymorphism encountered in this genus. Application of nuclear microsatellite markers proved especially valueable to analyse patterns of differentiation within and among the three model species *Boechera divaricarpa*, *B. holboellii*, and *B. stricta*. This multilocus marker system revealed introgressions and infraspecific differentiations which have not been seen with nuclear (nrDNA ITS) and chloroplast DNA sequences (*trn*L intron, *trn*L/F IGS). Microsatellite allelic variation was further used, together with data on pollen morphology, to estimate the ploidy levels of herbarium specimens. Additionally, these data were successfully used to correlate modes of reproduction with historic events leading to contemporary geographic distribution patterns.

7.7.7. Immigration of thermophilous key species to Svalbard: Can past patterns be used to predict the future?

P. B. Eidesen[1], I. G. Alsos[1], D. Ehrich[1], G. Jacobsen[1], I. Skrede[1], P. Taberlet[2], K. Westergaard[3], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway, [2]Laboratoire d'Ecologie Alpine, CNRS UMR 5553, Université Joseph Fourier, Grenoble, France, [3]Tromsø Museum, University of Tromsø, Tromsø, Norway.

The arctic archipelago of Svalbard was almost completely ice-covered during the last glaciation. The most thermophilous plants occurring there today must therefore have arrived postglacially by long-distance dispersal. As climate models predict an increase of the average temperature in Svalbard, even more thermophilous species may establish, given that they are able to cross the oceans. We study established as well as possible immigrant species to 1) identify the source areas and frequency of previous immigrations, 2) estimate the dispersal potential of species that have not yet arrived in Svalbard, and 3) compare species with different modes of dispersal. A total of 18 widespread plants, including several circumpolar species, have been sampled throughout their distribution range and are subjected to AFLP analysis. We observe regional structuring in all species analysed so far, and it appears that the Svalbard archipelago mainly has been colonized from the east (western Russia).

7.8.1. Recent progress in the systematics of Apocynaceae

S. Liede-Schumann;
Dept. of Plant Systematics, Bayreuth, Germany.

Since the last IBC in St. Louis, progress has been made in almost all parts of the family. In the more plesiomorphic Rauvolfioideae and Apocynoideae, efforts have focused on elucidating tribal circumscriptions. In Apocynoideae, almost all tribes recognized in the most recent classification are not monophyletic, and work is underway tribe by tribe to remedy the situation. In the "Higher Apocynaceae" (Periplocoideae, Secamonoideae, Asclepiadoideae), the situation is somewhat better. Reasonably stable tribal concepts have been established, and for some of the larger tribes, subtribal concepts are emerging. Some of the long-standing disputes about generic limits have been resolved (e.g., *Cynanchum*, *Sarcostemma*); others are about to be solved (*Hoya*, *Dischidia*). The issue of homoiologies has been clarified in many cases, and hypothesis about their origin have been suggested. Much work remains to be done in all parts of the family, presenting numerous opportunities for young systematists.

7.8.2. Phylogenetic relationships and character evolution in Mesechiteae (Apocynoideae, Apocynaceae)

A. O. Simões[1], M. E. Endress[1], T. van der Niet[1], L. S. Kinoshita[2], E. Conti[1];
[1]Institute of Systematic Botany, Zürich, Switzerland, [2]Universidade Estadual de Campinas, Campinas, Brazil.

Mesechiteae, one of the tribes comprising Apocynoideae, includes ca. 160 species distributed throughout the neotropics. Recent phylogenetic studies resulted in significant changes in its composition and new insights on the relationships of its constituent genera. Thus defined, Mesechiteae comprises four genera dispersed among three subclades and is characterized by four morphological synapomorphies: presence of leaf colleters, style-head with 5 longitudinal ribs, stamens and style-head united by cellular fusion and anther bases non-sagittate. The gynostegium structure provides useful morphological characters within Mesechiteae, supporting the exclusion of *Secondatia*, inclusion of *Forsteronia* and the distinction between *Mandevilla* and the clade formed by *Mesechites* and *Tintinnabularia*. *Mandevilla*, by far the largest genus of Mesechiteae, shows a remarkable variation in morphological traits. Some characters, like the arrangement of leaf and calycine colleters, form of anther base and number of nectaries proved to be phylogenetically reliable, but others, like the shape and size of the corolla tube, are discordant with the current phylogeny.

7.8.3. Progress in systematics of Apocynaceae s. str.

T. Livshultz[1], D. J. Middleton[2], **M. E. Endress**[3], J. Williams[4];
[1]Harvard University, Cambridge, MA, United States, [2]Royal Botanic Garden, Edinburgh, United Kingdom, [3]Institute of Systematic Botany, Zürich, Switzerland, [4]Sam Houston State University, Huntsville, TX, United States.

Of the five subfamilies currently recognized in Apocynaceae, two - Rauvolfioideae and Apocynoideae - comprise the Apocynaceae s. str. Over the past ten years most progress in higher level systematics in Apocynaceae s. str. has been made in the heterogeneous subfamily Rauvolfioideae. During the past couple of years research has focused more on tribal delimitation in Apocynoideae, which are much more homogeneous and with more subtle differences defining tribes and genera than in Rauvolfioideae. These studies have yielded results indicating that the five Apocynoideae tribes recognized in the latest family level classification are not monophyletic and are in need of revision following current criteria and convention. In addition these studies, in agreement with earlier work, show the three subfamilies of the former Asclepiadaceae as nested within the Apocynoideae but failing to form a monophyletic group. Here we present the most important of these new findings in Apocynaceae, particularly in subfamily Apocynoideae.

7.8.4. Relationships in Periplocoideae (Apocynaceae), and the multiple origins of complex morphological structures

G. M. Ionta, W. S. Judd;
University of Florida, Gainesville, FL, United States.

Periplocoideae, a small Old-World subfamily of Apocynaceae s.l., have long been recognized as a group based on the presence of unique scoop-shaped translators (hardened secretions of the stylar head), upon which pollen is shed as tetrads or pollinia. Recent phylogenetic analyses confirmed the monophyly of this group and showed Periplocoideae to be nested within "Apocynoideae", but relationships within the subfamily remained poorly resolved. We utilized data from morphological characters and sequences obtained from plastid DNA and nrITS in a cladistic analysis of Periplocoideae. The resulting phylogeny allowed us to infer relationships within the subfamily and provided a framework which we subsequently used to explore patterns of morphological evolution in Periplocoideae, focusing on the transition from pollen tetrads to pollinia. Pollinia are found in Orchidaceae and in three subfamilies of Apocynaceae: Periplocoideae, Secamonoideae, and Asclepiadoideae. Our results show that pollinia most likely evolved independently in Periplocoideae, and indicate that there are multiple origins of this complex morphological trait within the subfamily.

7.8.5. *Ceropegia* L. (Apocynaceae-Ceropegieae-Stapeliinae): paraphyletic but still taxonomically sound

U. Meve;
Department of Plant Systematics, University of Bayreuth, 95440 Bayreuth, Germany.

The status and phylogenetic position of most genera within Ceropegieae (48 genera, 770 species) have been verified by analyzing cp and nrDNA datasets. Four morphologically and molecularly sufficiently characterized groups have been newly described as subtribes. The terminal one, the Stapeliinae (containing *Brachystelma*, *Ceropegia*, and all stapeliads), is still not fully resolved with regard to phylogenetic structure and taxonomy. The large genus *Ceropegia*, which is convincingly characterized by its pitfall flowers, is scattered over a grade of clades. One clade is shared by some *Ceropegia* and all *Brachystelma* species, making *Ceropegia* (without *Brachystelma*) paraphyletic. All Madagascan *Ceropegia* taxa investigated and the African *C. robynsiana* share a terminal, but mostly unresolved clade with the stapeliads. Thus, again, *Ceropegia* without the stapeliads, is paraphyletic. These results are incongruent with current taxonomy. Because no adequate morphological, anatomical or karyological characters supporting a taxonomical reclassification in accordance with the cladistic analysis were found, maintenance of the current taxonomy is proposed.

7.8.6. Diversification in Neotropical Asclepiadoideae (Apocynaceae)

A. Rapini, C. van den Berg;
Universidade Estadual de Feira de Santana, Feira de Santana, Brazil.

Molecular phylogenetics has greatly improved our understanding of relationships in Asclepiadoideae, but studies designed to explain their distribution are still needed. Asclepiadoideae originated in the Old World, probably during the Oligocene. A phylogenetic analysis with available sequences of trnL-F was carried out to estimate the age of the four independent New World clades; taxonomic information and other phylogenetic results were also considered to discuss patterns of diversification. We found a main lineage of New World species that evolved in an isolated South America. This lineage radiated in South America, dispersing northwards and undergoing secondary diversifications in Central-North America. The other three invasions were younger, probably arriving in North America through a northern land bridge in the Miocene. They dispersed to South America before the Panamanian Isthmus connection, soon becoming widespread but not yet rich in species number. Because of their recent origin, diversification of New World Asclepiadoideae seems to be driven by cycles of rapid dispersion followed by regional radiation.

7.8.7. Floral diversity and phylogenetic relationships in subtribe Asclepiadinae (Apocynaceae: Asclepiadoideae)

D. J. Goyder[1], A. Nicholas[2], S. Liede-Schumann[3];
[1]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [2]University of KwaZulu-Natal, Durban, South Africa, [3]University of Bayreuth, Bayreuth, Germany.

A first approximation of evolutionary relationships within Asclepiadinae is inferred from two DNA datasets - ITS, and *trnT-L* & *trnL-F* spacers & *trnL* intron. Both the subtribe as a whole, and the radiation of largely herbaceous genera around *Asclepias* are monophyletic and well supported in all analyses. While resolution within the *Asclepias* complex is limited, some lineages can be identified with confidence. These demonstrate that current generic delimitation is unsatisfactory. *Asclepias* should either be restricted to New World members of the subtribe, or expanded to encompass the entire radiation. In the African species, it is shown that although the corona is taxonomically important for recognising species, it can be misleading as an indicator of phylogenetic relationships. Vegetative similarities often prove a more reliable guide, but more detailed studies are needed to refine these lineages and to detect morphological characters to aid in their practical recognition.

7.9.1. Taxonomy of monadoid and coccoid green algae: Conflict of classic and modern approaches

T. Proeschold;
Culture Collection of Algae and Protozoa, Dunbeg by Oban, United Kingdom.

Traditionally monadoid and coccoid green algae were classified in the orders Volvocales resp. Chlorococcales according to the morphological species concept. For example, in the genus Chlamydomonas (including Chloromonas), one of the largest green algal genera, more than 800 species are described by using only morphological characters of vegetative cells. However, phylogenetic analyses of nuclear-encoded SSU and ITS rDNA sequences of more than 100 strains of both genera have shown that Chlamydomonas and Chloromonas consists to eight independent monophyletic lineages partly together with coccoid green algae (e.g. Chlorococcum, Tetracystis) within the CW (basal bodies displaced clockwise) subgroup of the Chlorophyceae. Using polyphasic approaches (e.g. secondary structures of SSU and ITS rDNA sequences, results of crossing experiments, sporangium autolysin data and studies of life cycles), a new generic and species concept within the CW-subgroup (traditionally designated as "Volvocales" and "Chlorococcales" s.str.) can be designed demonstrated here by "Chlamydomonas and its relatives".

7.9.2. Toward natural systems of species/genera of microalgae based on the comparative light and electron microscopy and robust phylogenetic results

H. Nozaki;
Dept. of Biological Sciences, Graduate School of Science, Univ. of Tokyo, Tokyo, Japan.

Species/genera of the microalgae were traditionally classified based on the light microscopical attributes that the phycologists believed important. However, such characters may be unstable and it is very difficult to identify species in some microalgal genera. Furthermore, recent molecular phylogenetic analyses demonstrated that morphologically delineated taxa may be nonmonophyletic. Therefore, comparative light and electron microscopy of cultured materials are needed to obtain stable taxonomic characters, and such characters should be examined based on the robust phylogenetic results in order to construct natural taxonomic systems of microalgae. Such studies at species level have been carried out in the green algal genera *Chlorogonium*, *Vitreochlamys*, *Asterococcus* etc. However, natural classification of genera needs robust phylogenetic results that are not generally resolved using only single-gene information. We recently carried out multigene phylogeny (6021bp) of the advanced members of the colonial Volvocales (*Eudorina*, *Pleodorina* and *Volvox*) and divided *Pleodorina* into two genera based on the new morphological diagnosis.

7.9.3. Phenotype versus genotype in Chlorellaceae

W. Luo, L. Krienitz;
Leibniz-Institute of Freshwater Ecology and Inland Fisheries, Berlin, Germany.

Classical approaches using morphological characters for the circumscription of taxa do not adequately reflect the phylogenetic relationships. According to traditional systematics, Chlorella (spherical, solitary, without spines and mucilage) and Micractinium (spherical, mostly in coenobia, with spines and mucilage) belong into different families of the Chlorophyta: Chlorellaceae and Micractiniaceae. However, investigations on 18S rRNA phylogeny revealed a very close relationship of the two genera. Using culture medium of Brachionus phenotypic plasticity in Micractinium was studied. Unspined Micractinium cells can develope spines during incubation with Brachionus culture medium. These results suggest that morphological characteristics like spines formation represent phenotypical adaptations to the conditions in the ecosystem. A genus and species concept in Chlorellaceae remains provisional, because there is still a lack of combination of classical and molecular approaches to identify clear phylogenetic lineages.

7.9.4. Phenotypic plasticity in algae: useful rather than problematical

E. Shubert;
The Natural History Museum, London, United Kingdom.

Algae have successfully colonised aquatic, terrestrial and subaerial habitats world-wide. As a consequence of their diverse ecology, algae have evolved a variety of mechanisms for adapting to changing environments. One such mechanism is phenotypic plasticity. This occurs when a genotype produces morphological alternatives, through differential gene expression, when exposed to different environmental conditions. Despite overwhelming evidence of phenotypic plasticity in algae, the implications for taxonomy, ecology and evolution have not been adequately recognised. Examples will be given to show how phenotypically plastic algae can be used as “model organisms” to elucidate the systematics, ecological and phylogenetic relationships of +algae, by combining culture studies with high resolution microscopical techniques (Scanning Electron Microscopy, Transmission Electron Microscopy, Confocal Laser Scanning Microscopy), biochemical, physiological, and/or molecular analyses.

7.9.5. Coccoid trebouxiophytes dominate green algal biofilms on air-dry artificial hard substrates

T. Friedl, K. Holst, O. Mudimu, I. Lang, E. Zufall-Roth, J. Müller;
Albrecht-von-Haller-Institut für Pflanzenwissenschaften, Göttingen, Germany.

The green algal class Trebouxiophyceae comprises mainly coccoid algae from subaerial habitats. Its monophyly is still challenging and division into rDNA clades is incongruent with morphology-based concepts of families/orders. Biofilms on air-dry artificial substrates (e.g. roof tiles) are an excellent habitat to further investigate the diversity of the class and provide an expanded taxon sampling with which its phylogeny can be better addressed. DGGE, rDNA cloning and sequencing revealed a high diversity of trebouxiophytes on such substrates and was higher than with morphospecies alone. For many of the discovered phylotypes there were no close sequences available or if available, identification was unequivocal at genus/species levels (reference sequence were from unidentified species or polyphyletic genera). Within the same morphotype distinct "cryptic" species were found, but the combination of 18S/ITS rDNA sequencing with AFLP genotyping allows the molecular definition of species. However, also re-investigation of morphological characters is required and the molecular phylogenies point to key taxa which may exhibit important characters.

7.9.6. Pioneer aerophytic microorganisms on outer building surfaces - a comprehensive approach

W. Hofbauer[1], K. Breuer[1], G. Gärtner[2];
[1]Fraunhofer Institut für Bauphysik Holzkirchen (IBP), Valley, Germany, [2]Leopold Franzens Universität Innsbruck, Institut für Botanik, Innsbruck, Austria.

Biological growth on façades and other external building components became more evident in recent years and is increasingly recognized as a topic of scientific and industrial concern. There is still significant uncertainty regarding the composition, the taxonomic structure of different types of microbiological growth and their ecophysiologic and environmental prerequisites. In addition to biological research, chemical/physical processes are investigated and documented as a part of interdisciplinary collaboration at the Fraunhofer Institute for Building Physics (IBP). Influences of global change, modifications in construction as well as alterations in the composition of air pollution are discussed. Based on the taxonomic differentiation of observed biological communities the conditions for the development of pioneer growth can be assessed. More than 120 different taxa have been documented and investigated as essential colonisers of external building components so far.

7.9.7. Are there really conflicts between classical and modern taxonomy in coccoid green algae?

G. Gärtner[1], M. P. Stoyneva[2];
[1]Institute of Botany, Leopold-Franzens-University of Innsbruck, Innsbruck, Austria, [2]Faculty of Biology, University of Sofia 'S. Kliment Ohridski', Sofia, Bulgaria.

Since centuries algal species were defined on morphospecies (“classical”) concepts. Light microscope studies of field samples still do need such concepts, as far as possible with help of cultures. The development of molecular biological research lead to a phylogenetic (“modern”) species concept reflecting evolution patterns, affinities and discrepancies in morphologically homogenous taxa (e.g. *Chlorella*). This raised problems for a practicable species taxonomy applied in algal floras. Variability in form and function of many algal taxa is still poorly known (e.g. *Oocystis*) but defined structural and morphological data are required for a modern taxonomy in the same extent as a molecular defined status. Some pathways for a modest “polyphasic taxonomy“ connecting the classical and the modern concepts as applied in the “Süßwasserflora von Mitteleuropa” are presented.

7.10.1. Mechanisms of rRNA gene silencing

C. S. Pikaard[1], S. Preuss[1], R. Lawrence[1], K. Earley[1], O. Pontes[1], P. Costa-Nunes[2], M. Silva[2], N. Neves[3], W. Viegas[2];
[1]Washington University, Saint Louis, MO, United States, [2]Instituto Superior de Agronomia, Lisboa, Portugal, [3]Universidade Nova de Lisboa, Caparica, Portugal.

Allopolyploidy is a significant evolutionary process, resulting in new species bearing sets of chromosomes from two or more progenitors. One consequence of genomic merger in *Arabidopsis suecica*, the allotetraploid hybrid of *A. thaliana* and *A. arenosa*, is dominance of the *A. arenosa* rRNA genes and silencing of *A. thaliana* rRNA genes. This phenomenon, known as nucleolar dominance, involves an epigenetic switch mechanism in which concerted changes in promoter cytosine methylation and histone modifications define the on and off states of the rRNA genes. Using transgene-induced RNAi to knock down whole families of chromatin modifying activities, we have identified a number of modifier genes required for uniparental rRNA gene silencing, including both DNA and histone modifying activities. Our progress in understanding how DNA methylation and histone modifications are interwoven to regulate rRNA gene transcription and NOR condensation/de-condensation will be presented.

7.10.2. Nucleolar proteins and the structural organization of preribosomal RNA synthesis and processing in the nucleolus

F. González-Camacho, **F. J. Medina**;
Centro de Investigaciones Biológicas (CSIC), Madrid, Spain.

The nucleolar protein NopA100 was identified as a major component of the soluble fraction of nuclear proteins from onion root meristematic cells. This fraction contains RNPs active in the nuclear RNA metabolism. NopA100 is the most phosphorylated protein of this extract, but it is also present in the nuclear matrix. When detected *in situ*, it showed a preferential nucleolar location in the fibrillar components, where the early pre-rRNA processing takes place. Using microscopy and Western blotting, a correlation of the levels of NopA100 and its phosphorylation with the nucleolar activity, the cell proliferation status, and the cell cycle progress, was observed. NopA100 undergoes a physiological process of proteolytic maturation, associated with the increase in pre-rRNA transcription and processing and, consequently, with the activity of the protein. This activity was the upmost in the G2 phase of the cell cycle, when ribosomal genes reach their highest transcriptional rate. NopA100 is a plant homologue of mammalian nucleolin and its features reflect the close relationship of the structure and function of the nucleolus to cell proliferation.

7.10.3. Organisation and evolution of *Solanum* rDNA and nucleolar dominance in alloploids

N. Y. Komarova[1], V. Hemleben[1], **R. A. Volkov**[2];
[1]ZMBP, University of Tübingen, Tübingen, Germany, [2]ZMBP, University of Tübingen, Tübingen, Germany / University of Chernivtsy, Chernivtsy, Ukraine.

In the genus *Solanum*, amplification/deletion of subrepeats in the intergenic spacer (IGS) was the main event in the molecular evolution of the 35S ribosomal RNA genes (rDNA). Three species, *S. lycopersicum* (tomato), *S. tuberosum* (cultivated potato), and *S. bulbocastanum* (wild Mexican potato) demonstrate prominent differences in the number/organization of repeated elements upstream and downstream of the transcription initiation site (TIS). Uniparental activity of the 35S rDNA is observed in interspecific hybrids. To test whether the preferential transcription of the parental rDNA could be influenced by the repeated elements, expression of parental rDNA was evaluated in somatic hybrids between the three *Solanum* species and in back-crossed plants. An expression hierarchy was found: In leaves of the respective allopolyploids, rDNA of *S. lycopersicum* dominates over rDNA of *S.*

tuberosum, whereas rDNA of *S. tuberosum* dominates over that of *S. bulbocastanum*. Hence, in the allopolyploids of *Solanum* evolutionary novel rDNA carrying more repeated elements downstream of TIS is transcriptionally dominant over the rDNA with ancestral organization.

7.10.4. Evolution and expression of ribosomal RNA genes in two allopolyploids of recent and recurrent origin

A. Kovarik[1], C. Pires[2], A. Leitch[3], Y. Lim[3], A. Sherwood[4], R. Matyasek[1], J. Rocca[5], D. Soltis[5], P. Soltis[5];
[1]Academy of Sciences of the Czech Republic, Brno, Czech Republic, [2]University of Wisconsin, Madison, WI, United States, [3]Queen Mary College, University of London, United Kingdom, [4]Washington State University, Pullman, WA, United States, [5]University of Florida, Gainesville, FL, United States.

We have investigated copy number and expression of parental ribosomal RNA genes in multiple populations of Tragopogon mirus and T. miscellus, two allotetraploids that formed recurrently within the last 80 years following the introduction of three diploids (T. dubius, T. pratensis, and T. porrifolius) from Europe to North America. In most present-day populations of both tetraploids, the rDNA of T. dubius origin is reduced and may occupy as little as 5% of total rDNA in some individuals. However, in two populations of T. mirus the general trend was reversed indicating bidirectional concerted evolution within a single species. In plants having a low rDNA contribution from T. dubius, the rDNA of T. dubius origin was nonetheless expressed and T. dubius transcripts often outnumbered transcripts made from the partner genome. We detected cases of no, partial or complete nucleolar dominance within a single species; in one population of T. mirus the rDNA expression patterns varied even among the progeny of a single plant suggesting that rRNA gene silencing may have limited stability in these recent allopolyploids.

7.10.5. Suppressed concerted evolution and main traits of reticulation in agamospermous polyploid dandelions (Taraxacum, Compositae)

L. Drabkova[1], J. Kirschner[1], C. Vlcek[2];
[1]Institute of Botany ASCR, Pruhonice near Prague, Czech Republic,
[2]Institute of Molecular Genetics ASCR, Prague, Czech Republic.

In mainly agamospermous *Taraxacum* reticulation combined with polyploidization represents one of the major evolutionary step. We analysed the association between dandelions ITS1& ITS2 sequence polymorphism, agamospermy, polyploidy, hybridization, and the phylogenetic information. To characterization intragenomic variation and to readdress the evolutionary impact of hybridisation in *Taraxacum* we sequenced ten clones from a single individual of *Taraxacum* sections *Leucantha, Suavia* and *Stenoloba.* Main results of our study are: (1) Reticulation is an important process in the evolution of *Taraxacum* and ITS data have proven useful for reticulate phylogeny of this intricate complex. (2) Sequenced alleles display a complex pattern of different ITS repeat types and putative recombinants among repeat types that persist due to lack of concerted evolution across loci or at least its reduced rates. (3) The position of cloned spacer sequences in the tree revealed reticulated network among C Asian *Taraxacum* and suggest hybridisation from lineages of sect. *Leucantha* to sections *Suavia* and *Stenoloba.*

7.10.6. rDNA loci as chromosomal markers in studies of plant development and phylogeny

J. Maluszynska;
Department of Plant Anatomy and Cytology University of Silesia, Katowice, Poland.

The rRNA gen loci, present and express in each cell as housekeeping genes, offer several advantages for cytogenetic and molecular studies. The number and distribution of 5S and 18S-5.8S-26S rDNA loci provides useful markers of chromosomes to study genome evolution and chromosomal variation. Comparative analysis of the distribution of rDNA sites in chromosomes of allopolyploids and their diploid ancestors is a valuable indicator of evolutionary dynamic. The number and distribution of rRNA loci in chromosomes of individual plants indicates intraspecific variation or their structural and numerical rearrangements. Similarly, the level of polyploidization and/or DNA amplification in cells during ontogenesis or plant culture *in vitro* can be evaluated in interphase nuclei through the number of rDNA sites. The variation in the number of rDNA loci in diploid and polyploid species of *Brassicaceae* family, the genus *Chenopodium* and in liverwort species, detected through fluorescence *in situ* hybridization, will be presented and the processes leading to reorganization of genomes will be discussed.

7.10.7. 5S rDNA transcription regulation in *Arabidopsis thaliana*

S. Tourmente, I. Vaillant, J. Douet, S. Tutois;
UMR-CNRS 6547 Biomove, AubiÃ¨re, France.

We are interested in the epigenetic mechanisms involved in the regulation of the polymerase III-transcribed 5S rDNA in Arabidopsis thaliana. 1000 copies of 5S rDNA units are organized in tandem arrays present in heterochromatic pericentromeric regions of chromosomes 3, 4 and 5. In the transcribed 5S rDNA loci, the major 5S rDNA genes are expressed whereas the minor ones (containing one or two mutations) are repressed. In leaf nuclei of mature plants, the transcribed fraction makes loops that emanate from chromocenters. These loops which are enlarged in mature ddm1 nuclei are enriched for histone H3 acetylated at lysine 9 and methylated at lysine 4 compared to the heterochromatic chromocenters. Results obtained with the remodeling chromatin mutant ddm1 have shown the involvement of the chromatin structure in the repression of the minor 5S rDNA genes.

Up to four days after germination, heterochromatin is not fully developed, the 5S rDNA resides in pre-chromocenters, does not form conspicuous loops and minor 5S RNA are present. All together, our results indicate that expression and chromatin organization of 5S rDNA genes change during chromatin establishment.

7.11.1. Are methodological constraints limiting our knowledge on dispersal?

O. Tackenberg;
Institute of Botany, Regensburg, Germany.

Dispersal types of diaspores are commonly categorized by the vectors transporting the diaspores. Most often these dispersal types are derived from diaspore morphology. Diaspore morphology, however, affects only one aspect of dispersibility, dispersal potential which may be defined as the probability of diaspores to be dispersed over long distances. However, recent studies are questioning the often presumed overriding effect of commonly used morphological traits on dispersal potentials. Diaspore production, the availability of dispersal vectors in both, quality and quantity, as well as differences in dispersal kernels may override the effect of diaspore morphology.

Several dispersal type spectra of large species sets, calculated using different methods for assessing dispersal types, calculated using different methods, will be compared. The methods comprise a morphological approach, field and lab-experiments, a rule based approach and a database approach. Besides detected methodological differences, the results suggest that on the landscape level dispersal type spectra are predominantly regulated by the availability of dispersal vectors.

7.11.2. Directed dispersal selects for mechanisms that ensure germination under nurse plant shade

M. Kos, P. Poschlod;
University of Regensburg, Regensburg, Germany.

In the Kalahari an assemblage of fleshy fruited perennials and annuals grows mainly under acacias. Seed rain is concentrated under trees due to the behaviour of their dispersal vectors, birds and ungulates. We hypothesize that canopy species have developed mechanisms to germinate only under well shaded conditions because under canopies the quality of shade varies spatially. We tested this for diurnal temperature amplitude (DTA), the duration of moist conditions and soil moisture perse. Germination of all fleshy fruited canopy species was inhibited at high DTA compared with constant temperature or low DTA. Germination of annual canopy species was reduced by high DTA in only two species. In the other species DTA had a positive or no effect. We found a significant correlation between germination lag and canopy association. However, this was not significant when data were corrected for the effect of ingestion. No relation between canopy association and germination response to a moisture gradient was found. We predict that the use of DTA to detect optimal canopy conditions for germination is widespread among bird dispersed species depending on nurse plants.

7.11.3. Can evolutionary age, colonization and persistence ability explain to which extent species fill their potential range?

F. M. Schurr[1], G. F. Midgley[2], A. G. Rebelo[2], G. Reeves[2], P. Poschlod[3], S. I. Higgins[4];
[1]University of Potsdam, Potsdam, Germany, [2]South African National Biodiversity Institute, Cape Town, South Africa, [3]University of Regensburg, Regensburg, Germany, [4]Technical University of Munich, Freising-Weihenstephan, Germany.

We test whether the extent to which a species fills its potential range depends on evolutionary age, colonization and persistence ability. For 37 species of Proteaceae, we estimate potential range sizes using bioclimatic models, evolutionary age using molecular phylogenies, persistence ability using field based estimates of longevity, and colonization ability using a process based seed dispersal model, the spatial arrangement of potential habitat, and data on local abundance. We find, in most of 180 alternative phylogenies, a phylogenetically independent increase of range filling with colonization ability. Moreover, range filling increases more rapidly with colonization ability for persistent species. Evolutionary age and contemporary abundance do not explain a significant proportion of the residual variation in range filling. We conclude that, although our analysis provides evidence that range dynamics of the study species can be described by metapopulation models, the dynamics appear too complex to be well described by the simple Levins metapopulation model.

7.11.4. Dispersal limitation in bird-dispersed species: bridging the seed rain and the seedling recruitment stages. A Mediterranean highland study at a community level

J. L. García-Castaño[1,2], J. G. P. Rodríguez-Sánchez[1,3], P. Jordano[1];
[1]Integrative Ecology Group, Estación Biológica de Doñana (CSIC), Sevilla, Spain, [2]Depto. de Biología Vegetal y Ecología, Universidad de Sevilla, Sevilla, Spain, [3]Área de Ecología, Universidad Pablo de Olavide, Sevilla, Spain.

Dispersal limitation exists when the number of recruiting individuals at a given site is constrained by the availability of delivered seeds. In bird-dispersed species, an unequal delivery of seeds to different microhabitats might saturate some of them leaving others underexploited; in this context, dispersal limitation could operate, depending on microhabitat quality. We studied the relationship between seedfall and seedling emergence for a fleshy-fruited plant community at a landscape scale, in the same years (2-3 years) and sites (considering 6 distinct, patchily-distributed microhabitats), in a Mediterranean highland ecosystem of SE Spain. We set seed traps to sample seed rain, estimated seedling recruitment in adjacent plot, and analyzed their spatial concordance at an overall basis as well as the differences for this relationship among the species and microhabitats considered. The importance of the transitional stages between the seed rain and the seedling emergence stages is discussed.

7.11.5. Spatio-temporal dynamics of seedfall and seedling emergence in animal-dispersed species: bridging dispersal and establishment

A. Hampe[1,2], J. L. García-Castaño[2,1], E. W. Schupp[3,1], P. Jordano[1];
[1]Estación Biológica de Doñana (CSIC), Sevilla, Spain, [2]Depto. de Biología Vegetal y Ecología, Universidad de Sevilla, Sevilla, Spain, [3]Dept. of Forest, Range, and Wildlife Sciences and Ecology Center, Utah State University, Logan, UT, United States.

Seed dispersal creates the initial template for the regeneration of plant populations. Particularly in perennial plants, it is also the most variable and least predictable stage of the life cycle. Given the typically very small probability that a given dispersal event will result in establishment of an adult plant, long-term studies are therefore required to reveal which microsites in the landscape receive consistently more seeds than others, and if this consistency results ultimately in the existence of recruitment ‘hotspots’. We explore patterns of year-to-year consistency in the spatial distributions of seedfall and seedling emergence of three animal-dispersed woody species growing in contrasting habitats. Among-year variation of seedfall across microsites is largely determined by two factors, the crop size of fruiting plants (‘source component’) and the pattern of dissemination resulting from disperser activity (‘dispersal component’). We dissect these two factors and quantify their respective influence on the spatial and temporal consistency of seedfall and seedling recruitment patterns.

7.11.6. Flood dispersal and establishment limit distribution of *Juncus atratus* on different scales

K. Alsleben, M. Burkart;
Botanic Garden, Potsdam, Germany.

Juncus atratus is a perennial from regularly-flooded river corridors. Populations are patchily distributed on both local and regional scales. Suitable habitats also show a patchy distribution. Only a fraction of them are colonized. To which extent do germination, establishment and dispersal limit colonization on population, local and regional scales? Germination rate of seeds is sufficient under various conditions, indicating that germination is never limiting, given sufficient water supply. Germination is best in water. Seeds have high floating ability and can thus be dispersed over long distances. Many may germinate when floating. These seedlings, however, can establish only shortly after germination, which limits long-distance dispersal by water. Establishment is also poor for seedlings emerging in turf, indicating site-specific limitation. We conclude that establishment limits both colonization on the smaller scales and long-distance dispersal by water.

7.12.1. Vascular epiphytes as indicators of changing environmental conditions

H. Griffiths[1], T. Dawson[2], M. Mejia-Chang[1];
[1]Department of Plant Sciences, Cambridge, United Kingdom,
[2]Integrative Biology, UC, Berkeley, CA, United States.

Certain Cloudforest formations are seriously threatened by two human impacts which influence the overall hydrological cycle, namely climate change and deforestation. Epiphytes represent an important community which are poised at the interface of forest canopy and the atmosphere, and so provide a remarkable model system to investigate the impact of a changing climate on water and nutrient availability and use. Stable isotopes act as markers of photosynthetic limitation (C), nutrient sources (N) as well as water source and transpiration (18O, Deuterium). Most recently, by using these isotopes in combination, we have the potential to provide additional on the physiological dynamics of these populations. For instance, isotopes can be used to partition water sources (whether meteoric or occult precipitation via 18O) and carbon gain (via 13C) and so the historical record of plant material in herbarium specimens could provide a proxy for recent periods of rapidly changing climates. Additionally, we need to review the status of epiphyte communities, whether by examining the annual changes in standing biomass components or by following recovery of populations after disturbance and deforestation. The aim of this introductory talk is to review the latest developments and provide a platform for collaborative proposals developing more integrated research programmes for the future within this important area.

7.12.2. Stable isotopes as integrators of exposure and habitat preference in epiphytic bromeliads

M. Mejia-Chang[1], C. Reyes-Garcia[1], H. Griffiths[1], K. Winter[2];
[1]Department of Plant Sciences, Cambridge, United Kingdom,
[2]Smithsonian Institure for Tropical Research, Panama City, Panama.

Epiphytic bromeliads are subject to intermittent precipitation inputs, such as rainfall and fog, which can be exploited over varying timescales, depending on seasonality, growth form (use of tank and/or trichome), and exposure within the forest canopy. By comparing leaf-water and organic material 18O signals, as well as ŭ13C composition, along an altitudinal and latitudinal gradient between Panama and Mexico, we relate the habitat preference of C3 and CAM bromeliads to exposure, and seasonality of precipitation inputs. We examine the 18O isotopic relationship between precipitation inputs, leaf water and variation along the monocot leaves, and the analysis of water vapour to distinguish isotopic enrichment due to evaporation and transpiration. We will show how epiphytes act as sensitive markers of changing environmental conditions and could be used throughout the neotropics to characterise environmental gradients and changing climatic conditions.

7.12.3. Gender in the mistletoe *Loranthus europaeus* - females work harder

G. Glatzel[1], M. Popp[2];
[1]Institute of Forest Ecology, Vienna, Austria, [2]Department für Chemische Ökologie und Ökosystemforschung, University of Vienna, Vienna, Austria.

The mistletoe *Loranthus europaeus* is trioecious with small flowers, which is a rare exception among the Loranthaceae, which usually have brightly coloured, bird pollinated hermaphroditic flowers on the same plant. In *L. europaeus* the population of hermaphroditic plants is functionally male, as almost all flowers are shed once the pollen is spent and very view fruits develop. Male and female plants differ in their morphology and physiology. Male plants are more ortho geotrophic and stout and less pendulous than female plants. Water potential is lower in female plants when compared to male plants under the same conditions. Autumnal leaf abscission is significantly later in females. This indicates that female plants have to work harder to support fruit development and maturation. Foliar element analysis as well as stable isotope analysis is currently performed and the results will be presented at the congress.

7.12.4. Population dynamics of epiphytes related to host branch characteristics

M. Winkler[1], K. Hülber[2], P. Hietz[1];
[1]Dep. of Integrative Biology, Univ. of Natural Resources and Applied Life Sciences, Vienna, Austria, [2]VINCA-Vienna Institute for Nature Conservation and Analyses, Vienna, Austria.

The demography of epiphytes is complicated by the fact that they live in a three-dimensional space defined by their host trees with strong gradients of resources and substrate stability. We studied populations of several orchid and bromeliad species in a Mexican humid montane forest over several years and modelled their population dynamics using matrix models. Proportional odds ratio models showed an effect of exposure or branch type on the probabilities of survival and of reaching reproductive size. Mortality decreased with increasing branch exposure in the orchids *Jacquiniella leucomelana* and *J. teretifolia* and the bromeliad *Catopsis sessiliflora*, which are common also in more open or disturbed vegetation, but increased in the orchid *Lycaste aromatica*, which is restricted to closed forests. In most species, survival increases with the bryophyte cover on the branch, and population growth rates depend mainly on survival rates of reproducing plants. Matrix projection suggests that under the current environmental conditions several populations - especially that of *Lycaste aromatica* - are declining and will be nearly extinct within one hundred years.

7.12.5. How much do we learn from ecophysiological studies with vascular epiphytes about the comportment of populations in a changing world?

G. Zotz;
Institute of Botany, Basel, Switzerland.

A principal question of ecophysiology is how physiological attributes contribute to survival, growth and reproduction under the particular habitat conditions of a species. The underlying assumption, however, i.e. that physiological limitations translate into a similar role in populations, has rarely been tested. I present physiological and long-term demographic data for the epiphytic bromeliad Werauhia sanguinolenta that show that the scaling from ecophysiology to demography is not straightforward. E. g., although water stress has been identified as the principal abiotic limitation for epiphytes, population growth did not vary with annual precipitation over a 7-year period. On the other hand, the most plastic response to resource availability was found in smaller plants, both in physiological experiments and demographic observations. Discrepancies arise because host tree dynamics (from small twig to entire tree) may influence epiphyte population dynamics more than abiotic constraints. Hence, global change may affect epiphytes not only due to a change in climate, but at least as much due to the proposed increase in the dynamics of tropical forests.

7.12.6. Evolution of epiphytism and crassulacean acid metabolism in Bromeliaceae in relation to changing environments and palaeoclimates

J. A. C. Smith[1], D. M. Crayn[2], K. Winter[3];
[1]University of Oxford, Oxford, United Kingdom, [2]National Herbarium of New South Wales, Sydney, Australia, [3]Smithsonian Tropical Research Institute, Balboa, Panama.

The family Bromeliaceae represents one of the most distinctive and ecologically diverse groups of vascular epiphytes. Approximately half of the 3000 species are epiphytic and show one or more adaptations that have enabled colonization of xeric microhabitats, such as water-impounding phytotelmata, absorptive epidermal trichomes, and possession of the crassulacean acid metabolism (CAM) mode of photosynthesis. Phylogenetic reconstruction indicates that both the epiphytic habit and CAM photosynthesis have arisen multiple times in the family's history. In subfamily Tillandsioideae, the epiphytic habit preceded the evolution of CAM photosynthesis, whereas CAM photosynthesis and the terrestrial habit are plesiomorphic in subfamily Bromelioideae, with the epiphytic habit appearing subsequently. In the almost complete absence of a fossil record for the family, analysis of molecular-phylogenetic trees based on nucleotide sequence data from appropriate loci can be used to delimit the timing of the origins these key functional traits, and to consider their possible relation to changing environmental conditions during the Tertiary.

7.12.7. Neotropical epiphyte diversity - present patterns, past causes, and lessons for the future

N. Köster, H. Kreft, W. Küper, J. Nieder, W. Barthlott;
Nees Institute for Biodiversity of Plants, Bonn, Germany.

We present an overview on Neotropical epiphyte diversity at different spatial scales, based on a biogeographic analysis of plot inventories and local and national checklists of vascular epiphytes. The main focus of our study was the dependence of epiphyte diversity and endemism on elevation and climatic factors. The influence of elevation and rainfall on epiphyte diversity is strongly scale dependent. On local and national scale, both diversity and endemism of vascular epiphytes reach a maximum at mid elevations in Andean cloud forests. Amount and seasonality of rainfall are the major determinants of epiphyte diversity for local inventories of lowland sites. Plot diversity is only weakly correlated with rainfall and not with elevation, with the most species-rich plot located in Western Amazonia. We discuss reasons for different diversity patterns at different spatial scales and the role of the Andean orogenesis as well as past and present rainfall patterns in the generation and maintenance of epiphyte diversity in the Neotropics. Potential implications for priority settings of protected areas in the light of future climate change are given.

7.13.1. Functional chemistry of leaf surfaces

M. Riederer;
Universität Würzburg, Würzburg, Germany.

Leaf surfaces are the interfaces between the physiologically most active tissues of higher plants and the abiotic and biotic environment. Primary plant surfaces are covered by a cuticle which acts as a signal in epidermal cell differentiation, as a transport-limiting skin and as a substrate for biotic interactions. The symposium will assess the state of knowledge on how functions are related to the chemical composition of plant cuticles. Major contributions will cover the role of cuticles in epidermal development and differentiation, the chemical basis for the barrier function of plant cuticles, and the physical properties and ecological relevance of epicuticular waxes. Further topics will include the role of cuticular waxes and cutin constituents in plant/microbe and plant/insect interactions. The objective of the symposium is to advance the integrative view of plant cuticle chemistry and function, and to lay the foundations for a modern biology of plant surfaces.

7.13.2. Wax biosynthesis and cuticular permeability

G. Vogg, J. Leide, M. Riederer;
Lehrstuhl für Botanik II, Würzburg, Germany.

Cuticular waxes play a pivotal role in limiting transpirational water loss across all primary above-ground plant surfaces. The relationship between the chemical composition of the cuticular waxes and its function as a transpiration barrier as well as their biosynthesis, however, is still unclear. It is the aim of our group to correlate all these three parameters using one single plant system. Intact tomato fruits (Lycopersicon esculentum), due to their astomatous surface, are an ideal model system to integrate this biosynthesis-composition-function relationship. Additionally, tomato is an important crop with sufficient genetic and genomic tools available. Using mutants with genetically manipulated cuticular wax compositions are analysed for their transpiration barrier properties. One mutant with significant changes in the composition of very-long-chain aliphatic compounds due to a gene knock-out in a fatty acid elongase ß-ketoacyl-CoA synthase showed a dramatic increase in cuticular transpiration. Recent progress in this project will be presented.

7.13.3. *Arabidopsis* requires signal pathways for the formation of epidermal cuticle

Y. Machida[1], H. Tanaka[2,3], T. Tanaka[1], C. Machida[2,3], M. Watanabe[1];
[1]Division of Biological Science, Graduate School of Science, Nagoya University, Nagoya, Japan, [2]College of Bioscience and Biotechnology, Chubu University, Aichi, Japan, [3]CREST, Japan Science and Technology Agency, Tokyo, Japan.

Leaf epidermis of plants plays an important role to restrict permeability of water-soluble molecules across the surface of organs and inhibit unfavorable adhesion between organs. To exert the epidermal function, it is necessary to express genes involved in biosynthesis of components for cuticle, establish the polar transport of the components and to deposit the cuticle on the outer surface. Using molecular-genetic approaches involving a new method to visualize defects in cuticle [1], we have identified several genes that control proper formation of cuticle on epidermal and protodermal surfaces of *Arabidopsis thaliana*. They include the *ABNORMAL LEAF SHAPE1* (*ALE1*) gene encoding subtilase (putative serine protease) [2], the Arabidopsis homologue of the maize *Crinkly4* gene (*ACR4*) encoding a receptor-like protein kinase [3], and the *ABNORMAL LEAF SHAPE2* (*ALE2*) gene encoding a receptor-like protein kinase as well as genes for presumptive metabolic enzymes for condensation of fatty acids [1]. Mutations in these genes cause various morphological defects in all the plant organs including abnormal shapes of embryos and fusion between leaf-like organs. Shapes of protodermal and epidermal cells of *ale1, acr4*, and *ale2* mutants are also rudimental. Electron microscopic analyses show partial loss of a cuticle layer on the surfaces of these cells. Although loss-of-function mutations in any one of *ALE1, ACR4*, and *ALE2* genes exhibit relatively weak epidermal defects, mutations in *ALE1* and *ACR4* or those in *ALE1* and *ALE2* result in markedly severe defects in morphology of epidermal cells of seedlings and in cuticle on the epidermal surface. The above results suggest that these genes play critical roles in the formation of proper cuticle. We propose that at least two independent pathways, each including ALE1 and ALE2/ACR4, might control the formation of epidermal cuticle in Arabidopsis.

7.13.4. Digestion of the cuticular barrier leads to pathogen defence

C. Chassot[1], C. Nawrath[2], J. Métraux[1];
[1]Département de biologie, Université de Fribourg, Fribourg, Switzerland, [2]Département de biologie moléculaire végétale, Université de Lausanne, Lausanne, Switzerland.

Components of the cuticle such as hydroxylated fatty acids were shown to be potential elicitors for defence reactions (Schweizer et al., Plant J., 10, 331-341, 1996). This was further tested in our group by overexpressing a cell wall-targeted fungal cutinase of the pathogen Fusarium solani in Arabidopsis thaliana under a constitutive or an inducible promoter. Transformed plants have a reduced cuticle and exhibit an increase in resistance to the necrotrophic fungal pathogen Botrytis cinerea. Experiments were undertaken to understand the basis of this counterintuitive result. Compared to controls, cutinase-expressing plants showed changes in gene expression (determined by DNA microarray analyses) indicating sensing of the surface defects. Amongst others, the genes of polygalacturonase-inhibiting proteins, a potential barrier to Botrytis penetration, were induced. The direct toxicity of the fungal cutinase, its products, or other components leaking out at the surface of the transformed plants was also tested. Among these, only yet uncharacterized components showed a fungistatic effect against Botrytis. These components will be analyzed further.

7.13.5. Leaf epicuticular wax signals for pathogen specificity

D. Engelmeier, F. Hadacek;
Faculty of Life Sciences, Vienna, Austria.

The leaf epicuticular wax represents a protective layer against pathogens. Conversely, it may provide the first signals involved in host plant recognition to a specialized pathogen. Chemically, it mainly consists of cutin and wax esters matrix, also including terpenoids and phenolics in its inner structure. This composition also affects the micromorphology of the layer.

Several studies pointed out that constituents of the cuticle influence germination and appressorium formation of pathogens. Our experiments with Pyricularia grisea, the causative agents of rice blast disease, and Erwinia amylovora, the fire blight on apples, suggest that detection of stimulatory and inhibitory effects of leaf epicuticular waxes are influenced by the choice of extraction solvent. Different extraction capacities of various solvents decisively affected the extract activity. The exemplification of such signals might contribute to the elucidation of host recognition mechanisms of pathogens.

7.13.6. Plant surfaces from the insects' view

C. Müller;
Julius-von-Sachs Institute for Biosciences, Wuerzburg, Germany.

When phytophagous insects alight a plant, they first encounter the species-specific chemical and morphological structure of the cuticular surface which can be used as cue for discrimination of susceptible from non-acceptable hosts. To test the influence of the plant cuticle on feeding and oviposition, different bioassays were developed in which side-specific characteristics of leaf chemistry and morphology were considered. Due to the degree of specialisation, insects may respond differently to wax cues of the same plant species. Presence of epicuticular waxes was crucial for oviposition acceptance in a monophagous leaf beetle, while some oligophagous species did not discriminate between leaves with and without intact wax layer. In contrast, a generalist leaf beetle was shown to prefer de- waxed leaves of this plant which was a poor quality host for its development. The wax layer can serve as recognition cue, but might also cover feeding stimulants of the inner plant tissue.

7.14.1. Ecological linkages between soil and above-ground communities

R. D. Bardgett;
Institute of Environmental and Natural Sciences, Lancaster, United Kingdom.

Soil biological communities are intimately linked to the plant community. The increasing recognition of the influence of these components on each other has led to there being much interest amongst ecologists in the role played by aboveground-belowground feedbacks in controlling ecosystem processes and properties. This talk will use selected examples from recent studies to explore the nature and ecological significance of feedbacks between plants and soil biological communities in relation to soil nitrogen and carbon cycling. The talk will also examine recent studies that address the question of whether variations in the diversity of soil biological communities are of significance for these feedbacks between plants and soils. The overall aim of the talk is to illusrate the importance of soil biota and their interactions with plants as major structuring forces in plant communities.

7.14.2. Earthworms as ecosystem engineers in below-aboveground interactions

S. Wurst[1], D. Dugassa-Gobena[2], R. Langel[3], M. Bonkowski[4], S. Scheu[4];
[1]Centre for Terrestrial Ecology, Netherlands Institute of Ecology (NIOO), Heteren, The Netherlands, [2]Institut für Pflanzenpathologie und Pflanzenschutz, Georg-August Universität Göttingen, Germany, [3]Kompetenzzentrum Stabile Isotope, Georg-August Universität Göttingen, Germany, [4]Institut für Zoologie, Technische Universität Darmstadt, Germany.

Earthworms play a mayor role in nutrient cycling and have pronounced impacts on plant growth. We studied the effects of earthworms in combination with soil heterogeneity and other soil organisms (mycorrhiza, plant feeding nematodes) on growth, competition and defensive chemistry in plants, and the consequences on aboveground herbivore performance. The experimental plants were a grass (*Lolium perenne*), a non-legume forb (*Plantago lanceolata*) and a legume (*Trifolium repens*). Due to different root morphologies and N acquisition strategies the plants responded differently to earthworms. In *P. lanceolata* we found changed levels of defense related compounds (iridoid glycosides, phytosterols) in the presence of earthworms. Since effects of earthworms on plants are mediated by nutrient availability and microorganisms, the effects vary under different soil conditions. By changing the food quality of plants, earthworms can thus affect aboveground herbivore performance.

7.14.3. Interactions between insects and arbuscular mycorrhizal fungi

A. C. Gange;
Royal Holloway, Egham, United Kingdom.

Arbuscular mycorrhizal fungi are ubiquitous in nature and associate with the roots of about 75% of all vascular plants. The association is considered to be mutualistic, because the mycorrhiza donates mineral nutrients to the plant in return for a supply of organic carbon. Both of these features mean that a mycorrhizal plant may represent a very different food source for an insect herbivore, compared with a non-mycorrhizal individual. Mycorrhizal effects on plants that could be of importance to insects include altered nutritional quality, chemistry or simple physical features such as overall size. Our knowledge of how mycorrhizas can affect phytophagous insects is restricted, but here I will give an outline of the interactions that have been found and will attempt to produce a synthesis of these patterns. I will address the mechanisms by which these interactions occur and will place the work in a multitrophic context by considering higher trophic levels as well.

7.14.4. Effects of belowground and aboveground organisms on plant floral traits and seed set

K. Poveda[1], I. Steffan-Dewenter[1], S. Scheu[2], T. Tscharntke[1];
[1]Agroecology, 37073 Göttingen, Germany, [2]Institut für Zoologie/Technische Universität Darmstadt, 64287 Darmstadt, Germany.

In animal-pollinated plants, fitness is influenced by floral traits that function as advertisement and reward for pollinators. It is increasingly recognized that belowground and aboveground communities are highly interdependent and studies on how belowground organisms affect flowering traits and seed set may lead to a more integrative view of the functioning of terrestrial ecosystems. In a three-factorial common garden experiment we investigated single and combined effects of root herbivores, leaf herbivores and decomposers on floral traits and seed set of wild mustard (*Sinapis arvensis*). Reduced nutrient availability through leaf herbivory affected primarily floral traits that could be important for pollinator attraction. Improved nutrient supply through decomposer activity was invested in seed production but did not affect floral traits. Our results suggest that *S. arvensis* faced no strong selection pressure from pollen limitation. Ultimately, this study may lead to a more detailed understanding of how belowground and aboveground plant-animal interactions shaped the evolution of plant species.

7.14.5. Linking above and belowground multitrophic communities: consequences for diversity and ecosystem functioning

T. M. Bezemer[1,2], W. H. Van der Putten[3];
[1]Laboratory of Nematology, Wageningen, The Netherlands,
[2]Laboratory of Entomology, Wageningen, The Netherlands,
[3]Netherlands Institute of Ecology, Heteren, The Netherlands.

Aboveground and soil dwelling communities are spatially separated. Plants exist both aboveground and in the soil and as primary producers they obviously influence both compartments. Evidence is now accumulating that organisms living above- and belowground can also influence each other via the plant. Most of this evidence is based on single interactions using one host plant and one aboveground and belowground organism. Using artificial grassland communities consisting of plant, soil, and aboveground communities, we will show how in a complex system above- and belowground communities can influence each others dynamics. Soil community composition influenced plant diversity and ecosystem functioning. Moreover, aboveground plant primary and secondary chemistry changed depending on soil community composition, resulting in reduced herbivore populations, but increased performance of the natural enemy of the herbivore, leading to an aboveground trophic cascade mediated by belowground organisms.

7.14.6. Nutrient competition may cause spatially structured herbivory on lupines at Mount St. Helens.

J. G. Bishop[1], S. E. Wills[1], J. L. Apple[1], R. A. Gill[2];
[1]Washington State University, Vancouver, WA, United States,
[2]Washington State University, Pullman, WA, United States.

A 3 yr nutrient addition experiment on primary successional substrates at Mount St. Helens, USA, demonstrated N limitation of most community members, but P limitation of *Lupinus lepidus*, the N-fixing, dominant colonist. P addition increased the proportion of lupin seeds filled (yr 1) and % cover (yr 3). Forb % cover also increased by yr 3 in P plots, suggesting N-P co-limitation of the community. Removing neighbors around focal plants increased lupin relative growth (RGR), survivorship, and the RGR response to P fertilization. *L. lepidus* is subject to intense herbivory by lepidopteran larvae in low density patches that is absent in the high density patches studied here. Larvae raised in captivity typically have higher RGR on leaves from low density patches, which are usually higher in N and P. However, larval RGR and gross growth efficiency increased with leaf P content but not leaf N. In glasshouse, P fertilization increased leaf N and P and larval RGR. In the field, larvae placed on plants 1 yr after neighbor removal consumed more leaf surface area. We hypothesize that P limitation of lupin under competitive conditions excludes herbivores from high density patches.

7.14.7. Above- and belowground pathogens: driving the evolution of plant sexual reproduction?

K. J. F. Verhoeven;
Netherlands Institute of Ecology, Heteren, The Netherlands.

A popular but largely unproven hypothesis on why sexual reproduction is so widespread is that the production of variable offspring provides better protection against rapidly evolving pathogens. Scarce empirical tests of this hypothesis in plants have focused on the effects of aboveground pathogens. Increasing awareness that belowground pathogens can play an important role in shaping plant diversity prompts us to consider the potential role of soil pathogens. Do these pathogens pose selection pressures that are strong and specific enough to shape genetic variation within plant populations, and to drive the evolutionary maintenance of plant sexual reproduction? And how do their effects compare to or interact with those of aboveground pathogens attacking the same plant species? I will discuss existing views on this, and will outline a strategy to address the issue empirically using dandelions as a model system - a species that has sexual as well as asexual forms and that is attacked by both aboveground and belowground pathogens.

7.15.1. Human impact, ecosystem management and ecosystem conservation in protected areas

E. Poli-Marchese;
D.A.C.P.A. - Section: Biologia ed Ecologia vegetale - Università di Catania, Catania, Italy.

The earth has always been under transformation by natural forces, but today it is being transformed by human action. The human imprint on the earth’s landscape is profound : natural ecosystems are being transformed into highly altered systems. Even in protected areas, some ecosystems have been seriously degrated or destroyed. The consequences are : loss of biodiversity at all levels of organization, habitat destruction, extinction and endangerment of species. This is particularly serious in areas with a long history of intense use by humans and at the same time with high level of biodiversity. Among these areas those located in Mediterranean region are very significant. Here there are many hot spots of biodiversity. We urge that, particularly on protected areas, ecosystem management be conservative. In this areas the core of ecosystem management should be ecosystem protection and restoration. Therefore, where it is necessary to use natural resources we must carry out ecosystem management strategies which ensure to maintain their ecological integrity. Sustainable resource use is necessary to ensure the future of life on the earth.

7.15.2. National Parks Kopaonik and Tara (Serbia) - management and nature conservation challenge

O. Vasic;
Natural History Museum Belgrade, Beograd, Serbia and Montenegro.

Two out of five National Parks in Serbia, Tara and Kopaonik Mts were enounced in the same year and are placed into the same law category, but they did not have the same destiny. The long-term negative influence on Kopaonik culminated in building of a huge hotel complex and ski paths at the ecologically most important and floristically richest area of the mountain. Consequences of direct and indirect negative influence, destruction, degradation and change of natural structure of phytocenoses led to serious disturbance of stability of ecosystems. The only chance for stopping this process and recovery of the area is the strict application of ecological principles and extremely sustainable use of natural resources on Kopaonik. On Tara Mt, due to controlled use of resources, there are some spacious very well preserved forest complexes, the main asset of which are the relict biocenoses and species. The state of ecosystems, conservation challenges and possibilities of sustainable development in both National Parks will be discussed.

7.15.3. The importance of eco-coenotic conditions to the conservation of threatened plant populations from the natural reserves of Transylvania (Romania)

V. Cristea[1], **S. Hentea**[2], D. Gafta[1], O. Rosca Casian[1], A. Suteu[2], I. Goia[2];
[1]'Babes-Bolyai' University, Cluj-Napoca, Romania, [2]'Al. Borza' Botanical Garden, Cluj-Napoca, Romania.

Following a general presentation of the conservation strategies in Romania, we focus on the influence of eco-coenotic conditions on the structure of some threatened taxa populations distributed in Transylvanian protected areas. The studies performed on 4 taxa revealed significant differences with implication in their survival and *in situ* conservation: - the mean density, height and number of fertile shoots/*Astragalus peterfii* ramet are larger in *Stipa*-dominated open communities than in closed grasslands; - the number of flowers/*Trollius europaeus* individual is larger in sedge communities invaded by *Phragmites* compared with those free of reed, probably because of eutrophication; - *Dianthus petraeus* ssp. *orbelicus* has higher values of fertile shoots, number of flowers/shoot and shoot density/unit of basal leaf area in *Thymetum comosi* than in basophilous grasslands, probably because of a low competition in the pioneer community; - *Aquilegia nigricans* ssp. *subscaposa* has a larger morphometric variance in the oak-beech forest than in the adjacent grassland, most likely because the increased spatial/temporal heterogeneity of the forest understory.

7.15.4. Origin, present and future of the flora and vegetation in Pannonian protected areas

A. Borhidi[1], J. Csíky[2], B. Kevey[2], Z. Molnár[1], R. Pál[2];
[1]Institute of Ecology & Botany, Hungarian Academy of Sciences, Vácrátót, Hungary, [2]Botanical Department & Adaptation Biology Res. Group, University of Pécs, Pecs, Hungary.

Main values of the Pannonian flora and vegetation are protected in 10 National Parcs, Land Protection Areas and more than 700 nature conservation areas in ca. 10 % of the national territory of Hungary. Their origin has been delineated in the Ösmátra (Ancient-Mátra) Theory put into new light in recent palynological, taxonomic, floristic and ecological evidences stimulating to arise a new vision, create a new scenario consisting of several thesis concerning the late glacial and Holocene evolution of the Pannonian flora and vegetation. A new interpretation of paleoendemics, holoendemics, schizo- and neoendemics has been elaborated for the region, delineating new relic areas for protection and proposing new areas for botanical research including tasks for the national nature conservation authorities. The parallel evolution of the Pannonian and the Ucrainian-Russian steppes, different models of evolution of the mountain and lowland endemics, the wooded vs. treeless character of the Hungarian lowland, the primer vs. secondary origin of the alkali vegetation and the main values of the flora and vegetation, their threat and conservation are also discussed.

7.15.5. Conservation and management of phytocoenoses in protected areas (central europe)

F. Pedrotti;
Università, Camerino, Italy.

The conservation of phytocoenoses is one of the most difficult environmental problems of our time. Phytocoenosis alterations involve changes to species composition and structure due to processes of degeneration: introduction of exotic species, disappearance of characteristic species, and simplification of the structure; those that provoke the disappearance of the phytocoenosis are regression, fragmentation, reduction and elimination. Theoretically, it is easier to conserve stable primary (zonal) phytocoenoses, which are self-governed by the process of fluctuation (such as forests) and hence only undergo natural disturbances; more complex is the conservation of secondary phytocoenoses (meadows, etc.) inasmuch as they undergo anthropic disturbances, and thus are not stable. The stable and azonal phytocoenoses (such as marshy associations) can be conserved only if the ecosystems are maintained in their entirety. Phytocoenosis conservation is of first priority in the protected areas, where man should intervene as little as possible in the primary phytocoenoses, and adopt particular interventions of management in the secondary and azonal ones.

7.15.6. Vegetation-ecological management and restoration in and around protected areas in Japan

A. Miyawaki;
Japanese Center for International Studies in Ecology(JISE), Yokohama, Japan.

In proportion to rapid nature destruction and urbanization seen in these 50 years, natural areas ranging from large natural parks to small shrine groves have been protected for the preservation of natural/ semi-natural ecosystem, biodiversity and their specific landscapes. Only preservation and management in protected areas, however, is not enough to deal with today's global nature devastation. It is mandatory to restore positive green environments, especially indigenous forests, in our living areas. Since the 1960s, we have been conducting field investigations of all kinds of vegetation including that of nature reserves. We identify the potential natural vegetation through research and keep planting tree species from it, for the restoration of quasi-natural ecosystems. We regenerated green environments at about 1500 sites including 1200 sites in Japan as well as in Borneo and China. Our tree-planting activity is future-oriented, proactive nature preservation, not mere maintenance and elucidation within limited protected areas. This is a mission for human existence that field botanists of all over the world have to carry out in their own regions.

7.15.7. Primary succession on barren substrates: lessons for restoration of protected lands

R. del Moral;
University of Washington, Seattle, WA, United States.

Primary succession requires amelioration, dispersal, establishment, and development. Biotic interactions, landscape effects, changing safe-site qualities, and chance all affect succession. Studies on many volcanoes (e.g. Etna, Fuji, St. Helens, Tolbachik, Tarawera, Kilauea) reveal lessons to improve restoration of damaged habitats within protected areas. Trajectories develop at different rates due to stress and in different ways due to priority effects and dispersal limitations, producing natural mosaics. Recovery can be hastened by alleviating stress through appropriate fertilization. Very short distances limit dispersal of most species, so managers must continually facilitated dispersal. Competition and herbivory can slow succession, so active management may be needed. Alien species may be controlled by biotic factors. Natural processes can produce several alternative, stable, natural plant communities, so a mosaic of vegetation in protected natural areas should be encouraged. Monitoring through permanent plots is required to detect invasions by alien species and responses to climatic changes.

7.16.1. *Kawa Kharpo* and *Kinabalu*: Comparative alpine ethnobotany in the Subtropics and Tropics

J. Salick;
Missouri Botanical Garden, St Louis, MO, United States.

Kawa Kharpo (6740m) is a Tibetan sacred peak in the eastern Himalayas; *Kinabalu* (4101m) is a Dusun sacred peak in Borneo. The flora, use and meaning of these two mountains differ dramatically and yet have striking similarities. Both have steep elevational and corresponding vegetational gradients, however in the tropics biodiversity declines predictably with elevation, while in the Himalayas the highest biodiversity is found in Alpine Meadows. In both areas useful plants, predominantly medicinals, are directly correlated with biodiversity. Furthermore, numerous plant resources are managed on *Kawa Kharpo*: Tibetans collect mushrooms, pasture yaks, grow crops, offer religious plants, and nurture famous Himalayan horticultural plants - lilacs, peonies, primrose, fritillaries, rhododendrons. For both ethnic groups, conservation is traditionally sacred, but recently they must address tourism, commercial interests, and government policy. Global warming affects both massives, pushing threatened alpine flora - including valuable medicines - toward extinction. Alpine ecology and culture - Ethnoecology - account for much similarity and difference.

7.16.2. Alpine ethnobotany in the Caucasus and Central Asia

T. Shulkina[1], G. Nakhutsrishvili[2];
[1]Missouri Botanical Garden, St. Louis, USA, St. Louis, MO, United States, [2]Institute of Botany, Georgian Academy of Science, Tbilisi, Georgia.

More than 7,000 species of economic plants are listed for the former Soviet Union, mainly from two botanically rich mountain regions: the Caucasus and Central Asia. Above timberline, there are about 90 useful spp in the Caucasus and about 150 in Central Asia (Tien Shan, Pamiro Alay). These Alpine areas are threatened by habitat loss to development and overgrazing. The Caucuses and Central Asia have distinct flora with few species in common; cultural differences are likewise great and ancient. Some species present throughout the areas are used for different purposes (e.g. *Paeonia* sp. by Georgians and Kazkhs; *Gentiana schistocalyx* by Adjars and Abkhazs), while different but related species are used for the same purposes (*Valeriana daghestanica,* Caucasus by Daghetanians and Ossetians, *V. fedtshenkoi,* Central Asia by Kirgyzs). Limited supplies of useful plants at lower elevation have forced people to use alpine plants for new purposes (e.g. *Comarum salesovianum* as a tea, in Pamir by Tajiks; *Berberis sphaerocarpa* for vine production, in Central Asia by Kazakhs). These high mountain vegetations are endowed with new species, new uses and new directions in Ethnobotany.

7.16.3. Unconventional wild plant and insect consumption in the southern Alps of Friuli, Italy

M. Paoletti, A. Dreon;
Dip Biologia, Padova, Italy.

Folk diets include wild plants and a few invertebrates in Friuli that are peculiar in the Alps. Recovery of scattered knowledge is valuable for maintaining use and enhancing a base for agroecology, conservation and ecotourism. *Pistic, Frita, Litum* are common names from about 80 herbs collected in field margins, hay meadows, woodlands and the wild, most commonly in spring. To eat, most herbs are boiled and later sauteed with butter or lard and garlic. In the higher range traditional alpine slopes have supported seasonal sheep and cow grazing. Summer pastoral communities have traditionally used plants for salads, soups, spices and cheese production. Collections of these useful alpine plants include: *Chenopodium bonus-henricus, Aruncus dioicus, Cicerbita alpina, Rumex pseudoalpinus, Carlina acaulis, Myrris odorata.* Some insects are also eaten in these meadow areas such as adult Lepidoptera (Zygaeidae and Ctenuchidae). These local traditional uses need more ethnobiological attention and study.

7.16.4. At the edge of the tree line: Ethnobotanical importance of high elevation sites in the Northwestern North American interior region

N. J. Turner[1], C. Mellott[1], D. Deur[2];
[1]University of Victoria, Victoria, BC, Canada, [2]University of Washington, Seattle, WA, United States.

The Coast and Cascade mountains of northwestern North America, from central British Columbia to northern California, have immense ethnobotanical significance, with well over 50 culturally important plant species documented. For millennia, indigenous peoples living in the valleys below have been moving up to the high country in the summer months, camping at the tree line, hunting and harvesting diverse plant resources, including foods (e.g., *Vaccinium membranaceum*, *Claytonia lanceolata*, *Erythronium grandiflorum*, *Pinus albicaulis*), medicines (e.g., *Veratrum eschscholtzii*, *Valeriana sitchensis*) and materials such a fuel. Upland plant communities have been traditionally managed in myriad ways. These montane areas are essential traditional territory, and although still required for nutritional, educational, and cultural purposes, people's access to them has often been restricted. Their biodiversity and productivity have been threatened by mining, overgrazing, logging, invasive species, fire suppression, and even tourism. Yet, these areas are still critically important within the indigenous communities and the ecology of the entire region.

7.16.5. Crop and wild plant biodiversity in the Andes: traditional management, threats, and conservation in highland communities

E. Emshwiller[1], W. M. Roca[2], T. Medina[3];
[1]The Field Museum of Natural History, Chicago, IL, United States, [2]Centro Internacional de la Papa, Lima, Peru, [3]Instituto Nacional de Investigación y Extensión Agraria, Lima, Peru.

All alpine regions have elevational gradients, but the Andes' unique shape and location provide a moisture gradient between the dry western flank and the cloud forests of the eastern slopes, as well as a long latitudinal gradient with a range of seasonality and photoperiod cues. This ecological heterogeneity fosters extreme endemism in the tropical montane regions. The Central Andes are unparalleled among alpine regions as a center of crop domestication and agrobiodiversity. Traditional management of agroecosystems and crop diversity includes terracing, burning high pasturelands, multicropping, cultivating diverse homegardens, and community-level sectoral crop rotation/fallowing. Andean heterogeneity means that threats to biodiversity vary across the region: crop diversity is threatened by overpopulation in some areas and depopulation in others, deforestation threatens wild crop relatives, mining pollutes rivers, and the future effects of global climate change are yet unknown. How exchange of propagation material affects the genetic structure of clonal crop populations is currently under study to aid both old and new methods of conservation.

7.17.1. Golden Rice: Genetic engineering technology against malnutrition.

I. Potrykus[1,2];
[1]Institute of Plant Sciences, Zürich, Switzerland, [2]Institute of Plant Sciences, ETH Zürich, Switzerland.

Vitamin A-malnutrition is responsible for ca 6'000 death per day, and leads to 500'000 blind children per year. Biofortification could lead to sustainable and cost-effective solutions. 'Golden Rice' contains transgenes which lead to synthesis and accumulation of provitamin A. Since the proof-of-concept publication (Science 2000) the provitamin A-content has been increased to ca. 20-fold above that publication. A typical daily diet of rice can prevent VADD if based on Golden Rice. The trait has been transferred to and is functioning in more than 30 popular rice varieties. The first field release experiment did not indicate any agronomic problem, a professional taste trial was positive, and no ecologist can propose a substantial risk to any environment. Free licences for humanitarian projects for IPR involved allow for use by small-scale farmers and traders without any costs, there is no additional agronomic input reqired, and the farmer can use part of his/her harvest for the next sowing. Golden Rice could save numerous children from blindness and death but extreme precautionary regulation and radical GMO opposition are preventing this, so far.

7.17.2. Production of natural products by plant cell biotechnology

A. Alfermann, E. Fuss;
Institut für Entwicklungs- und Molekularbiologie der Pflanzen, Düsseldorf, Germany.

In 1959 Tulecke and Nickel were the first to report the mass cultivation of plant cells in some hundred liters with the intention to produce natural products. More than 20 years later in 1982 Mitsui Petrochemical Company in Japan established the first commercial process of natural product (shikonin) formation by plant cell cultures. Whereas shikonin is produced on a rather small scale, in 2004 Phyton Deutschland GmbH in Ahrensburg (Germany) announced a real breakthrough, the production of the anticancer compound paclitaxel by *Taxus* cell suspension cultures in a 70 m^3 (working volume 50 m^3) bioreactor which is used by Bristol-Myers Squibb for Taxol^R production.(press release by Phyton in 2004). The reasons why it took so long time before the dream of the large scale commercial production of a medicinal compound became true will be discussed. Additionally however, the numerous possibilities still offered by plant cell biotechnology concerning natural product formation will be described using lignan accumulation in *Linum* cell cultures.

7.17.3. Biotechnological applications for the improvement of grapevines

D. Mendonça, M. S. Lopes, L. Braz, **A. da Câmara Machado**;
DCA, Angra do Heroismo, Portugal.

Plant biotechnology as an interdisciplinary science is able to provide solutions to agricultural challenges, particularly in the case of woody fruit crops, e.g. by rapid propagation of selected cultivars, conservation of valuable germplasm, phytosanitary and genetic improvement and safeguarding human health not only through nutritional, but also through ecological aspects. Data obtained from the molecular characterisation of 5 Portuguese Vitis vinifera ssp. sylvestris indicate that wild grapevines had a major influence on the domestication of cultivars. From a greenhouse collection of V. vinifera sylvestris, accessions were introduced in vitro as a conservation strategy and to obtain quickly propagation material under axenic conditions to be used for studies to identify genotypes with putative resistance to the fungi Plasmopara viticola and Uncinula necator.

7.17.4. Somatic embryogenesis - the gateway to biotechnology in conifers

K. Zoglauer, H. Ross, A. Rahmat, J. Thiel, C. Aurich, T. Taryono;
Humboldt University, Institute of Biology, Botany and Arboretum, Berlin, Germany.

Clonal propagation by conventional techniques of most of the conifer species used as forest or Christmas trees is difficult or inefficient. Biotechniques, primarily somatic embryogenesis (SE), provide a powerful alternative for establishment of clonal varieties and shortening of breeding programs. In gymnosperms, somatic embryogenesis has been demonstrated for the first time in 1985 and, up to now, shown in more than 50 species and hybrids. In the recent years, integration of SE into breeding strategies and commercialisation of SE based propagation has been started. Additionally, embryogenic cultures are an ideal target for Agrobacterium-mediated and direct gene transfer as well as fundamental studies in embryology. In the presentation fundamentals of SE in conifers, present achievements in practical application and limitations will be discussed based on own results in Larix, Abies and Pseudotsuga species.

7.17.5. Differences and common features of developing somatic and zygotic embryos of oak (*Quercus robur* L.)

E. Wilhelm[1], C. Prewein[1], V. Sunderlikova[2], J. Salaj[2];
[1]ARCS, Seibersdorf, Austria, [2]Institute of Plant Genetics and Biotechnology, Slovak Academy of Sciences, Nitra, Slovakia.

In several broad-leafed tree species, including also oak, somatic embryo (SE) maturation represents a major barrier to the commercialization of this vegetative propagation system. To improve the quality and germination frequency of SEs, comparative biochemical and molecular studies were performed to study the physiological changes during zygotic and SE development. The water status, proline, starch, endogenous ABA and IAA levels of the developing embryos were monitored in relation to morphological characters. The temporal and tissue specific expression patterns of the *legumin* gene, the major storage protein of oak, and several oak *lea* genes (late embryogenesis abundant proteins) were investigated. Differential expression patterns of some *lea* genes were found, whereas the expression in zygotic and somatic embryos of other *lea* genes is embryo specific and developmentally regulated. Variations in phytohormone levels in combination with changes in tissue water status seem to be important factors for both zygotic and somatic embryo development.

7.17.6. *In vitro* collection and sanitation of valuable germplasm of temperate fruit trees

M. Laimer[1], E. Borroto[1], V. Hanzer[1], I. Balla[2], H. Katinger[1];
[1]IAM, Vienna, Austria, [2]Research Institute of Fruit growing and Ornamentals, Budapest, Hungary.

Conservation and utilization of biodiversity in a sustainable manner represent major priorities. To conserve genetic resources in different type of genebanks (*in vitro, in situ, ex situ*), genetic markers may support an informed choice of genotypes, e.g. molecular markers like RFLP; AFLP and SSRs. Improved strategies for the production of elite plants of pathogen-free stone fruit cultivars include on one hand the application of rapid, reliable, user-friendly, sensitive and cost effective methods for the detection and elimination of the major stone fruit tree viruses and phytoplasmas and on the other hand the elaboration of molecular markers for genotype characterisation. An *in vitro* collection of apricots and peaches containing cultivars testing positive for Plum Pox Virus (PPV) and European Stone Fruit Yellows (ESFY), was established and used as model system for virus and phytoplasma elimination. Different *in vitro* techniques, i.e. meristem culture and heat therapy *in vitro* were applied either alone or in combination and results compared. Protocols were validated for high survival rates of plants and for their effectiveness for pathogen elimination.

7.17.7. In vitro culture for propagation and breeding of ornamental plants

T. Winkelmann, M. Serek;
Institute of Floriculture, Tree Nursery Science and Plant Breeding, University of Hannover, Hannover, Germany.

In vitro culture techniques are commercially used for clonal propagation of high value crops, among which many ornamental species are found. The statistics of German commercial tissue culture labs clearly demonstrate the special impact of micropropagation for orchids, mainly in the genus Phalaenopsis. Since the high input of manual labour results in high prices, part of the production is transferred to low wage countries. An alternative approach is automation, for which liquid culture systems are particularly suited. In vitro culture techniques are not only applied for mass propagation of high priced species in floriculture, but we cannot imagine multiplication of vegetatively propagated ornamentals without virus elimination by meristem culture and clean nuclear stocks. For commercial micropropagation, axillary branching is the method of choice for the vast majority of species. Regeneration via organogenesis and somatic embryogenesis plays only a minor role, but is very important for the production of transgenic ornamentals. The applications of somatic embryogenesis for propagation and breeding of Cyclamen persicum will be given as an example.

8.1.1. Specificity in auxin signalling

O. Leyser;
Department of Biology, York, United Kingdom.

Auxin regulates transcription by reducing the stability of Aux/IAA transcriptional repressor proteins. Aux/IAAs repress transcription by dimerising with members of the ARF family of DNA binding proteins. Degradation of the Aux/IAAs destroys the dimmers allowing activation of transcription. Furthermore, Aux/IAA proteins can dimerise within the family. Such Aux/IAA-Aux/IAA dimers could regulate the formation of ARF-Aux/IAA dimers by competition. There are 29 Aux/IAAs and 23 ARFs in the Arabidopsis genome, and thus a large number of possible dimers. This suggests a network in which diverse, tissue and dose-dependent auxin responses are encoded by tissue-specific expression, and changes in the relative abundance of Aux/IAA-ARF network components. To test this model we are using stabilised Aux/IAA mutants. Strikingly, such mutants can have entirely opposite phenotypes. For example, stabilised BDL/IAA12 produces highly bushy plants, but similar mutations in AXR3/IAA17 confer reduced shoot branching. To understand how such functional specificity is encoded, we are using promoter swapping, domain swapping, and mis-expression experiments.

8.1.2. N-terminus of a rice ABRE binding factor controls transcriptional activation function by protein phosphorylation

I. Yoon[1], J. Hong[1], M. Nam[2], M. Chae[1], S. Suh[1];
[1]National Institutle of Agricultural Biotechnology, Suweon, Republic of Korea, [2]Korean Basic Science Institute, Seoul, Republic of Korea.

Abscisic acid (ABA) mediates responses of a plant to environmental stresses in which diverse protein kinases and transcription factors are involved. Here, we characterized a rice ABA-response element binding factor (OREB1) previously identified as an *in vitro* substrate of a rice SnRK2 kinase. OREB1 has transcriptional activation activity in yeast and deletion of N-terminus of 92 amino acid resulted in a complete loss of the activity. Sub-deletion analysis showed that both positive and negative regulatory domains are present in the N-terminus region and amino acid from 42 to 119 showed the possibility to act repressive function. MALDI-TOF MS analysis of the *in vitro* phosphorylated OREB1 revealed a site of phosphorylation to ser-44 by a rice SnRK2 kinase. Indeed, a triple mutant of serine-43, 44, 47 to alanine resulted in an increase of transcriptional activation activity in yeast, implicating that these phosphorylation sites are important to control the repressive function. Our present findings indicate that SnRK2-mediated phosphorylation of the N-terminus of OREB1 is an important mechanism to regulate its function, possibly, in the negative regulation.

8.1.3. Cytokinin signaling regulates vascular morphogenesis

Y. Helariutta, A. Mähönen, A. Bishopp, K. Nieminen;
Institute of Biotechnology, University of Helsinki, Finland.

Cytokinin regulates several aspects of plant development and physiology. Our lab is studying the genetic control of vascular morphogenesis during root development in Arabidopsis. A recessive mutation, *wooden leg* (*wol*), in the *CRE1*/*WOL*/*AHK4* gene coding for a cytokinin receptor, results in reduced cell proliferation and exclusive xylem differentiation (Mähonen *et al.* Genes&Dev. 14, 2938-2943; Inoue et al. Nature 409, 1060-1063). This indicates the involvement of a specific cytokinin mediated morphogenetic pathway during early stages of vascular development. In order to more systematically approach the genetic control of cell proliferation during vascular development, we have carried out an EMS based screen for suppressors of *wol* based on root growth pattern. Both extra- and intragenic suppressors were identified. The presentation will focus on the further charaterization of these mutations.

8.1.4. The transcription factor FUSCA3 controls developmental timing in *Arabidopsis* through the action of multiple hormones

P. McCourt;
Department of Botany, Toronto, ON, Canada.

Morphological differences among closely related species can often be explained by shifts in the relative timing of developmental programs. Understanding the molecular basis of what regulates these shifts in plants and animals has led developmental biologists to identify genes that regulate the timing of appearance of various organs and structures through an organism's lifespan. In Arabidopsis, loss-of-function (lof) mutations in the *FUS3* gene cause embryonic leaves to take on more adult fates while constitutive misexpression produce cotyledon-like leaves during vegetative development. We find that the timing of *FUS3* expression specifies leaf identities by controlling the duration of the foliar organ program. One mechanism by which *FUS3* control foliar organ identify in Arabidopsis is by regulating the synthesis of two hormones, abscisic acid and gibberellin. These hormones in turn, regulate the rates of cell cycling during organ formation to determine whether an embryonic or adult leaf will emerge. *FUS3* expression is also dependent on the distribution of the patterning hormone, auxin, and therefore acts as a nexus of hormone action during embryogenesis.

8.2.1. Protein import into chloroplasts

J. Soll;
Ludwig-Maximilians-University, Munich, Germany.

Chloroplasts are of endosymbiotic origin. During this process most of genes were transferred from the endosymbiot to the arising host nucleus. Therefore chloroplasts have to import between 3000 and 4000 different polypeptides. These proteins are synthesized in the cytosol as precursor proteins, which contain in most cases an N-terminal targeting signal, also called transit peptide. The transit peptide is recognized at the chloroplast surface and translocation is initiated. This task is accomplished by two distinct translocons localized in the inner and outer envelope in a GTP and ATP dependent manner. In the stroma the transit peptide is cleaved. Protein import is regulated by phosphorylation and GTP on the cytosol / chloroplast interface and by redox control as well as calcium at the stroma / inner envelope interface. Furthermore, the composition of the protein import translocon depends on developmental status of the organell as well as the plant organ. Therefore chloroplast protein import is highly regulated at the molecular and cellular level.

8.2.2. Chloroplast protein import in *Arabidopsis thaliana*

F. E. Kessler;
Institute of Botany, University of Neuchatel, Neuchatel, Switzerland.

In Arabidopsis, a small family of six Toc-GTPases, consisting of a subgroup of four large proteins (atToc159/132/120 /90) and two smaller ones (atToc34/33), controls access of precursor proteins to the chloroplast. The Toc-GTPases are organized in Toc-complexes. The minimal Toc-complex is considered trimeric. It consists of one large and one small Toc-GTPase as well as atToc75, a protein-conducting channel. Mutant analysis of the Toc-GTPases has led to the operational definition of two classes of precursors: photosynthetic proteins relying on Toc159/90/33 for import and housekeeping proteins relying on Toc132/120/34. Moreover, the existence of corresponding Toc-complexes involving the different sets of Toc-GTPases has been demonstrated. Biochemical studies indicate that the GTP-binding domains of Toc-GTPases play a key role in the assembly of Toc-complexes. Here, we present data on the role of atToc90 in the import of photosynthetic precursor proteins. In a second part, we will detail the role of specific amino acid residues and guanine nucleotides in the assembly of atToc33 and -159.

8.2.3. Protein targeting into "complex" diatom plastids: Analysis of a new type of targeting motif.

P. G. Kroth[1], O. Kilian[2], A. Gruber[1];
[1]Department of Biology, University of Konstanz, Konstanz, Germany,
[2]School of Botany, University of Melbourne, Melbourne, Australia.

Secondary endocytobioses, i.e. the incorporation of a photoautotrophic eukaryotic cell by a eukaryotic host cell and the subsequent transformation into a plastid, dramatically enhanced the complexity of the resulting chimeric cells. As a result diatom plastids have four envelope membranes, the outermost being continuous with the endoplasmic reticulum („chloroplast ER"/"CER"). *In vivo*-analyses of targeting of fusion proteins consisting of presequence domains fused to GFP indicate that protein import into diatom plastids involves at least two steps: a cotranslational transport step at the CER or the cytosolic ER and a further import step resembling protein import into plastids of higher plants. Utilizing deletion constructs we found accumulation of the GFP fusion proteins in a compartment that apparently is attached to the envelope membranes of the plastids, having a „blob"-like or reticular structure. Comparison of different presequences revealed a so-far unknown conserved "AFAP" or "ASAF" motif at the N-terminus of the transit peptide. Site directed mutagenesis revealed that the phenylalanine residue is essential for successful protein import.

8.2.4. Targeting and import of peroxisome membrane proteins

A. Baker[1], C. Hawes[2], L. Brown[1], D. Hadden[1], I. Sparkes[2];
[1]Centre for Plant Sciences, Leeds, United Kingdom, [2]School of Biological and Molecular Sciences, Oxford Brookes University, Oxford, United Kingdom.

Peroxisomes perform a wide range of vitally important functions in plant cells. In addition to well established roles in mobilisation of seed storage reserves and photorespiration new functions have recently emerged. These include formation and turnover of the major signalling molecules, NO and H_2O_2, and the biosynthesis of IAA (from IBA) and Jasmonic acid (from OPDA). Many of the functions of peroxisomes are mediated by membrane proteins, and membrane proteins play essential roles in the import of all the other matrix located proteins of peroxisomes. Our knowledge of peroxisome membrane protein targeting and insertion is rather incomplete. For example whether some peroxisome membrane proteins traffic to peroxisomes from the endoplasmic reticulum is still a matter of debate, as is the role of potential receptor/chaperone molecules. Our studies indicate that two peroxisome membrane proteins, AtPEX10 and AtPEX2 are not trafficked to peroxisomes via the ER. AtPEX10 interacts with the membrane protein chaperone AtPEX19 which is proposed to bind peroxisome membrane proteins in the cytoplasm and chaperone them to the peroxisome membrane.

8.2.5. Nucleo-cytoplasmic partitioning of transcription factors: a tool for the regulation of signalling.

T. Merkle;
Lehrstuhl für Genomforschung, Bielefeld, Germany.

The separation of transcription and translation by the nuclear envelope offers an additional level to control gene expression in eukaryotic cells that is not available in prokaryotes. Regulated nucleo-cytoplasmic partitioning of transcription factors can be achieved by controlling nuclear import, nuclear export, and/or degradation. In Arabidopsis thaliana, we characterised the nuclear export pathway that depends on the nuclear export receptor exportin 1. Identifying a nuclear export signal in a transcription factor strongly suggests a role of nuclear export in the regulation of gene expression. As a novel approach to plant signal transduction we screened for Arabidopsis transcription factors that contain nuclear export signals. Many different transcription factors that belong to different families were identified in this way. Our results indicate that nuclear export is an important tool to regulate diverse signalling pathways in plants.

8.2.6. Exploring plastid division pathways in *Arabidopsis*

S. G. Møller;
University of Leicester, Leicester, United Kingdom.

Plastids arise by division and the control of division site placement is mediated in part by AtMinD1 and AtMinE1 in *Arabidopsis*. We have shown that AtMinE1 is a topological specificity factor and that AtMinE1 forms homodimers and heterodimers with AtMinD1. AtMinE1 and AtMinD1 show specific intraplastidic localisation patterns and a C-terminal helix deletion in AtMinD1 results in inappropriate localisation and disrupted plastid division. Using FRET we have shown that AtMinD1 is capable of forming homodimers inside chloroplasts and that this dimerisation capacity is abolished by a single C-terminal A296G mutation. Our data demonstrates that AtMinE1 and AtMinD1 act in concert and that the formation of AtMinD1 homodimers and AtMinD1/AtMinE1 heterodimers is paramount for correct intraplastidic localisation patterns and correct division machinery placement. The assembly of the different AtFtsZ proteins in chloroplasts in relation to the AtMinD1/AtMinE1 protein complex will also be discussed. GIANT CHLOROPLAST 1, a positive factor involved in plastid division will briefly be described. A working model of plastid division will be presented.

8.2.7. Friendly: a mitochondrial dynamics mutant defective in mitochondrial inheritance?

D. C. Logan, A. K. Tobin;
University of St Andrews, St Andrews, United Kingdom.

Mitochondria are ubiquitous and vital eukaryotic organelles. Although identified over 50 years ago as the site of oxidative energy metabolism little is known about the genetic control of mitochondrial shape, size, number and distribution (collectively termed mitochondrial dynamics) in higher plants. We identified a suite of *Arabidopsis* mutants with altered mitochondrial dynamics and are using these as tools to identify the underlying genes, proteins and mechanisms. In one mutant, *friendly (fmt*), mitochondria form clusters of tens of organelles. The *fmt* locus was identified and the gene, *FMT,* is homologous to the *D. discoideum cluA and S. cerevisiae CLU1* genes that are known to be involved in the maintenance of the correct cellular distribution of mitochondria. Apart from a tetratricopeptide repeat domain, the FMT protein has no significant homology to proteins of known function. We will present data testing the hypotheses that: (i) FMT is involved in association of mitochondria with the cytoskeleton and (ii) the clustered mitochondrial phenotype in *friendly* perturbs the stochastic inheritance of mitochondria into daughter cells during cell division.

8.3.1. Specifying the site of tip growth and the plane of asymmetric division in fucoid algae

D. L. Kropf;
University of Utah, Salt Lake City, UT, United States.

Eggs of fucoid algae are initially apolar cells and fertilization initiates a developmental program that breaks the symmetry resulting in selection of a site of localized tip growth. Growth site selection, which is influenced by a variety of environmental vectors, involves assembly of a cortical actin network nucleated by an Arp2/3 complex at the presumptive growth site. This nascent axis is labile and perception of subsequent spatial cues results in disassembly of the existing cortical actin and reassembly at the newly established growth site. Once tip growth has been initiated, the growth axis positions the mitotic spindle, which in turn determines the plane of asymmetric division. The spindle is positioned by centrosomal microtubules that interact with the cell cortex preferentially at the growth site, perhaps mediated by the microtubule-associated protein EB1. We anticipate that identification of additional molecules involved in signal transduction, actin assembly and microtubule search and capture will be facilitated by ongoing genomics projects.

8.3.2. Immediate upright *(imm)*, a mutant of the marine macroalga *Ectocarpus siliculosus* (Phaeophyceae, Ectocarpales) affected in polarity and development

A. F. Peters, S. M. Coelho, J. M. Cock;
UMR 7139 CNRS-Goemar-UPMC, Station Biologique, Roscoff, France.

Sporophyte and gametophyte are independent generations in *Ectocarpus siliculosus*. Wild-type sporophytes show bilateral symmetric germination resulting in the development of a prostrate, branched filament. The first germ tube is positively phototropic in response to unilateral white light. Erect thalli develop by 'mediate differentiation' i.e. they do not form before the prostrate thallus has reached a certain size. Gametophytes, in contrast, exhibit a developmentally asymmetric bilateral germination and 'immediate differentiation'. The first germ tube is negatively phototropic and develops into a thin rhizoid, whereas the second germ tube immediately develops into a broader and erect (positively phototropic) filament. We describe a spontaneous mutant *immediate upright* in which the sporophyte has a germination pattern resembling that of gametophytes, including negative phototropism of the first germ tube and immediate development of an upright filament. Crossing studies showed that the mutation is recessive compared to the wt and is located on an autosome. This is the first genetic study of a developmental mutant in *Ectocarpus*.

8.3.3. Signalling, actin, endosomes and root hair tip growth

J. Samaj[1,2], B. Voigt[1], M. Ovecka[3], I. Lichtscheidl[3], A. Hlavacka[1], M. Preuss[4], E. Nielsen[5], H. Hirt[6], F. Baluska[1], D. Menzel[1];
[1]Institute of Cellular and Molecular Botany, Bonn, Germany, [2]Institute of Plant Genetics and Biotechnology, Slovak Academy of Sciences, Nitra, Slovakia, [3]Institute of Ecology, University of Vienna, Vienna, Austria, [4]Donald Danforth Plant Science Center, St.Louis, MO, United States, [5]Donald Danforth Plant Science Center, St. Louis, MO, United States, [6]Gregor-Mendel-Institue of Molecular Plant Sciences, Vienna Biocenter, Vienna, Austria.

Root hair tip-growth is actin- and signalling-dependent process. Both endogenous and YFP-tagged SIMK, a stress-induced mitogen-activated protein kinase (MAPK), accumulate in vesicle-rich tip regions of Medicago and Arabidopsis root hairs. SIMK distribution and function correlates with the organization of the actin cytoskeleton visualized by immunolabelling and with new F-actin *in vivo* marker GFP-ABD2. MAPK inhibitor UO126 abolished tip growth by disrupting vesicular traffic but overexpression of constitutively active SIMK overcomes this growth inhibition, suggesting a role of SIMK in actin-dependent vesicular traffic. Overexpression of SIMK activator SIMKK in *Arabidopsis* resulted in overactivation of *At*MPK6 (SIMK homologue) and phenotype of ectopic and branched root hairs. Additionally, several MAPKs associate with endomembranes and endosomes in control and stressed cells. New endosomal molecular markers FYVE and RabF2a were developed and will be presented as useful tool for studies on actin-dependent motility of endosomes in root hairs.

8.3.4. Microtubules in *Medicago truncatula* root hairs during hair development and response to rhizobial signal molecules.

B. Sieberer[1], T. C. J. Timmers[2], A. C. Emons[1];
[1]Wageningen University, Wageningen, The Netherlands, [2]CNRS/INRA, Toulouse, France.

Tip-growing legume root hairs have two populations of microtubules: cortical microtubules (CMTs), which are present in all stages of root hair development, and - differently from Arabidopsis root hairs - a dense array of endoplasmic microtubules (EMTs), which the hairs acquire during the initiation of tip-growth and maintain until growth stops. EMTs are crucial to the polar distribution of cytoplasm, to nuclear positioning, and to a high growth rate.

In tip-growing hairs, signal molecules of symbiotic rhizobacteria (Nod factors) cause a subtle and transient shortening of the EMT array, whereas in growth-arresting hairs this effect is more pronounced and leads to a complete disintegration of the EMT array. The latter have a short EMT array and respond to Nod factors with a distinct change in hair morphology, called root hair deformation. The Nod-factor induced disappearance of EMTs correlates with a loss of polar cytoarchitecture and straight growth directionality, whereas the reappearance of EMTs correlates with the new set up of polar cytoarchitecture and new growth potential in growth-arresting hairs. CMTs showed no obvious response to Nod factors.

8.3.5. Vacuole form and movement in growing root hairs.

M. E. Galway[1], G. O. Wasteneys[2];
[1]St. Francis Xavier University, Antigonish, NS, Canada, [2]University of British Columbia, Vancouver, BC, Canada.

Tip-growing root hairs are useful models of polarized plant cell growth. Root hair vacuoles must expand rapidly as hair tips grow to maintain turgor pressure through water uptake. Vacuolar biogenesis in plant cells is a complex and variable process. We are using growing root hairs of the model plant *Arabidopsis thaliana*, plus ER or vacuole specific dyes and targeted green fluorescent proteins, to examine the form, distribution, movements, and expansion of root hair vacuoles. Vacuoles are labeled with the fluorescent pH indicator BCECF by growing seedling roots in a low concentration of the dye, which has no significant effect on hair growth. In wild type hairs, labile tubular elements of the vacuole extend into the cytoplasm-filled subapical regions. In *rhd3-1* mutants (which have a defective secretory pathway and altered ER morphology), vacuole morphology is also altered as spherical elements appear near the hair tips. This morphology may contribute to the defective control of tip growth direction that is characteristic of the mutant hairs.

8.3.6. The role of the cytoskeleton in the intracellular accommodation of microsymbionts by plant cells

K. N. Demchenko[1], N. P. Demchenko[1], K. Pawlowski[2];
[1]Komarov Botanical Institute, Russian Academy of Sciences, St.-Petersburg, Russian Federation, [2]Albrecht von Haller Institute for Plant Sciences, Plant Biochemistry, University of Göttingen, Göttingen, Germany.

Two groups of plants can enter root nodule symbioses with nitrogen-fixing soil bacteria. Gram-negative, unicellular rhizobia induce nodules on legume roots, while Gram-positive mycelial actinomycetes of the genus *Frankia* induce nodules on the roots of plants from eight angiosperm families, mostly woody shrubs, collectively called actinorhizal plants. Based on molecular phylogenetic studies, both types of root nodule symbioses are supposed to go back to a common ancestor. We compared infection thread growth in actinorhizal and legume nodules by immunolocalization of components of the cytoskeleton. We used myosin VIII-specific antibodies and antibodies against actin and tubulin to analyse the intracellular accommodation of microsymbionts in legume (*Medicago truncatula*, pea) and actinorhizal symbioses (*Casuarina glauca, Datisca glomerata*) on light microscopy and TEM level. Myosin VIII accumulated around infection threads in actinorhizal systems, but not around legume infection threads. This study was supported by the Russian Foundation for Basic Research (04-04-48282) and by the German Research Council (DFG).

8.3.7. Biophysics of tip growth in fungi

S. Bartnicki-Garcia[1], G. Gierz[2];
[1]CICESE, Ensenada, Mexico, [2]University of California, Riverside, CA, United States.

Much is known about the cytology and biochemistry of tip growth in fungal hyphae, but a fuller understanding requires knowledge of physical aspects, namely the spatial pattern of cell-wall expansion and the force expanding the wall. A 3-D mathematical model of hyphal morphogenesis was the basis to design and interpret experiments to elucidate the pattern of cell-wall expansion. The 3-D model was built under the assumption that polarized growth arises from a gradient of wall-building vesicles released by an advancing vesicle supply center (VSC). The VSC corresponds in position and function to the Spitzenkörper. We analyzed the trajectory of external and internal hyphal wall markers in *Rhizoctonia solani* and discovered that they followed orthogonal paths. Such finding supports the long-held view that turgor pressure, and not the cytoskeleton as recently suggested, drives cell wall expansion. The VSC model predicts that a polarized growth process with a decreasing coefficient of anisotropy generates the orthogonal pattern of wall expansion; this conclusion contradicts an earlier belief that tip growth in fungal hyphae is mainly an isotropic process.

8.4.1. Variation and similarities in pollen features in some basal angiosperms with some taxonomic implications

F. B. Sampson;
School of Biological Sciences, Victoria University of Wellington, Wellington, New Zealand.

An illustrated exploration is made of variation in pollen features within and between species and genera in several basal angiosperm groups including members of the Trimeniaceae (one species of which has dimorphic pollen), Winteraceae and Monimiaceae (*sensu lato*). Is there any variation in pollen morphology within a species, from one region to another? Stability in pollen features in a genus or species is not always reflected in stability in other characters, such as floral structure and organ venation in these plants of ancient lineage. For example, no two stamens in a single flower of some species of Winteraceae have the same venation. On the other hand, the strictly dimerous nature of the unilocular gynoecium of *Takhtajania*, so different from the carpels of the other members of the family, seems an enigma. These non-pollen features are discussed and illustrated too. The possible taxonomic implications of variation in pollen morphology within genera and possible links between pollen features and pollination ecology is noted.

8.4.2. Identification of fossil angiosperm pollen and its bearing on interpretation of the origin of angiosperms.

M. S. Zavada[1], J. M. Osborn[2];
[1]Providence College, Providence, RI, United States, [2]Truman State University, Kirksville, MO, United States.

Studies in the 1970's reporting the occurrence of fossil pollen types in the Cretaceous, coupled with surveys of extant pollen morphology of primitive flowering plants, laid the foundation for proposing a Lower Cretaceous origin of angiosperms. Over the last 30 years, morphological, ultrastructural, and ontogenetic studies of both extant and fossil pollen have provided an array of new characters and character states, as well as greater resolution in defining character polarities. Moreover, a range of fossil pollen types exhibiting angiosperm characters occur in low frequency within Triassic and Jurassic sediments. In this presentation we examine the use of pollen characters to track the origin and early evolution of angiosperms. Pollen data provide evidence for a pre-Cretaceous origin. For example, speciation and extinction rates were likely equal during the Triassic and Jurassic, resulting in the paucity of angiosperm pollen types from different geographic areas in the Atlantic rift zone. Not until the Lower Cretaceous did origination rates exceed extinction rates, resulting in the subsequent diversification of angiosperms.

8.4.3. Importance of pollen morphology for reconstructing plant evolutionary history: a comparison of Myristicaceae (Magnoliales) and Proteaceae (Proteales)

H. Sauquet;
Swedish Museum of Natural History, Stockholm, Sweden.

The implications of a recent phylogenetic study of Magnoliales for pollen character evolution are presented, with an emphasis on Myristicaceae. In several instances, long-standing ideas on pollen evolution are completely turned upside down. In particular, columellar exine structure is unambiguously resolved as the ancestral state of Magnoliales whereas granular exine structure evolved later within the order, at least twice independently. Other characters, such as the shape of pollen grain in Myristicaceae, turn out to be too homoplastic to be given any phylogenetic significance. These results illustrate the crucial importance of studying pollen evolution in a broader phylogenetic context, using hypotheses derived from additional sources of data. This approach is critical to reconstruct the biogeographic history of Proteaceae (Proteales), with a specially rich pollen fossil record, whose assignment to modern taxa of the family needs complete revision to use the benefits of the cladistic approach and new data on phylogenetic relationships within Proteaceae.

8.4.4. Compound pollen formation in *Annona* and *Cymbopetalum* (Annonaceae)

C. Tsou, Y. Fu;
Institute of Plant and Microbial Biology, Taipei, Taiwan Republic of China.

Anthers of *Annona* are septate and polysporangiate, each sporangium contains a single microsporocyte. Meiotic tetrads build up a well-developed proexine proximally but only a thin pronexine distally while enclosed in the callosic envelop. During callose digestion, due to the tight conjugation between the distal pronexine and the envelop and, probably, the presence of celluloses in the envelop, the four microspores move out of the chamber in rotation but are bound to a central, undigested callosic-cellulosic mass. The mass then transforms into the binding core of the tetrad pollen. In *Cymbopetalum* each sporangium contains two microsporocytes; abundant cytoplasmic bridges exist between them and the two soon developed callosic envelopes. While each microspore tetrad undergoes microspore rotation and the formation of a binding core as in *Annona*, the two binding cores in each sporangium integrate into a central one to keep the eight microspores as one unit; the eight microspores soon distribute evenly and constitute a perfect octad.

8.4.5. The fossil history of Araceae pollen revisited

M. Hesse;
Department of Palynology, Institute of Botany, University of Vienna, Vienna, Austria.

Only few years ago the fossil pollen record of Araceae was extremely sparse, consisting of a single record dating from the Late Miocene (Spathiphyllum type). Recent findings of unequivocal Araceae pollen types have now changed the situation completely. Based on comparisons with extant taxa we found in various fossil assemblages distinctive Araceae pollen types with an elaborated sporopollenin ectexine. These types, namely a polyplicate-inaperturate type (similar to the Spathiphyllum type), a zona-aperturate-foveolate type (similar to the Monstera/Gonatopus type), and a spiny-ulcerate pollen (representing the Limnobiophyllum/Pandaniidites type) are usually not rare in their respective assemblages, and sometimes the samples consisted of practically 100% of such a pollen type. The fossil history of this extant monocot family now extends into the late Early Cretaceous. By the Latest Cretaceous to the Paleocene and Eocene these Araceae pollen types are widespread and provide clear evidence that several Araceae lineages have developed since the Mid Cretaceous and became diverse in the Paleogene.

8.4.6. Exploding pollen

M. Weber, H. Halbritter;
Institute of Botany, 1030 Vienna, Austria.

Montrichardia arborescens (Araceae) is distributed in tropical America and West Indies. It grows in tranquil freshwater habitats, forming dense stands along river margins. Pollen grains of Montrichardia are inaperturate with psilate ornamenation. The pollen wall is formed by a thin ektexine and an extraordinary thick intine. Contact with water leads to a rapid swelling of the intine followed by an explosive opening of the exine. Within few seconds a thick tube is formed, which is not the pollen tube. At the tip of the tube the pollen protoplast is situated. So far, the function of the intine tube is unknown. Apparently it is not involved in pollination. Gibernau et al. (2003) report beetle-pollination for Montrichardia. Lit.: Gibernau M, Barbé D, Labat D, Cerdan P, Dejean A (2003) Reproductive biology of Montrichardia arborescens (Araceae) in French Guiana. J Tropical Ecol 19: 103-107.

8.4.7. Comparative structure and development of the pollen and tapetum in Pandanales.

C. A. Furness, P. J. Rudall;
Royal Botanic Gardens, Kew, Richmond, United Kingdom.

The newly recircumscribed monocot order Pandanales now includes five families: Cyclanthaceae, Pandanaceae, Stemonaceae, Triuridaceae and Velloziaceae. We present new data and a review of pollen morphology, microsporogenesis and tapetal characters in Pandanales in a systematic context. Probable plesiomorphic character states include monosulcate apertures, perforate to reticulate sculpturing, a columellate exine with a foot layer, successive microsporogenesis, and a secretory tapetum. These correspond to generalised monocot or lilioid pollen and anther character states and all occur within Dioscoreales, the sister group to Pandanales. Within Pandanales, there are apparently homoplastic trends in each family towards either reduction in aperture size or covering the aperture with exine, resulting in a reduction in the delicate apertural area exposed to dessication and entry of pathogens. Apomorphic character states in Pandanales include ulcerate, inaperturate or operculate pollen, pollen surfaces with protruberances, exine reduced to a foot layer, granular exine, absence of endexine lamellae, and possibly an invasive tapetum.

8.5.1. Comparative genomics of angiosperm MADS Box genes

V. F. Irish;
Yale University, New Haven, CT, United States.

One of the central issues in evolutionary developmental biology is understanding the extent to which changes in developmental genetic pathways have resulted in new morphologies. We have focused on investigating the MADS box genes, which encode transcription factors controlling various aspects of floral development. We are examining the extent to which gene duplication, regulatory diversification and differences in protein function have been important in modifying the roles of MADS box genes during angiosperm evolution. As a first step, we have developed strategies to rapidly identify all MADS box genes from a given species in order to carry out comprehensive phylogenetic and functional analyses. Using these data, we have initiated analyses of the roles of tomato MADS box genes in flower development. In addition, we have developed methods to carry out functional analyses in non-model lower eudicot species. These approaches are paving the way for a greater understanding of how these genes have diversified to specify different aspects of floral architecture.

8.5.2. Genetic basis of shape differences in *Antirrhinum* species

N. B. Langlade[1], X. Feng[2], A. Hudson[2], E. Coen[1];
[1]John Innes Centre, Norwich, United Kingdom, [2]University of Edinburgh, Edinburgh, United Kingdom.

Our project aims to identify the genes responsible for organ size and shape differences between *Antirrhinum* (snapdragon) species. Genetic natural variation was dissected by crossing a large organ species (*A. majus*) with a small one (*A. charidemi*) and generating an F2 population and recombinant inbred lines (RILs). A molecular map has been constructed for these populations. Traits, such as organ area or length, are easily measured but shape is more difficult to describe numerically. We have therefore adapted statistical shape modelling methods to describe leaf and flower shapes. Each independent shape variation in our population is described by a Principal Component (PC). Thus, each flower or leaf shape is characterized by figures (corresponding to the deviations to the mean). This allowed us to identify QTLs responsible for these complex shape transformations (ie the PCs). Furthermore, marker-assisted selection of Near Isogenic Lines (87.5% *A. majus*) allowed us to accurately dissect and characterize the effects of QTLs generating inter-specific shape variation.

8.5.3. Developmental and molecular genetics of traits affecting mating system: Self pollination, floral symmetry and protandry

S. Kalisz;
The University of Pittsburgh, Pittsburgh, PA, United States.

The role of floral symmetry and the relative developmental flexiiblity of male and female phases within a flower are discussed in the context of plant mating system evolution. The genus, *Collinsia (Plantaginaceae)*, contains species that differ dramatically within an individual flower's lifespan in the timing of autonomous selfing. I present data on the variation within and among species in floral developmental traits in a phylogenetic context. Our data suggests that developmental flexibility in herkogamy and dichogamy has allowed species to move between more selfing and more outcrossing modes. These results challenge the idea of selfing as an evolutionary dead end and suggest a role for developmental lability in the evolution of plant mating systems. Second, we are conducting molecular genetic investigations into the role of floral symmetry genes in affecting protandry. Floral symmetry genes like CYCLOIDEA, first identified in snapdragon, *Antirrhinum majus*, are implicated in timing of anthesis. A general model for the role of CYCLOIDEA in mating system evolution will be presented.

8.5.4. 'Great and curious blunder in dame nature' (C. Darwin 1860): An evo-devo analysis of the origin and diversification of andromonoecy.

P. K. Diggle[1], J. S. Miller[2];
[1]University of Colorado, Boulder, CO, United States, [2]Amherst College, Amherst, MA, United States.

Andromonoecy is a sexual system in which plants produce both hermaphroditic and staminate flowers. Comparative analyses of hermaphroditic and andromonoecious species of the genus *Solanum* have provided insight into the developmental transitions associated with the origin and diversification of this sexual system. Andromonoecy in *Solanum* arose as a phenotypically plastic response to the resource demands of developing fruit. Due to existing developmental gradients within inflorescences, this plastic response was specific to ovary function of distal flowers. In the common ancestor of the andromonoecious taxa, the developmental innovation of pre-anthesis termination of gynoecial maturation in distal flowers resulted in the evolution of morphologically staminate flowers. This mechanism drew upon a gradient of developmental potential already present in the hermaphroditic ancestor. The production of morphologically staminate flowers was initially a plastic response to the presence of developing fruit. Subsequently, this same phenotype of staminate flower production in distal positions became a fixed aspect of the phenotype in more derived taxa.

8.5.5. Genetics of reproductive barriers in *Petunia*

J. Stuurman, M. Hoballah, J. Moore, C. Kuhlemeier;
Institute of Plant Sciences, University of Bern, Bern, Switzerland.

Petunia (Solanaceae) has two frequently syntopic species (*P. integrifolia* (*P.i.*) and *P. axillaris* (*P.a.*)) that do not naturally hybridise. Gene flow is hindered ecologically by floral pollination syndromes for bees (*P.i.*) or hawkmoths (*P.a.*) and genetically by unilateral or bilateral pollen-style incompatibilities.

Genome segments of bilaterally incompatible accessions of *P.i.* and *P.a.* were bred into a laboratory strain of *P. hybrida*. Phenotypic and QTL analyses revealed a complex genetic basis for most components of the pollination syndromes (morphology, nectar, fragrance), except petal colour which is under major gene control. In contrast, genetic barriers are under relatively simple control and can be broken by allelic exchanges at two or three loci expressed in pollen or style. From combined data in *Petunia* we propose that step-wise ecological differentiation for insect pollinators has reinforced a primary isolation event based on pollen-style incompatibilities. We seek further evidence by identifying molecular components of both gene flow barriers in nearly isogenic lines.

8.5.6. Evolutionary genetics of carpels: using California poppy (*Eschscholzia californica* Cham.) as a basal eudicot model system

A. Becker[1,2], D. R. Smyth[1];
[1]Monash University, Clayton, VIC, Australia, [2]Bremen University, Bremen, Germany.

The evolutionary origin of the enormous variety of carpel morphologies among flowering plants, and its molecular basis, are not clear. Carpel development genes are being defined in Arabidopsis, a higher eudicot. To test if these genes play a conserved role in carpel development, we have chosen to examine them in California poppy, a new model basal eudicot species that can be manipulated transgenically. Flower development in the poppy has been described in detail to allow interpretation of defects in poppy development following transgenic approaches. Also, poppy has been successfully transfected with Agrobacterium and transgenic calli have been obtained expressing the GFP gene. We have been able to identify homologs of the Arabidopsis carpel development genes AGAMOUS, CRABS CLAW, and SPATULA in the poppy. Comparison of the role of these genes in California poppy, Arabidopsis, and rice will help reveal core genes that underlie carpel development in all angiosperms.

8.6.1. Vascular plant cyanobacterial symbioses: ancient associations for ancient environments

B. A. Osborne;
University College Dublin, Dublin, Ireland.

The origin, evolution and past significance of vascular plant-cyanobacterial symbioses (*Gunnera,* cycads) remains an enigma. Most evidence suggests that they were a globally-significant component of many ecosystems in the past, possibly up to the Cretaceous period, but now show a much more restricted distribution. Based on the occurrence of fossil pollen and the current restriction of many species to wet or waterlogged environments I propose that the reason for their past success was because of their ability to fix nitrogen in anoxic/sulphidic environments where N availability was likely to be severely limited because of the reduced decomposition of organic material. Such environments were more common in the past due to significantly higher sea levels, with inland seas or seaways a common feature of many continental interiors, particularly in the Cretaceous. The subsequent decline of vascular plant cyanobacterial symbioses is associated with increasing aridity and reduced sea levels. Viewed in this way the cycads and *Gunnera* may represent relict ‘gymnosperm’ and angiosperm responses, respectively, to environmental conditions that are uncommon today.

8.6.2. Evolution of cyanobacterial symbioses

J. A. Raven[1], K. M. Usher[2];
[1]Plant Research Unit, University of Dundee at SCRI, Invergowrie, United Kingdom, [2]Microbiology, University of Western Australia, Crawley, Australia.

Cyanobacteria occur in symbiosis with a wide range of eukaryotic partners. The putative selective advantage for the eukaryote is added metabolic capacities: photosynthesis, sometimes with nitrogen fixation, for non-photosynthetic partners, and nitrogen fixation where the partner is photosynthetic in its own right or through another symbiosis. Evolution of symbiosis requires a recognition system, and the bypassing of any anti-biophage mechanisms. Continuation of the symbiosis involves either horizontal or vertical transmission of the cyanobiont. Horizontal transmission could involve problems with partners finding each other, but permits choice of partner genotypes appropriate to the local environment. Vertical transmission overcomes the problem of finding a partner, but restricts partner choice. Vertical transmission occurs via asexual or sexual propagules; in the latter case it is typically through eggs in oogamous organisms, but in at least one case it involves sperm. Plastids arose from vertically transmitted, obligately symbiotic cyanobionts, with transfer of many genes from the cyanobiont to the host nucleus, or gene loss from symbiosis.

8.6.3. Cycad genomics: a platform to study the rise of the seed plants and their symbionts.

E. D. Brenner[1], D. Stevenson[1], E. de le Torre[1], M. Katari[1], S. Rudd[2], S. Runko[1], R. Martienssen[3], D. McCombie[4], G. Coruzzi[5];
[1]New York Botanical Garden, Bronx, NY, United States, [2]Bioinformatics group, Turku Centre for Biotechnology, Finland, [3]Cold Spring Harbor Labs, Cold Spring Harbor, NY, United States, [4]Cold Spring Harbor Labs, Woodbury, NY, United States, [5]New York University, New York, NY, United States.

The cycads are the oldest extant seed plants, which exhibit characteristics intermediate in evolution between seed-less plants, vs. more derived plants such as angiosperms. Among the plesiomorphic characters found in cycads are dichotomous branching, circinate vernation, flagellated gametes and ovules borne on leaf-like sporphylls. Apomorphic characters found in cycads include the production of seeds, pollen and corraloid roots. Corraloid roots in cycads have nodule like structures that house nitrogen fixing bacteria and are the oldest living plants which form root nodules. In order to tap into the rich genetic history of cycads, we have created an end sequence tag (EST) database made from tissues of developing cycads. To date, we have sequenced nearly 10,000 ESTs for comparative genomic studies. Current analysis is ongoing to study these genes in the formation of reproductive and vegetative structures will help understand the evolution of such important characters such as ovules as well as the development of corraloid roots to begin to understand the intimate relationship between plants and nitrogen-fixing, symbiotic bacteria.

8.6.4. How evolved is the Azolla-Anabaena symbiotic system?

F. Carrapiço, A. L. Pereira;
Universidade de Lisboa, Faculdade de Ciências, Departamento de Biologia Vegetal, Centro de Biologia Ambiental, 1749-016 Lisboa, Portugal.

Azolla is a heterosporous aquatic fern with a fossil record dating back to the mid-Cretaceous. The leaves are overlapping, each with a floating and a submersed lobe. In the chlorophyllous dorsal lobe (floating) exists an ovoid cavity with a filamentous nitrogen-fixing cyanobacteria, usually referred to as Anabaena azollae, and several genera of bacteria. This leaf cavity behaves as both the physiological and dynamic interface unit of this symbiotic association where the main metabolic and energetic flows occur. In this sense, it can be considered as a natural microcosm.

Traditionally considered as a 'lower' vascular plant, Azolla exhibits symbiotic characteristics more evolved than the other vascular plant-cyanobacterial symbioses. This unique symbiosis is sustained throughout the fern's life cycle, where the cyanobacteria and bacteria are always present, in contrast to the more evolved vascular plant groups that associate with cyanobacteria. In this sense, we can consider this symbiotic association as a successful co-evolved system that also makes important contributions to the ecological, biofertilization and biotechnological fields.

8.6.5. New perspectives in plant-cyanobacterial symbioses: the putative roles of insect dispersal and diazotroph replacement

J. Rikkinen;
Department of Biological and Environmental Sciences, University of Helsinki, Helsinki, Finland.

Many aspects of the biology of plant-cyanobacterial symbioses remain virtually unstudied and two potentially rewarding examples will be discussed. Firstly, flying insects are frequently seen around *Gunnera* rhizomes and some of them may respond to visual and/or chemical signals produced by unusual stem glands. These insects could effectively transport compatible *Nostoc* symbionts from old, decomposing rhizomes, to young seedlings. Pollination biology abounds with analogous examples that improve evolutionary fitness through associations involving insect vectors. Secondly, only two monotypic liverworts, constituting a basal group among the hepatics, invariably associate with *Nostoc*. However, the slime papilla, that has an important functional role in *Nostoc*-liverwort symbioses, constitutes a common feature of all extant liverworts. It is possible that the slime papilla of many derived liverworts still functions in N-fixation, but now forms symbiotic associations with non-cyanobacterial diazotrophs.

8.7.1. Problems of transferring Tertiary plant record into potential vegetation maps

Z. Kvacek;
Charles University, Prague, Czech Republic.

Problems that hinder producing maps of potential Tertiary vegetation are in different palaeogeographic configuration of land & sea and relief that changed by orogeny, in variation in global climate, atmospheric circulation and the world ocean, and the extinct flora. To overcome these problems, palinspastic maps and well-determined and -dated spectra of leaf, fruit & seeds and spore & pollen records are relevant. Each plant organ is differently biased and expresses parts of vegetation. It is difficult to transfer the fossil spectra quantitatively into a community due to overproduction of fossil organs and taphonomic processes, although abundance of elements may indicate vegetation changes (NAP vs. AP). Contrary to previous models of vegetation units that were intuitively coined on a fossil plant assemblage, the newly developed system for the European Neogene stresses differences between zonal, azonal and extrazonal formations, impact of precipitation and uses objective definitions based on diversity percentages of components.

8.7.2. Climatic changes in the Miocene of Central Europe - the potential of using fossil angiosperm wood

J. Sakala;
Charles University, Prague, Czech Republic.

Fossil angiosperm wood is often neglected as a source of complementary information in palaeoclimate reconstruction. Nevertheless its potential to improve climatic data is great. Climate variables can be determined using the statistical model based on angiosperm wood characters without any systematic background. Insufficient number of wood types is however the weakest point of this type of palaeoenvironmental reconstruction method. On the other hand, the Nearest Living Relative (NLR) approach is very sensitive to the exact systematic attribution of the fossil wood and to the recognition of its closest living analogue. The difference between the two methods is demonstrated in the case of the Miocene wood floras of the Czech Republic and Germany focusing on the time interval of Early to early Middle Miocene. The results are also compared to the climatic data based on other palaeobotanical approaches.

8.7.3. Neogene ferns : often neglected but not forgotten

M. E. Collinson;
Royal Holloway University of London, Egham, Surrey, United Kingdom.

Many specialists on Neogene floras focus their studies on angiosperm fossils because these are very powerful tools for reconstructing vegetation and climate using both near living relative and physiognomic approaches. Both angiosperms and conifers figure strongly in Neogene plant community reconstructions. In contrast, ferns (and other spore bearing plants) are rarely studied in comparable detail and often do not appear in reconstructions. In this presentation examples of Neogene ferns will be reviewed. Examples will be chosen to demonstrate Neogene fern communities and fern associations and to consider to what extent ferns may contribute to palaeoclimate reconstruction. These examples will be drawn from both the macrofossil and palynological records. Attention will also be drawn to unresolved issues, such as the origin, and recognition in the fossil record, of epiphytic and climbing ferns.

8.7.4. The Late Miocene Karlovo Basin (Bulgaria, SE Europe): vegetation and climate reconstructions based on pollen analysis

D. A. Ivanov, E. Slavomirova;
Institute of Botany, Sofia, Bulgaria.

The sediments of Bulgarian Neogene basins contain important floristic information for understanding the evolution of the local and regional Neogene flora, vegetation patterns, palaeoecology, and palaeogeography of the Balkan Peninsula. The present report focuses on palynological studies of the freshwater deposits of Karlovo Graben situated in the Central Bulgaria, and provides data on Late Miocene-Pliocene vegetation and climate.

Based on floristic data the main plant communities were outlined. The dominant species in the zonal vegetation were floristic elements growing in temperate or warm-temperate climatic conditions, while thermophillous floristic elements are sporadically presented. The studied palaeoflora shows a stage in the long-term evolution of the Neogene flora on Balkan Peninsula, connected with the reduction of palaeotropical elements, dominance of arctotertiary taxa in the vegetation structure, and increasing distribution of grass vegetation.

8.7.5. Late Miocene to late pliocene floristic, vegetational and climatic changes in northern and central Italy as indicated by plant macrofossils

E. Martinetto;
Dipartimento di Scienze della Terra, Torino, Italy.

In northern and central Italy macrofossil assemblages (mainly carpofloras) have been recently detected and studied in some time intervals which were not covered by macrofloral documentation up to now. In addition, the stratigraphic context of several historical localities (Senigallia, Gabbro, Montajone, Upper Valdarno, Sarzanello, Mongardino, etc.), which provided large leaf collections, has been re-examined on the basis of recent geological work. Consequently, the analysis of macrofloral data now permits to provide a less fragmentary reconstruction of the floristic, vegetational and climatic changes in the late Miocene to Late Pliocene time interval. Long gaps in the documentation still exist in the Early Pliocene (from 5.3 to 4.0 Ma), in the early Middle Pliocene (3.5 to 3.1 Ma), and in the Late Pliocene of northern Italy (about 2.5 to 2.0 Ma). Most of these gaps are filled up by palynological data published by other authors. The good Late Miocene and Pliocene stratigraphic record in Italy will certainly permit detection of new assemblages in those time intervals which are still poorly known.

8.7.6. Climate and vegetation derived from a Pliocene-aged leaf flora from SE Shanxi Province, North China

Q. G. Sun[1,2], R. A. Spicer[3], Y. F. Wang[1], C. S. Li[1];
[1]Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences, Beijing, China, [2]State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, Xi'an, China, [3]Earth Sciences Department, The Open University, Milton Keynes, United Kingdom.

The Zhangcun Formation (36° 58' 01'' N, 112° 50' 55'' E), located at the boundary of Yushe and Wuxiang Counties in SE Shanxi Province, North China, was deposited in an intermontane lake basin. CLAMP (Climate Leaf Analysis Multivariate Program) was used to determine the palaeoclimate quantitatively and yielded an MAT (mean annual temperature) of 9.67°C± 1.17°C (2ů) a WMMT (warm month mean temperature) of 21.84°C±1.58°C and a CMMT (cold month mean temperature) of -1.47°C±1.88°C. CLAMP also suggested a RH (mean annual relative humidity) of 71.66% (±7.4). The precipitation during the growing season was estimated to have been 764.5mm ± 336mm. A moderately distinct wet and dry season was indicated with the precipitation during the wettest three months estimated as 476.7mm ± 140mm and the three driest months totaling 361.9mm ± 93mm. The climate of Zhangcun area during the Pliocene is similar to that of Yushe in SE Shanxi today.

8.7.7. The integrated plant record: the ultimate tool to reconstruct Neogene zonal vegetation in Europe

J. Kovar-Eder[1], H. Jechorek[2], Z. Kvacek[3], V. Paraschiv[4];
[1]State Museum of Natural History, Stuttgart, Germany, [2]State Museum of Natural History, Görlitz, Germany, [3]Charles University, Prague, Czech Republic, [4]University of Bucarest, Bucarest, Romania.

Palaeovegetation maps are presented based on the records of the leaf, fruit and pollen floras. During the interval 17-14 (-12.5) m.a., subtropical broad-leafed evergreen forests (BLEF) and partly subtropical subhumid xerophytic forests (SXF) were spread in more (south)-western parts of Europe, while (warm-)temperate broad-leafed deciduous (BLDF) and partly mixed mesophytic forests (MMF) prevailed from the Carpathians eastwards. BLEF had a wide N/S distribution. During 12-8 m.a. BLDF and MMF were widespread in Central Europe, reaching as far as Spain, while the distribution of BLEF shrank to climatically favourable regions. SXF are documented from the Balkan Peninsula, and landscape opening is indicated in southern parts of the Russian Plain. During the interval 7-4 m.a. MMF are widespread. BLEF were once again restricted to refuge areas. SXF extended largely beyond today´s 45° latitude. Xeric open woodland was developed from central Italy southwards; records of grassland are available from the Russian Plain.

8.8.1. Are plant chromosomes different?

D. Schweizer[1,2];
[1]Department of Chromosome Biology, University of Vienna, Austria, [2]Gregor Mendel-Institute, Vienna, Austria.

Comparative genome analyses at various levels provide detailed insight into the changes in chromosome structure, which have occurred during evolution. Here, we ask what it is about plant chromosomes that distinguishes them from animal chromosomes and hence makes them unique. To answer this question, we will compare various features of the genomes/chromosomes of higher plants and higher animals, including (1) the composition and prevalence of the repetitive fraction of DNA, (2) the structure and organisation of centromeres and telomeres, (3) the higher order chromatin structure, (4) the existence and extent of epigenetic imprints and (5) the structure and behaviour of mitotic and meiotic chromosomes. As specific examples, we will give a detailed description of the architecture of plant telomeres, outlining how this differs from their mammalian counterparts, and we will address the roles played by the proteins Mre11 and Est1 during the genome remodelling events of mitosis and meiosis. Finally, we will ask to what extent genomics can help us to understand plant genome dynamics such as polyploidy.

8.8.2. Differences in rDNA amplification during common bean (*Phaseolus vulgaris* L.) evolution and domestication

A. Pedrosa-Harand[1,2], C. C. S. Almeida[2], M. Mosiolek[1], M. Guerra[2], D. Schweizer[1,3];
[1]University of Vienna, Vienna, Austria, [2]Federal University of Pernambuco, Recife, Brazil, [3]Gregor Mendel Institute, Austrian Academy of Sciences, Vienna, Austria.

Common bean (2n=22) is the world’s most important grain legume for direct consumption, especially in Latin America and Africa. Although little is known regarding its genomic organization, the evolution and the domestication history of this species have been intensively studied. *P. vulgaris* originated in Ecuador/Peru and dispersed both northwards and southwards establishing the Mesoamerican and Andean gene pools. In each region, single or multiple domestication events took place. In five random cultivars analysed previously, a high degree of variation in the number and size of 45S rDNA loci was observed. In the present work, the 45S and 5S rRNA gene loci have been chromosomally assigned by fluorescent *in situ* hybridization in more than 25 wild and cultivated accessions from different gene pools and of different geographical origins. Three to four 45S rDNA loci were present both in wild and cultivated Mesoamerican genotypes. In contrast, in the Andean group, from three to seven loci were identified in wild genotypes, but cultivars had six to eight loci only. The correlation between genomic rDNA distribution and the evolution of the species will be discussed.

8.8.3. On the karyotype evolution of three grasses with an unusually low number of chromosomes

V. Kotseruba[1], K. Pistrick[2], D. Gernand[2], A. Meister[2], A. Ghukasyan[3], I. Gabrielyan[3], A. Houben[2];
[1]Komarov Botanical Institute of the Russian Academy of Sciences, St.-Petersburg, Russian Federation, [2]Institute of Plant Genetics and Crop Plant Research (IPK), Gatersleben, Germany, [3]National Botanical Institute of Armenia, Erevan, Armenia.

The low basic chromosome number of two of the genera Zingeria and Colpodium is unusual considering that the basic number of chromosomes of the Poaceae family is seven. Analyses of the karyotypes of Z. biebersteiniana (Claus) P.Smirn. (2n=4, 2C=3.5pg), Z. trichopoda (Boiss.) P.Smirn. (2n=8, 2C=5.3) and C. versicolor (Stev.) Schmalh. (2n=4, 2C=2.4pg) revealed next dynamic evolution of the genomes: (1) Only four of the eight chromosomes of Z. trichopoda are strongly labelled after GISH with genomic DNA of Z. biebersteiniana. Therefore, Z. trichopoda is of amphidiploid origin and evolved from a hybrid involving Z. biebersteiniana and another species with four chromosomes. (2) The 45S rDNA loci of the Z. biebersteiniana's subgenome of Z. trichopoda vanished after amphiploidisation. (3) Although the ITS1-5.8S-ITS2 sequences of C. versicolor and Z. trichopoda are highly similar, GISH of Z. trichopoda with labeled genomic DNA of C. versicolor did not result in a subgenome-specific labeling of Z. trichopoda chromosomes. Thus, the contemporary species C. versicolor is a closely related but not the direct ancestor of the allopolyploid species Z. trichopoda.

8.8.4. Karyotype evolution in *Nicotiana*

K. Y. Lim[1], A. Kovarik[2], M. W. Chase[3], J. Clarkson[3,1], S. Knapp[4], R. Matysaek[2], A. R. Leitch[1];
[1]Queen Mary University of London, London, United Kingdom, [2]Institute of Biophysics, Brno, Czech Republic, [3]Royal Botanic Gardens, Kew, United Kingdom, [4]Natural History Museum, London, United Kingdom.

The genus Nicotiana (Solanaceae) has 76 species in 13 sections and makes an excellent model system to study plant evolution and speciation. The base chromosome number is n =12, but the numbers can vary at both the diploid and tetraploid levels. The genus’ centre of diversity is S. America, most species occur in South/North America, and one large section, Suaveolentes, is found in Australia (and one species in Africa). The Australian distribution of Suaveolentes arose as a consequence of recent long-range dispersal. We have embarked on a systematic analysis of karyotype evolution in the genus by combining molecular phylogenies derived from multiple gene sequences and karyotype/chromosome analysis using FISH and molecular biology. We report patterns of chromosome divergence between diploid and polyploid sections and in sections of different ages. We show relationships between rates of speciation and of karyotype divergence.

8.8.5. Karyotype evolution in *Arabidopsis thaliana* and its close relatives as revealed by comparative chromosome painting

M. Lysak[1,2], R. Schmidt[3], A. Pecinka[1], **I. Schubert**[1];
[1]Institute of Plant Genetics and Crop Plant Research (IPK), Gatersleben, Germany, [2]Royal Botanical Gardens, Kew, United Kingdom, [3]Max-Planck-Institute of Molecular Plant Physiology, Golm, Germany.

The chromosome number of *A. thaliana* (2n=10) deviates from that of most other members of the genus and of related taxa with a presumed ancestral chromosome number of n=8. Little is known about evolutionary sequence of events that contributed to the chromosome number reduction in *A. thaliana.* We addressed this question by comparative multicolour painting of pachytene chromosomes from related taxa with n=5-8 chromosomes using pools of chromosome-specific BAC contigs arranged according to the comparative genetic map between *A. thaliana* and *Capsella rubella* (n=8). Homeologous chromosomes/chromosome regions of species with 6 to 8 chromosome pairs (*Hornungia alpina* n=6, *Turritis glabra* n=6, *Neslia paniculata* n=7 and *A. lyrata* n=8) were identified. Considering the homeology pattern of *C. rubella* and *A. lyrata* as the ancestral karyotype, we reconstruct the sequence of events along which the chromosome number was reduced from n=8 to 5 in the context of genome reshuffling and genome size decrease.

8.8.6. Evolutionary dynamics of telomeric sequences in *Othocallis* (Hyacinthaceae).

H. Weiss-Schneeweiss[1], K. Riha[2], D. Schweizer[2,1];
[1]Institute of Botany, University of Vienna, Vienna, Austria, [2]Gregor Mendel-Institute, Vienna, Austria.

Lack of *Arabidopsis*-type T_3AG_3 telomere sequences has recently been reported for the majority of investigated taxa of the monocot order Asparagales. Extensive cytogenetic and molecular analyses of chromosome termini of four *Othocallis* species (*O. amoena*, *ingridae*, *mischtschenkoana*, *siberica*) revealed that they are formed by long stretches of vertebrate-type $(T_2AG_3)_n$ repeats. Additionally, telomerase activity specifically synthesising vertebrate-type telomeric sequence was detected in *O. siberica*. *In situ* hybridization revealed also the presence of few additional interstitial, or terminally amplified telomeric signals in some chromosomes of *O. siberica* and *O. amoena*. These additional sites, often adjacent to or situated within heterochromatin, are highly polymorphic in *O. siberica*, and are apparently composed of large blocks of vertebrate- and *Arabidopsis*-type telomeric repeats. Thus, they may reflect a recent evolutionary switch from *Arabidopsis*- to vertebrate-type telomeric repeats in this plant group.

8.8.7. Genetically induced structural rearrangements of alien chromosomes in common wheat

T. R. Endo;
Laboratory of Plant Genetics, Graduate School of Agriculture, Kyoto University, Kyoto, Japan.

Chromosomes have been rearranged in evolution, spontaneously or by some driving forces, resulting in diverse karyotypes with different numbers and structures of chromosomes. A genetic system causing chromosome breaks has been found in wheat. When introduced into common wheat (*Triticum aestivum*, 2n=6x=42) from grass species (the genus *Aegilops*), certain *Aegilops* chromosomes called "gametocidal chromosomes" induce chromosome breaks in gametes lacking the gametocidal chromosome. They also cause breakage in alien chromosomes, such as rye and barley chromosomes, added to common wheat. Such chromosome breaks are sometimes non-lethal, and resultant deletions and translocations are stabilized in subsequent generations. In this paper the gametocidal chromosome and its action are briefly reviewed, and the evolutionary implications of the gametocidal chromosomes are discussed with some examples of chromosomal structural rearrangements induced by the gametocidal chromosome in rye and barley chromosome addition lines of common wheat.

8.9.1. Systematics and phylogeny of the Brassicaceae (Cruciferae): an overview

I. A. Al-Shehbaz;
Missouri Botanical Garden, St. Louis, MO, United States.

The presentation will cover various aspects of the family, including problems relating to classification, delimitation of taxa, and utilization of morphological and molecular characters in phylogenetic studies. It will also address problems of homoplasy, genome duplications, most challenging genera in evolutionary studies (e.g., *Boechera*, *Heliophila*), and character choice. The major monophyletic clades will be identified, and a new family-wide realignment will be proposed. A survey of the molecular coverage of the family will be presented, including numbers of species, genera, and markers in relation to geography. Numerous examples, covering the family worldwide, will be discussed, including problems relating to the basal clades (e.g., *Aethionema*). The final appeal is to conduct a phylogeny based on key "diploid" species, especially with small genome size, that represent major monophyletic clades in the family and conduct comprehensive, multi-locus comparative studies that involve several to many chloroplast, nuclear, and mitochondrial genes.

8.9.2. Molecules and migration: modern approaches to biogeography in cruciferous plants

M. Koch;
Heidelberg Insitute of Plant Sciences, Heidelberg, Germany.

This contribution summarizes major achievements in phylogeography among cruciferous plant species. The most prominent work is discussed and the attempt is to cover many major lineages of cruciferous plants (e.g from Arabis, Cardamine, Lepidium, Clusia, Capsella, Arabidopsis, Cardaminopsis, Rorippa, Dentostemon, Draba, Diplotaxis, Thlaspi, or Pennellia and others) as well as most geographic regions from world-wide temperate regions contributing to the enormous species diversity of this family. Several issues are addressed such as source areas of genetic diverstiy, refugial areas, vicariant patterns and colonization rotes. Some remarks will also focus on dating some of these processes and will summarize some divergence time estimates important for research among cruciferous plants. This talk is dedicated to the 65th. birthday of Herbert Hurka and is in honour of his contributions to our better understanding of evolution in the Brassicaceae.

8.9.3. Comparative genomics and karyotype evolution in *Brassicaceae*

M. A. Lysak;
Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

Since the sequencing of a small crucifer *Arabidopsis thaliana* was completed in 2000, Arabidopsis sequence data and resources have greatly expedited comparative genomics across plant families and particularly within *Brassicaceae*. The present contribution aims to give a short overview on the progress of comparative genomics in *Brassicaceae* five years after publishing the Arabidopsis sequence. The following aspects of genome evolution in *Brassicaceae* will be discussed: (i) the role of polyploidy and genome size variation, (ii) comparative genetic mapping and genome colinearity, (iii) comparative chromosome painting and reconstruction of karyotype evolution, and (iv) anchoring genomic data within robust phylogenetic trees. It will be shown that despite the steady progress, evolutionary genomics within *Brassicaceae* is still just an emerging field. Future perspectives of comparative studies on crucifers with particular emphasis on phylogenomics will be outlined.

8.9.4. Hybridization, reticulation and polyploidy in *Cardamine* and other Brassicaceae genera

K. Marhold[1,2], J. Lihová[1];
[1]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia, [2]Charles University, Department of Botany, Prague, Czech Republic.

Many examples of past or recent interspecific hybridization and polyploidization from the Brassicaceae demonstrate the evolutionary importance of these processes within the family. Several studies addressing the origin of polyploids or taxa of hybridogenous origin, their evolutionary and biogeographic history have been recently published. Hybridization and subsequent polyploidization have been often shown to be associated with Pleistocene climatic changes, and also examples are known where glaciations significantly shaped genetic variation patterns and current geographic distribution of several polyploids of pre-glacial origin. Reticulation and introgression complicate reconstruction of phylogenetic relationships within the genera, and strongly biased patterns might appear in some cases. Conflicting signals from chloroplast and nuclear markers, on the other hand, can reveal past hybrid or allopolyploid speciation. The present review is focused on the results from recent investigations in the genus *Cardamine* and other Brassicaceae genera, and illustrates the above-given evolutionary phenomena.

8.9.5. Using *Arabidopsis* to explore evolution within the Brassicaceae and beyond

J. L. Bowman;
UC Davis, Davis, CA, United States.

For approximately 20 years Arabidopsis has been a model system to investigate developmental and physiological questions in plant biology, leading to the identification of genes and genetic systems involved in many processes. I will discuss some progress in extending ideas arising from knowledge of developmental genetic systems in Arabidopsis to other species of the Brassicaceae and phylogenetically more distant taxa throughout land plants. Conservation and diversification of gene function extending from known functions in Arabidopsis is generally successful as compared to candidate gene approaches to novel morphologies, even in more closely related taxa. Specific examples will include the role of allopolyploidy in the evolution of floral ground plans in Lepidium, the role of CRABS CLAW in the evolution of nectary position in Brassicaceae and eudicots, and role of Class III HD-Zip genes in the evolution of meristems in land plants.

8.9.6. Evolution of flower development in Brassicaceae: a molecular genetics view

G. Theissen[1], P. Nutt[1], M. Hintz[1], K. Mummenhoff[2], B. Neuffer[2];
[1]Genetics Department, University of Jena, Germany, [2]Department of Systematic Botany, University of Osnabrück, Germany.

Flower and fruit development in Brassicaceae have much to offer for students interested in the relationship between the phylogeny of developmental control genes and the evolution of morphological and functional features. Traits currently under investigation range from the time to flowering affecting the plant habit via the structure of inflorescences and flowers and self-incompatibility mechanisms, to fruit shape and devices for seed dispersal. Besides being a cornucopia for studying microevolutionary events flower development in Brassicaceae may even provide model systems to investigate some especially enigmatic and controversial phenomena of macroevolution, such as saltational changes generating 'hopeful monsters'. We will provide instructive study examples for diverse evolutionary phenomena, with a focus on *Capsella bursa-pastoris*, one of the most successful weeds on a global scale, and the long-standing pet plant of Herbert Hurka.

8.9.7. Brassicaceae phylogenetics and the Hurka lab

F. Ehrendorfer;
Institute of Botany, Department of Systematic and Evoutionary Botany, Faculty of Life Sciences, University of Vienna, A-1030, Rennweg 14, Austria.

Major progress in evolutionary research of Brassicaceae is reviewed from the standpoint of comparative phylogenetics. Recurrent evolutionary syndromes in the family can be recognized and characterized by ± correlated organismic, phylogenetic and eco-geographical parameters. Examples demonstrate such syndromes as (1) outbreeding perennials with dysploidy and a strongly divergent anagenetic pattern; 2) outbreeding perennials with allopolyploidy and an expansive reticulate cladogenetic pattern; 3) partially apomictic perennials of hybrid origin with ± stabilized polyploidy (ortho- and anorthoploidy) + aneuploidy and an expansive mosaic cladogenetic pattern; 4) inbreeding annuals with di- and polyploidy, and an expansive ana- to cladogenetic pattern; 5) perennials with paleopolyploidy and a relic stasigenetic pattern. Considerable evidence for such a comparative approach is already available, and much of it is due to the excellent research efforts of Prof. H. Hurka and his former and present students and collaborators.

8.10.1. A comprehensive systematic appraisal of the Fagales with particular attention to the Juglandaceae

P. S. Manos;
Duke University, Durham, NC, United States.

An improved phylogenetic understanding of the order Fagales has been developed through various molecular data sets and recently described macrofossils. Advances have included data and methods drawn from the distinct fields of paleobotany, molecular systematics, and biogeography as applied to case studies in the families Betulaceae, Fagaceae, Juglandaceae and Nothofagaceae. A review of this progress will presented, highlighting long-standing questions. Collaborative research on Juglandaceae will be used to address the integration of fossils into potentially robust estimates of phylogeny based exclusively on living taxa. Specific goals are to (1) place fossils and compare multiple methods; (2) explore the impact of missing data (fragmentary taxa) on the topology; (3) simulate the effects of missing data using our molecular data sets; and (4) compare the impact of single and multiple fossil constraints in estimating the age of clades.

8.10.2. Paleobotany and former range of the Central American relict family Ticodendraceae (Fagales)

S. R. Manchester[1], **S. S. Renner**[2];
[1]Florida Museum of Natural History, Gainesville, FL, United States,
[2]Ludwig Maximilians University, Munich, Germany.

The extant Central American genus Ticodendron (Ticodendraceae) shares gynoecial and pollen characters with the Betulaceae but has foliage more closely resembling that of Fagaceae. Sequence data from multiple genes have placed Ticodendron sister to Betulaceae and both then sister to Casuarinaceae. The fossil record of Ticodendraceae has important implications for the divergence time of Betulaceae and Ticodendraceae, but fossils may have been unidentified, or misidentified, due to lack of modern comparative material (extant Ticodendron was not discovered and named until the 1980s). We report leaves from the middle and late Eocene of Oregon, and anatomically preserved fruits from the Eocene of Oregon (Clarno Formation) and Southern England (London Clay) that closely resemble Ticodendron. These European and North American Tertiary occurrences indicate that Ticodendron is a remnant of the Eocene boreotropical forest.

8.10.3. Fagalean woods--diagnostic characters and a critical review of the fossil record

E. A. Wheeler;
N.C. State University, Raleigh, NC, United States.

Wood anatomy of all families of Fagales is summarized and compared. Characters considered are vessel grouping and arrangement, vessel-ray parenchyma pits, imperforate element type, ray composition, and axial parenchyma distribution. Predominantly apotracheal parenchyma occurs in all families; septate fibers occur only in Nothofagaceae. The minute alternate intervessel pits of *Betula* differ from all other Fagales. Casuarinaceae, Fagaceae, Myricaceae, and Ticodendraceae share predominantly solitary vessels. Vessel-ray parenchyma pits with markedly reduced borders and of irregular shape occur in the Quercoideae. Fossil woods with characteristics of the Fagaceae (Quercoideae) occur in the Turnonian of the northern Hemisphere and are widespread in the Tertiary. Distinctive Betulaceae, Corylaceae, Juglandaceae, and Myricaceae woods occur in the Eocene. Nothofagaceae wood occurs in the Late Cretaceous and Early Tertiary of Antarctica.

8.10.4. Molecular systematics and biogeographical patterns in the birch family (Betulaceae): integrating fossils and molecules

F. Forest[1,2], S. R. Manchester[3], J. Wen[4], P. R. Crane[5];
[1]South African National Biodiversity Institute, Cape Town, South Africa, [2]University of Cape Town, Cape Town, South Africa, [3]Florida Museum of Natural History, Gainesville, FL, United States, [4]The Field Museum of Natural History, Chicago, IL, United States, [5]Royal Botanic Gardens, Kew, Richmond, United Kingdom.

The family Betulaceae comprises six extant genera (*Alnus*, *Betula*, *Corylus*, *Carpinus*, *Ostrya* and *Ostryopsis*) and about 150 species and is a dominant group in deciduous forests of the Northern Hemisphere. We review previous work on the systematics of Betulaceae and provide an overview of its fossil history. The well-documented fossils record of the family dates back to the Cretaceous and all extant genera, except the Asian endemic *Ostryopsis*, are represented in palaeoflora. In addition, many extinct genera attributed to the Betulaceae have been documented; some are even widely distributed such as *Palaeocarpinus*. We present a phylogenetic analysis of the family based on plastid (*trnL-F* region) and nuclear (ITS) sequence data. We reconstructed ancestral distributions onto the phylogenetic tree obtained with molecular data using dispersal-vicariance analysis (DIVA). The fossil record of the Betulaceae was used in combination with results from DIVA to infer patterns of dispersal, extinction and vicariance important in the phytogeographic diversification of this family in comparison with patterns inferred for other families of the Fagales.

8.10.5. Anatomically preserved fagalean fruits from the Eocene of western North America and their systematic implications

R. A. Stockey, R. A. Mindell, L. L. Elliott;
University of Alberta, Edmonton, AB, Canada.

Large numbers of fagalean fruits have been identified in calcareous nodules from the Eocene Appian Way locality of Vancouver Island. This study using anatomy and external morphology has revealed the presence of at least three types of Fagaceae fruits. These include triangular *Fagus*-like fruits with three locules and six ovules; small, two-loculed, cupulate, spiny fruits; and indehiscent, single-seeded, cupulate fruits with branched spines similar to *Castanopsis*. One of the two juglandaceous fruits is a dorsiventrally flattened nutlet with characters intermediate between subfamilies Engelhardioideae and Juglandoideae (Tribe Platycareae). Three dimensional reconstructions of these fruits using cellulose acetate peels and AMIRA 3.1 visualization software have allowed comparisons with fossil fruits from other well-known Tertiary localities and those of extant taxa. Internal anatomy and three-dimensional reconstruction make these among the best known fossil fagalean fruits, and their unique character combinations provide important phylogenetic information toward our understanding of the evolution of Fagales.

8.10.6. The fossil record and systematics of Fagaceae

Z. Zhou;
Kunming Institute of Botany, the Chinese Academy of Sciences, Kunming, China.

The Fagaceae family has a rich fossil records throughout the Tertiary of the Northern Hemisphere. A critical review of the fossil records provides a basis of understanding the evolutionary and biogeography of the beech family. Cupulate fruits and flowers of two extinct genera, *Protofagacea* and *Antiquacupula* from late Santonian stage of the, late Cretaceous of Georgia are the oldest unequivocal remains of Fagaceae. They are different in several significant characters and indicate that the divergence of at least two lineages of Fagaceae have been established by Late Cretaceous. It is obviously that an origin of Fagaceae no later than the Late Cretaceous. Fossil records and modern distributions of each genus of the family were discussed. The family achieved its greatest generic diversity in Eastern and Southeastern Asia and all modern genera had broader distributions in the Tertiary than today. The paleogeographical distribution of Fagaceae indicates that the family originated in the Northern Hemisphere.

8.10.7. Evolutionary history of the Casuarinaceae

R. Paull, R. S. Hill;
The University of Adelaide, Adelaide, Australia.

The Casuarinaceae are a morphologically distinct family with a long fossil record. Late Cretaceous pollen from Australia is indistinguishable from Betulaceae, the proposed sister taxon. The oldest Casuarinaceae macrofossils (Late Palaeocene, SE Australia) are assigned to the extant genus *Gymnostoma*, but fall outside its extant morphological range. *Gymnostoma* macrofossils also occur in South America and New Zealand (plus others with less certain affinities in the latter). *Gymnostoma* probably evolved in response to low soil nutrients, especially low P and N. Extant species occur on SW Pacific islands, New Guinea, New Caledonia, Malaysia and NE Australia. The oldest records (probably Oligocene) of two other genera, *Casuarina*, *Allocasuarina*, are from NE/SE Australia. Fossil and molecular data indicate they evolved tens of millions of years later than *Gymnostoma*, in response to low water availability and increasing aridity. Both genera are now widespread in Australia. *Casuarina* is also found in SE Asia and Pacific islands. The history of the fourth enigmatic genus *Ceuthostoma*, with two extant species in New Guinea and Indonesia, remains uncertain.

8.11.1. Apomixis in higher plants

Y. Savidan;
AGROPOLIS-IRD, Montpellier, France.

Apomixis is commonly defined as asexual reproduction through seeds. Seed embryos result from the parthenogenetic development of unreduced egg cells in the embryo sacs. While both the failure of meiotic reduction and the failure of fertilization are needed, additional factors seem to be required for a successful apomixis expression. Save rare exceptions, apomicts are polyploids, and we don’t really know why. Most of them exhibit a facultative apomixis, as part of their progeny is coming from a normal sexual development. Over 500 species have been reported to reproduce apomictically, in more than 40 different families, but high frequency of apomixis can only be found in three or four of these families. When apomixis and true sexuality are found together in the same species or agamic complex, Mendelian genetics usually suggests a single gene control, but molecular genetics shows that this control is located on a non recombinant segment of chromosome. While several molecular studies are underway aiming at transforming apomixis into a tool for breeding and crop propagation, too many questions that relate to the biology and expression of apomixis remain unanswered.

8.11.2. Perspectives on apomixis and taxonomy from Rosaceae subfamily Maloideae: better tools mean a less thorny problem

N. Talent[1,2], T. A. Dickinson[2,1];
[1]University of Toronto, Toronto, ON, Canada, [2]Royal Ontario Museum, Toronto, ON, Canada.

In spite of the handicap of long generation times, the knowledge base about certain genera of Rosaceae subfamily Maloideae (*Malus*, *Pyrus*) is considerable because of their great economic importance. The subfamily, as recently revised, is a natural group comprising several small genera and a few large ones (e.g. *Amelanchier*, *Cotoneaster*, *Crataegus*, and *Sorbus* sensu lato). While the former appear to be sexual diploids, the latter are taxonomically complex since they include both sexual diploids and apomictic polyploids. New tools that enable us to survey molecular and cytological variation are giving us a better understanding of them. In *Crataegus* we have been able to use flow cytometry to augment embryological studies with the ploidy levels of embryos and endosperm in mature seeds. This gives us a view of reproduction that is closer to its final outcome. We hope to shed light on the origins of polyploidy, the reproductive barriers, if any, between ploidy levels, and on the possibility of different solutions to the problem of endosperm balance with apomixis.

8.11.3. Unique reproductive system in dogroses (Rosa sect. Caninae) maintains successful and highly heterozygous genotypes

H. E. Nybom;
Balsgard-Dept Crop Science, Kristianstad, Sweden.

We have studied the mostly pentaploid (x = 7, 2n = 35) dogroses, *Rosa* section *Caninae*, where apomixis is only one of the means to maintain heterozygosity in homogeneous offspring. In four out of five investigated (micro)species, about 10 % completely maternal (according to RAPD and microsatellite DNA loci) offspring were encountered in interspecific crosses. The sexually derived offspring also resemble the seed parent more than the pollen parent. Due to the unique meiosis, three sets of 7 chromosomes occur as univalents and form 'passenger genomes' which are inherited only from the seed parent. The other 14 chromosomes form bivalents and constitute a diploid, highly homozygous genome, which takes part in recombination.Taxonomic distances are closely reflected by level of allele-sharing between univalent-forming chromosomes. Bivalent-forming chromosomes instead vary much more within species and less between. Segments of bivalent-forming chromosomes are likely to be exchanged within and even between taxa like in other outcrossing plant species groups. The univalent-forming chromosomes are instead passed on maternally, as in apomictic species.

8.11.4. Divergence and reticulation in the *Erigeron* sect. *Phalacroloma* apomictic complex.

R. D. Noyes;
University of Colorado, Boulder, CO, United States.

Reticulation has long been hypothesized to be important in the origin and diversification of apomictic complexes. *Erigeron* sect. *Phalacroloma* (Asteraceae) includes sexual diploid and apomictic triploid and tetraploid plants centered in the southeastern United States. This group traditionally comprises *E. annuus*, *E. strigosus*, and *E. tenuis*. Phylogenies for sexual diploids based on rDNA spacer sequences (ITS and ETS) reveal five distinct rDNA haplotypes that likely diversified from 650 to 925 mya. Sexual diploids that possess combinations of haplotypes, furthermore, are consistent with widespread reticulation at the sexual diploid level. Apomictic plants are diverse, exhibiting single or multiple rDNA haplotypes corresponding to those found in diploid plants, as well as novel haplotypes of unknown origin. Although the complex phylogenetic patterns are consistent with multiple origins of apomixis, they could also be explained by the widespread introgression of apomixis genes that have a single common origin. These alternative hypotheses are being tested in the group using comparative genetic mapping.

8.11.5. Evolution of polyploid agamic complexes using *Antennaria rosea* (Asteraceae) as a model group.

R. J. Bayer[1], G. T. Chandler[2];
[1]CSIRO, Plant Industry, Canberra, ACT, Australia, [2]University of North Carolina at Wilmington, Wilmington, NC, United States.

Antennaria (Asteraceae: Gnaphalieae) is useful as a tool for studying polyploid agamic complexes because both polyploidy and agamospermy are widespread in this genus. The diploids are morphologically well-defined and tend to be geographically restricted. The five polyploid complexes in the genus vary considerably with respect to ploidy levels, morphological variation and reproductive modes. The triploid/tetraploid gametophytic apomict, *Antennaria rosea*, is one of the most thoroughly examined complexes in the genus. The *Antennaria rosea* polyploid complex has a wider geographic range and possibly greater ecological amplitude than its diploid progenitors and is the result of multiple hybrid origins from as many as eight sexual diploid species. The diploids gave rise to *Antennaria rosea* through the processes of interspecific hybridization and backcrossing, and also through hybridization with facultatively sexual apomicts.

8.11.6. Evolutionary aspects in *Hieracium* subgenus *Pilosella*

J. Fehrer[1], B. Gemeinholzer[2], K. Krak[1,3], S. Bräutigam[4];
[1]Institute of Botany, PrŢhonice, Czech Republic, [2]Botanic Garden and Botanical Museum Berlin-Dahlem, Berlin, Germany, [3]Institute of Biology & Ecology, P.J. Šafárik University, Košice, Slovakia, [4]State Museum of Natural History, Görlitz, Germany.

The hawkweed subgenus Pilosella (Lactuceae, Asteraceae) is known for its notoriously complicated taxonomic structure due to ongoing reticulate evolution combined with a facultatively apomictic mode of reproduction. Recently, molecular approaches at clone, population and species level have begun to shed some light onto these processes. Geneflow across ploidy levels is common, and parental species of hybridogenous taxa often include apomicts, even as seed parents. Sexual taxa (diploid or polyploid) usually show high genetic variability. Apomicts vary from near clonality across large geographic distances to multiple origins on a small scale. Pilosella chloroplast haplotypes form two major groups whose separation predated most of the subgenus' speciation. Comparison of chloroplast and nuclear markers suggests two ancient hybridization events predating most of the speciation observed in the subtribe Hieraciinae: one between the Hieracium/Chionoracium subgenera ancestor and partly differentiated Pilosella, and a subsequent one between this introgressed Pilosella lineage and the closely related Andryala genus ancestor.

8.11.7. Identifying genes associated with apomixis in *Hieracium*

R. Bicknell[1], A. Koltunow[2], A. Catanach[1], S. Erasmuson[1], P. Fletcher[1], S. Johnson[2];
[1]Crop & Food Research, Christchurch, New Zealand, [2]CSIRO, Adelaide, Australia.

Hieracium is a daisy genus endemic to Eurasia and North America. The plants are small, easily cultivated and amenable to a wide range of experimental procedures. Seed formation within the genus *Hieracium* subgenus *Pilosella* occurs primarily by facultative apomixis, specifically by the mechanism of apospory (of the Hieracium type) coupled to autonomous endospermy. We study these plants as a model system for apomixis. The talk will present our understanding of the expression of genes within the *Hieracium* ovule during the initiation and progression of apomixis, the inheritance of apomixis determinants and the mapping of these regions. Particular emphasis will be given to our recent findings on the interactions occurring between the expression of sexuality and apomixis, and on inter-relationships between the components of apomixis in this system. The implications these data have for the possible engineering of this trait into target crops will also be discussed.

8.12.1. Nutrient limitation and stoichiometry of carnivorous plants: is it time to reassess the cost-benefit model for their evolution?

A. M. Ellison;
Harvard Forest, Petersham, MA, United States.

The cost-benefit model for the evolution of carnivorous plants posits a trade-off between photosynthetic costs associated with carnivorous structures and photosynthetic benefits accrued through additional nutrient acquisition. An implicit assumption of this model is that nitrogen is the primary limiting nutrient. A review of published data and results of on-going research show that phosphorus, potassium, or calcium often is the primary nutrient limiting carnivorous plant growth. Stoichiometric analysis further suggests that more than one of these nutrients may co-limit growth, depending on local and changeable environmental conditions. Further, variability in the production of carnivorous structures has been demonstrated in *Sarracenia, Utricularia, Drosera,* and *Pinguicula*, and this plasticity can be mediated either by the absolute or relative concentrations of limiting nutrients. These data are used to develop a model for the evolution of botanical carnivory that reflects stoichiometric relationships and evolutionary compromises in addition to trade-offs in nitrogen uptake and photosynthetic efficiency.

8.12.2. A Study on the pollination biology of selected Utricularia species (Lentibulariaceae) on Lateritic Plateaus in the Western Ghats, India

N. Hobbhahn[1], A. Watve[2], W. Barthlott[3], S. Porembski[1];
[1]Rostock University, Institute for Biodiversity Research, Rostock, Germany, [2]Agharkar Research Institute, Puna, India, [3]Bonn University, Nees-Institute, Bonn, Germany.

The pollination biology of carnivorous plants is, to a large extent, an unexplored field. An exemplary study on the pollination biology of three gregariously flowering terrestrial *Utricularia* species was conducted in the Indian Western Ghats. Flower visitors were observed and identified. In order to test for self-pollination exclosure experiments were conducted. In addition, data on anthesis, phenology, flower volatiles and nectar quantity and its sugar content were obtained. Nectar quantities were extremely small (< 1 µl), sugar content varied from 8% to 74 %. Self-pollination was excluded by spatial arrangement of reproductive organs, but can be mediated by visiting insects since all species are self-compatible.The flowers are visited by a broad spectrum of insects, several species of bees, butterflies, moths and hawk moths could be proven to be pollinators, though of different efficiency. This contradicted the morphology-based hypothesis of a highly specialized pollination syndrome.

8.12.3. Phylogeny, biogeography and character evolution in the carnivorous genus *Pinguicula* L. (Lentibulariaceae)

L. Legendre[1], K. Müller[2], T. Borsch[2], W. Barthlott[2];
[1]Laboratory of Plant Biology of aromatic and medicinal herbs - EA3061, Saint Etienne Cedex 2, France, [2]Nees-Institute for Biodiversity of Plants, Universität Bonn, Meckenheimer Allee 170, 53115 Bonn, Germany.

The Butterworts (*Pinguicula*) constitute one of the three genera of the carnivorous Lentibulariaceae, comprising approximately 80 species. Phylogeny inference using nucleotide sequences of the chloroplast gene *matK* and the *trnK* group II intron revealed six well supported major lineages within the genus. These lineages largely reflect radiations in clearly defined geographic regions (Mexican/Caribbean, Eurasian, East Asian, European, SE USA and the south American Andes, Mediterranean and NE Atlantic coast), whereas most previously recognized sections of the genus are para- or polyphyletic. A set of 32 morphological characters were defined and their evolution within the genus evaluated in the light of the phylogenetic data. It is suggested that the genus *Pinguicula* may have originated from an ancient paratropical vegetation belt and later migrated southward along the Andes. Major diversification events appear to relate to the growth habit with an adaptation to freezing (winter resting bud) or drier environments (succulent and non-carnivorous leaves).

8.12.4. Recent progress in understanding the evolution of Lentibulariaceae (Lamiales)

K. Müller[1], T. Borsch[1], L. Legendre[2], S. Porembski[3], W. Barthlott[1];
[1]Nees-Institut für Biodiversität der Pflanzen, Rheinische Friedrich-Wilhelms-Universität, Bonn, Germany, [2]Laboratory of Plant Biology of aromatic and medicinal herbs, Faculty of Science and Technology, University Jean Monnet, St. Etienne, France, [3]Institut für Biodiversitätsforschung, Allgemeine und Spezielle Botanik, Universität Rostock, Rostock, Germany.

Carnivorous plants have emerged as model systems for addressing many ecological and evolutionary questions, and since Lentibulariaceae comprise more than half of all known carnivorous species, they are of particular interest. Studies using various molecular markers have established that Lentibulariaceae and their three genera are monophyletic with Pinguicula being sister to a Genlisea-Utricularia-clade, while the closest relatives of the family remain uncertain. Character states of the carnivorous syndrome in related proto-carnivorous lamialean families apparently emerged independently. Genlisea and Utricularia exhibit substitutional rates that rank among the highest in angiosperms for the molecular markers analyzed. In Utricularia, the terrestrial habit has been reconstructed as plesiomorphic, and an extension of subgenus Polypompholyx is warranted. In the protozoan-attracting Genlisea, subgenus Tayloria is revealed as basal lineage. In Pinguicula, the six major lineages found reflect radiations in clearly defined geographic regions, whereas most previously recognized subgeneric taxa are non-monophyletic.

8.12.5. Adaptive evolution of cytochrome *c* oxidase: Infrastructure for a carnivorous plant radiation

R. W. Jobson[1], R. Nielsen[2], L. Laakkonen[3], M. Wikström[3], **V. A. Albert**[4];
[1]Department of Ecology and Evolutionary Biology, University of Michigan, Ann Arbor, MI, United States, [2]Center for Bioinformatics, University of Copenhagen, Universitetsparken 15, Bldg. 10, DK-2100, Copenhagen, Denmark, [3]Helsinki Bioenergetics Group, Programme for Structural Biology and Biophysics, Institute of Biotechnology, University of Helsinki, Biocenter 3, PB 65, FIN-00014, Helsinki, Finland, [4]The Natural History Museum and Botanical Garden, University of Oslo, P.O. Box 1172 Blindern, NO-0318, Oslo, Norway.

The highly conserved respiratory machinery of eukaryotic cells might seem an unlikely target for selection supporting novel morphologies. We demonstrate that a dramatic molecular evolutionary rate increase in subunit I of cytochrome *c* oxidase (COX) from an active-trapping lineage of carnivorous plants is caused by positive Darwinian selection. Bladderworts (*Utricularia*) trap plankton when water-immersed, negatively pressured suction bladders are triggered. The resetting of traps involves active ion transport, requiring considerable energy expenditure. As judged from the quaternary structure of bovine COX, the most profound adaptive substitutions are two contiguous cysteines absent in ~99.9% of databased COX I sequences. This motif lies directly at the docking point of COX I helix 3 and cytochrome *c*, and modeling of bovine COX I suggests the possibility of an unprecedented helix-terminating disulfide bridge that could alter COX/cytochrome *c* dissociation kinetics. Thus, the key adaptation in *Utricularia* likely lies in molecular energetic changes that buttressed the mechanisms responsible for the bladderworts' radical morphological evolution.

8.12.6. Genomes of Lentibulariaceae: some smaller than in *Arabidopsis thaliana*, and with chromosomes of bacterial size

J. Greilhuber[1], T. Borsch[2], K. Müller[2], A. Worberg[2], S. Porembski[3], W. Barthlott[2];
[1]Department of Botanical Systematics and Evolutionary Research, University of Vienna, Vienna, Austria, [2]Nees Institute for Biodiversity of Plants, University of Bonn, Bonn, Germany, [3]Institute for Biodiversity Research, University of Rostock, Rostock, Germany.

Angiosperms are currently estimated to vary about 800-fold in nuclear holoploid genome size (C-values), with the smallest established 1C-value of 155 Mbp recorded in A. thaliana. In Lentibulariaceae now three taxa were found ranging significantly lower: Genlisea aurea with 65 Mbp, G. margaretae with 67 Mbp, and Utricularia gibba with 88 Mbp. The smallest anaphase chromatids in G. aurea have 2.1 Mbp and are thus of bacterial size (NB: E. coli has ca 4 Mbp). Several Utricularia spp. range somewhat lower than A. thaliana or are similar. The highest 1C-value, in G. hispidula with 1506 Mbp, results in 23-fold variation for Genlisea and the Lentibulariaceae. Genome size variation in angiosperms is now more than 1900-fold. It is relevant for the understanding of genome miniaturization, that the Genlisea-Utricularia-clade exhibits among angiosperms in several genes the highest mutational rates, while this is not the case in Pinguicula, which varied in C-values only 1.4-fold from 487 to 693 Mbp.

8.12.7. Molecular phylogeny and structural evolution of carnivorous plant families within the Caryophyllidae s.l.

G. Heubl[1], G. Bringmann[2], H. Meimberg[1];
[1]Department Biology I, Section: Biodiversity Research, Systematic Botany, LMU, Munich, Germany, [2]Institute for Organic Chemistry, Julius Maximilians University, Würzburg, Germany.

Using comparative sequencing of the *mat*K gene, hypotheses of relationships between the carnivorous Droseraceae, Nepenthaceae and Dioncophyllaceae and ten other families of the Caryophyllidae s.l. were tested. Parsimony analyses gives evidence that the syndrome of carnivory has a monophyletic origin. Tree topology indicates Droseraceae in a most basal position and Nepenthaceae as sister to Ancistrocladaceae/Dioncophyllaceae. The exclusion of *Drosophyllum* from Droseraceae suggests no close relationship with this family. Concerning Dioncophyllaceae and Ancistrocladaceae, carnivory was lost in the evolutionary process, with the exception of *Triphyophyllum*. The close relationship of these taxa is also corroborated by several morphological and phytochemical characters. An evolutionary process of carnivory starting from adhesive glands via glands with digestive properties to special trapping devices is outlined.

8.13.1. Photoprotective energy dissipation and the bigger picture

B. Demmig-Adams, V. Ebbert, K. E. Mueh, W. W. Adams III;
University of Colorado, Boulder, CO, United States.

The process of photoprotective thermal energy dissipation will be placed in the context of the network of reactions serving in photoprotection and signaling. Several different types of thermal dissipation, including flexible and sustained processes, and their occurrence in different environments and different groups of plant species will be presented. The involvement of xanthophylls, trans-thylakoid pH gradient, and the PsbS protein as well as a possible role of other proteins will be discussed. Other proteins considered include (a) members of the PsbS-related subgroup of stress-induced proteins of the light-harvesting protein family and (b) proteins of the photosystem II core and their phosphorylation state. The association of sustained thermal dissipation in evergreen species with the photoinhibition of photosynthesis will be addressed, and the relationship between these processes and events at the level of the cell, leaf, and whole plant discussed. Parameters considered include leaf carbohydrate levels, leaf vein density, and whole plant source/sink balance.

8.13.2. Redox controls set the threshold for cell expansion, programmed cell death and systemic resistance to pathogens in *Arabidopsis thaliana*

C. H. Foyer;
Rothamsted Research, Harpenden, United Kingdom.

Programmed cell death (PCD), senescence and reactive oxygen species (ROS) are linked through complex genetic controls. Plants have optimized strategies for redox regulation, including mechanisms for controlling the generation of and a network of pathways of ROS detoxification. Vitamin C (L-ascorbic acid, AA) is the major redox buffer of the plant cell modulating physiological and stress responses in the cytoplasmic and apoplastic compartments. The *Arabidopsis* mutants deficient in AA (*vtc*) *vtc1* and *vtc2*, contain about 30% of wild type AA levels and exhibit micro lesions, expression of PR proteins and enhanced basal resistance against infections caused by *Pseudomonas syringae*. Evidence will be provided that cell death in the *vtc* mutants is not linked to senescence but rather to low redox buffering capacity. Low ascorbate limits cell expansion and triggers programmed cell death in a co-ordinated manner activating systemic enhanced resistance and enhancing basal resistance when cell growth has ceased.

8.13.3. Oxidative stress networks and nuclear control

B. J. Pogson;
The Australian National University, Canberra, ACT, Australia.

Limiting damage caused by oxidative and abiotic stress requires a complex set of physiological, biochemical and transcriptional responses. We are investigating components of the high light stress response and the extent to which drought and high light induce unique or common pathways. A combination of forward and reverse genetics in Arabidopsis and Chlamydomonas has identified mutants and genes that alter responses to a range of oxidative stresses. Ascorbate peroxidase 2 (APX2) is induced by excess light and catalyses the conversion of hydrogen peroxide to water. Thirteen *alx* (altered APX expression) mutations were identified by luciferase imaging. A gain-of-function mutation, *alx8,* has a five fold increase in APX2 expression under high light and is also extremely drought tolerant. With respect to loss-of-function, mutations and RNAi lines of high light-induced genes have one or more of the following: reduced APX2 expression, increased photobleaching, or reduced capacity to accumulate anthoycanins under stress. The suites of unique and common phenotypes demonstrate abiotic stress pathways are not simply linear pathways but are multifaceted networks.

8.13.4. Control of photosynthetic gene expression by the environment

S. Reinbothe[1], C. Reinbothe[2];
[1]Université Joseph Fourier et Centre National de la Recherche Scientifique, UMR 5575, Grenoble, France, [2]Lehrstuhl für Pflanzenphysiologie, Universität Bayreuth, Bayreuth, Germany.

No abstract received.

8.13.5. Plant peroxiredoxins in plant metabolism and stress tolerance

K. J. Dietz, I. Finkemeier, M. Laxa, P. Lamkemeyer, S. Jakob, M. Baier;
Faculty of Biology, Bielefeld, Germany.

Redox signalling and antioxidant defence are intricately involved in many aspects of plant metabolism particularly under stress such as salinity, heavy metals and excess light. The new group of peroxiredoxins (Prx) as thiol-based peroxidases play an important role in maintaining the redox homeostasis and possibly as redox sensors in signalling. Four examples illustrate indispensable Prx function in Arabidopsis thaliana. The mitochondrial Prx IIF is essential for normal root growth under stress. The cytosolic Prx IIC modifies plant response to salinity. The chloroplast 2-Cys Prx and Prx Q are related to photosynthesis and act as redox sensors modulating photosynthetic activities. Apparently, Prx have adopted diverse compartment-specific metabolic and signalling functions that cannot be substituted for by any other antioxidant present in the plant cell.

8.13.6. Plant phenylpropanoid metabolism in relation to oxidative stress

S. C. Grace;
University of Arkansas at Little Rock, Little Rock, AR, United States.

Phenylpropanoids and flavonoids play important structural roles in plants, as well as in defense against a variety of biotic and abiotic stresses. A wide range of environmental factors that predispose plants to oxidative stress, i.e., high light, UV radiation, low temperatures, ozone, and pathogens, have been shown to induce the synthesis phenolic metabolites with antioxidant properties. Until recently, phenolic compounds were not considered part of the antioxidant network of plants. However, biochemical studies of gene expression and physiological studies of plant stress responses suggest that certain phenolics may serve a primary role as antioxidants in plants. It is likely that phenolics act in concert with other protective molecules in plant cells, including enzymatic and non-enzymatic scavengers of reactive oxygen species, perhaps compensating for deficiencies of such molecules during periods of stress. A future challenge will be to elucidate mechanisms by which the antioxidant activity of phenolic compounds is coordinated in cellular environments and to identify how oxidative signals regulate the expression of phenylpropanoid defense genes.

8.13.7. Altered light acclimation in transgenic potato (*Solanum tuberosum* L. var. Desirée) plants with decreased leaf-ferredoxin (Fd) content

J. E. Backhausen, S. Holtgrefe, I. Voss, S. Jung, R. Scheibe;
Pflanzenphysiologie, Fachbereich Biologie/Chemie, Universität Osnabrück, Germany.

The effect of high light was analyzed in antisense potato plants with reduced leaf Fd contents. After a transfer of low-light acclimated plants into high light, the mutants developed an elevated PSII-redox pressure, but the stroma remained more oxidized. The amount of PSI proteins increased slightly, while the LHC-II level decreased. The chloroplast and nuclear-encoded thylakoid-protein levels changed in the same way in wildtype (WT) plants and in the mutants, indicating that chloroplast and nuclear gene expression are still coordinated. The major differences were an increased binding of Fd-NADP+ oxidoreductase to the Cyt b/f complex and a higher level of PSII phosphorylation. No indication for ROS formation was found. After pronounced high-light treatment, the total amount of thylakoids decreased, but their composition was still similar to WT plants. All changes were fully reversible within one week. The lack of Fd in the antisense plants induces a pronounced light acclimation, although the electron pressure only of intersystem carriers, but not of the stroma, was increased, and no ROS accumulated. A novel type of PSI modification may prevent ROS formation.

8.14.1. Interactions between global environmental change and biodiversity.

P. W. Leadley;
Université Paris-Sud XI, Orsay, France.

The purpose of this talk will be twofold: 1) to examine the effects of global environmental change on biodiversity and 2) suggest ways in which changes in biodiversity could alter the future trajectory of atmospheric and climatic change. Experiments, models and observations all suggest that global environmental change has and will continue to strongly modify biodiversity in terrestrial ecosystems. This has raised considerable concern about the conservation of species and ecosystems in a rapidly changing atmosphere and climate. I will provide an overview of current views on the effects of global environmental change on biodiversity and highlight key areas were our understanding is weak. It is now becoming increasingly clear that these changes in biodiversity - as well as those due to introduced species, land use change, etc. - will modify the functioning of ecosystems. I will review evidence that changes in biodiversity alter ecosystem functioning and response to perturbations, focusing on how biodiversity loss might alter plant productivity and ecosystem carbon storage responses to global change.

8.14.2. Global change and genetic erosion of dominant and keystone species

E. Huber-Sannwald, J. T. Arredondo Moreno, A. G. Alpuche Solis;
IPICYT, San Luis Potosi, S.L.P., Mexico.

Biological diversity at the landscape, community, species and genotype level has high priority in global change research as human induced changes in biodiversity may jeopardize the stability of ecosystems. A vast literature supports the notion that loss of plant species diversity negatively affects primary production. However, the relationship of genetic diversity and ecosystem function is poorly understood. Clear differences in tissue chemistry among genotypes from different grazing systems suggest that the genetic composition of populations may influence biogeochemical cycles. Hence, a decline in genetic diversity may adversely affect ecosystem processes especially in naturally species-poor communities such as semiarid grasslands in the Americas. With a cross-disciplinary approach spanning from molecular to ecosystem ecology we demonstrate that overgrazing may lead to genetic erosion of keystone species in grasslands with clear impacts on ecosystem processes. We discuss the emerging role of genotype diversity in the context of ecosystem function and for the maintenance of ecosystem services in a globally changing environment.

8.14.3. Invasive plant species, global change and biodiversity

R. J. Hobbs[1], H. A. Mooney[2], E. S. Zavaleta[3];
[1]Murdoch University, Murdoch, Australia, [2]Stanford University, Stanford, CA, United States, [3]University of California, Santa Cruz, CA, United States.

Invasive plant species are an important cause of biodiversity change at local, regional, and global scales today. A range of factors could inhibit or promote invasions at the introduction, establishment and spread stages in the next 100 years. Many trends contribute to the increase in introductions of potentially invasive alien species, particularly increases in global trade and the continuing introduction of plant species as new crop, pasture or horticulture varieties. The increased movement of organisms across former biogeographic barriers is matched with land use and global change trends that favor establishment and spread of newly introduced species. The future extent and impact of invasive alien species will depend on whether these exacerbating factors can be offset by effective new management practices and improved local and global institutional responses. Future biological diversity at all scales will depend on what paths we choose.

8.14.4. Impacts of anthropogenic nitrogen deposition on invasive and native species in southern California desert and shrublands

E. B. Allen, A. G. Sirulnik, R. J. Steers, L. Rao;
University of California, Riverside, Riverside, CA, United States.

Anthropogenic nitrogen deposition occurs at levels up to 30 kg ha-1yr-1 in the Mediterranean-type shrublands and Mojave Desert vegetation of southern California, mostly as dry deposition during summer. The native vegetation, which includes some 200 rare plant species, has been gradually declining during the last 40 years downwind of urban areas, with a concomitant increase in Mediterranean annual grasses (e.g., species of Schismus, Bromus) and forbs (Erodium, Brassica). To test the relationship between soil N and vegetation change, surveys were done along N deposition gradients in desert and shrubland. Extractable soil N (nitrate plus ammonium) ranged from 1 to 19 mg/kg in desert and 10 to 39 mg/kg in shrubland. Native plants declined from 92 to 34 species per site in shrubland, with a concomitant increase in exotic grass cover from 1 to 69%; diversity losses were similar in the desert gradient. The mechanisms of vegetation change include increased competition between nitrophilous exotic species and native species, and increased fire frequency of the productive N-fertilized grasses that prohibits future recruitment of native species.

8.14.5. Patterns of African plant diversity and the impact of future climate change - problems and perspectives

J. H. Sommer[1], W. Küper[1], J. Schnitzler[1], J. C. Lovett[2], W. Barthlott[1];
[1]Nees Institute for Biodiversity of Plants, University of Bonn, Bonn, Germany, [2]Centre for Ecology, Law and Policy, Environment Department, University of York, York, United Kingdom.

Where are the centers of plant diversity in sub-Saharan Africa and how will these patterns be affected by future climate change? We mapped large-scale diversity patterns of sub-Saharan Africa based on distribution data of more than 4500 plant species (c.10% of the flora). Bioclimatic range models were generated for each of the species to control for effects of disparate regional collection intensity. Further, species distributions were modeled under future climate scenarios. Centers of species richness are currently located in parts of the Guineo-Congolian rain forests, east African afromontane areas, and in Southern Africa. Many of these centers are already heavily threatened due to habitat conversion. Future climate scenarios, in addition, suggest a decline in climate suitability for many species in recent centers of diversity in lowlands, resulting in decreasing species richness. In contrast, afromontane centers of diversity are less affected. Sustainable conservation concepts should comprise landuse-induced and climate-change induced aspects of habitat conversion. Afromontane areas may be key areas in this context.

8.14.6. Spatial and temporal variation in the productivity-diversity relationship in Mediterranean plant communities

J. Kigel[1], I. Konsens[1], M. Sternberg[2];
[1]Hebrew University of Jerusalem, Rehovot, Israel, [2]Tel Aviv University, Tel Aviv, Israel.

Climate models predict changes in rainfall patterns of arid and semiarid regions in the Mediterranean basin that should lead to changes in primary productivity and diversity of their plant communities. Although rainfall is one of the main drivers of ecosystem functioning in these regions, there is yet no agreement as to how the productivity-diversity relationship is affected by rainfall. We propose that analysis of the variation in the relationships between rainfall, productivity and diversity occurring among years (temporal scale), across a steep geographic rainfall gradient (spatial scale) and after local rainfall manipulations should allow predictions about possible patterns of change in plant community structure and productivity due to climate change. Current results suggest that: a) the productivity-diversity relationship of the herbaceous plant community varied with rainfall regime across the gradient, but was less or not affected by inter-annual variation and rainfall manipulations, and b) variation in productivity was associated with changes in the frequency of species-functional traits in the community.

8.14.7. Coastal dynamics of the inland lakes in Central Asia

W. Wucherer, S. W. Breckle;
University of Bielefeld, Department of Ecology, Bielefeld, Germany.

The inland lakes of Central Asia - Aral Sea, Caspian Sea and Balkhash Sea - have experienced a drastic process of desiccation in the last century. The Aral Sea is in a critical process of drying out. The area of the dry sea floor, the Aralkum, is about 46, 000 km². From 1930 till 1977, the sea level of Caspian Sea declined by 3 m. The desiccated sea floor was about 50,000 km² in size and formed a new Caspian terrace. From 1973 till 1988, the sea level of Balkhash Sea declined by 2,5 m. Salt and sand deserts, salt meadows and mesophytic shrub vegetation have formed on the dry sea floors. The flora of the new coasts is an immigration flora in a stage of transformation, steady new developments and consist of about 400 species. Sedimentological and pedological factors determine vegetation and succession patterns. The typical pattern of landscapes, vegetation types and soils is striated. The actual trend in dry sea floor characteristics is the formation of the salt deserts and spreading of halophytic ecosystems, depending on the fluctuating water level. The coasts of the Aral Sea and Caspian Sea are large diversity centres of the halophyte flora and vegetation in Eurasia.

8.15.1. The 2010 challenge in ex situ conservation and threatened species recovery for botanic gardens and genetic resources communities.

P. S. Wyse Jackson[1], E. Dulloo[2];
[1]Botanic Gardens Conservation International, Richmond, Surrey, United Kingdom, [2]International Plant Genetic Resources Institute, Maccarese, Rome, Italy.

The adoption by the world community of Target 8 of the Convention on Biological Diversity's Global Strategy for Plant Conservation, to achieve "60% of threatened plant species in accessible *ex situ* collections, preferably in the country of origin, and 10% of them included in recovery and restoration programmes" by 2010, presents significant new challenges and opportunities for the botanic garden and plant genetic resources communities. It is currently estimated that the representation of threatened plant species in *ex situ* collections is no more than 20%, and perhaps only 2% in recovery and restoration initiatives. A rejuvenated and vigorous coordinated worldwide programme in *ex situ* conservation and species recovery will therefore be required to reach this target. The roles of botanic gardens and other *ex situ* conservation centres in the implementation of Target 8 will be outlined, highlighting specific milestones identified by an international working group of relevant stakeholders in 2004 for a proposed multi-year workplan towards 2010. Proposals for monitoring progress will also be outlined.

8.15.2. Targeting of threatened species for *ex situ* conservation

H. H. Kolberg;
National Botanical Research Institute, Windhoek, Namibia.

The concept of "threatened species", its various definitions, interpretations and approaches, is briefly introduced. Different terminology used and how this compares with the definition of "threatened species", is explored. Particular emphasis is placed on the IUCN system for red-listing of plants. The means to identify and subsequently prioritise and locate threatened species for seed collection for *ex situ* conservation are discussed from the perspective of a fieldworker in a developing country, Namibia. Sources of information and the difficulties in getting access to these, are mentioned. The challenges and rewards experienced in implementing such work are explained with examples. Opportunities and obstacles presented by Target 8 of the Global Strategy for Plant Conservation are briefly summarised against the background of the realities in developing countries.

8.15.3. Genetic integrity and risks in *Ex Situ* threatened plant collections:case studies in China

H. Huang;
Wuhan Botanical Garden/Wuhan Institute of Botany, The Chinese Academy of Sciences, Wuhan, China.

The ultimate goal of *ex situ* conservation for threatened plants is to maintain the genetic integrity of the species and to construct a self-sustaining population with evolutionary potential for reintroduction. However, many challenges remain unsolved for *ex situ* threatened collections in botanical gardens. Because *ex situ* conserved plants in botanical gardens are unavoidably small populations, genetic weakness must not be overlooked. Lack of research for genetic related issues to *ex situ* collections has greatly hampered success of implication of such *ex situ* conserved and artificially increased plant materials to reintroduction program in wild. This presentation provides a brief review of genetic issues related to *ex situ* threatened plants growing in garden environment, including loss of genetic diversity, inbreeding depression, hybridization and introgression and adverse effects from genetic adaptation to cultivation. These genetic effects should be rigorously addressed in well designed garden experiments for a wide range of threatened plants. Several case studies for *ex situ* threatened plants in Chinese botanical gardens are discussed.

8.15.4. The role of botanic garden horticulture in the global strategy for plant conservation, with particular relevance to target 8

D. A. H. Rae;
Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

The Global Strategy for Plant Conservation (GSPC) contains 16 targets for plant conservation to be met by 2010 and botanic garden horticulturists can contribute to at least 8 of these. Target 8 is of particular relevance as it calls for 60% of endangered species to be conserved *ex situ*, preferably in the country of origin, and for 10% of these to be used in recovery programmes. As a result of a survey carried out by the Royal Botanic Garden Edinburgh on behalf of PlantNetwork (the plant collections network of Britain and Ireland) it has been found that 67% of Britain's 204 red book-listed species are held as living plants in *ex situ* collections, but only a third of these are of UK origin. This project has now plotted the location of all the populations of each endangered species and has overlain this against the location of botanic gardens- the idea being to encourage botanic gardens to cultivate their locally endangered species. In this way, if each garden 'adopts' three or four species, sampled afresh from the wild, then the network of British botanic gardens will hold a devolved, networked, genetically structured collection of the country's endangered species.

8.15.5. Conservation of Chilean threatened species under the Millennium Seed Bank Project

P. León-Lobos[1,2], T. Ulian[3], M. Way[3];
[1]Instituto de Investigaciones Agropecuarias (INIA), Vicuña, Chile, [2]Centro de Estudios Avanzados en Zonas Aridas (CEAZA), La Serena, Chile, [3]Seed Conservation Department, Royal Botanic Gardens, Kew Wakehurst Place, United Kingdom.

The Millennium Seed Bank Project, led by the Royal Botanic Gardens Kew, is an international initiative aiming at conserving seeds from threatened plant species, principally from the drylands. Collaborative partnerships have been created worldwide and capacity for seed banking has been strengthened in-country through training, equipment and information. The Instituto de Investigaciones Agropecuarias in Chile has been working with Kew since 2002, developing a successful conservation programme centred on the endemic and threatened species from the Deserts and Mediterranean regions. Seeds from 211 endemic species including 83 threatened have been collected and conserved so far. However, the lack of updated red lists, scarce herbarium vouchers and botanical information, represent main obstacles for species targeting and conservation. Joint research will help meet recovery and restoration targets in the GSPC. Closer and more integrated collaborations between the different organizations and stakeholders involved in plant conservation would contribute to strength the national capacity for *ex situ* conservation.

8.15.6. *Ex situ* conservation - the role of plant tissue culture

M. M. Ramsay;
Royal Botanic Gardens, Kew, Richmond , Surrey, United Kingdom.

Cryopreservation of living material at or near the temperature of liquid nitrogen (-196°C) is among the best methods for securing conservation collections on a long term basis as the suspension of cellular metabolic activities extends the storage life of plant material and minimizes genetic drift. Plant tissue culture techniques are valuable for recalcitrant species whose seeds cannot be stored and for taxa that are difficult to propagate by conventional means or where there are dormancy requirements to overcome. Rapid multiplication under axenic conditions can result in large numbers of shoots from small quantities of initial material and can thus provide plants for re-establishment and scientific research without endangering existing populations. Challenges to effective utilization of *in vitro* techniques to meet GSPC targets include: quantifying what is stored, where and how; assessing effectiveness; identifying training and technology needs. The value and potential of these techniques in conserving threatened plant species will be described using examples from Kew and elsewhere.

8.15.7. Re-introduction of threatened species into the wild programmes

A. N. Hitchcock;
Kirstenbosch National Botanical Garden, Cape Town, South Africa.

Kirstenbosch National Botanical Garden's ex situ conservation program is not carried out in isolation, but is part of a strategy, which includes in situ conservation. Our focus is on conserving threatened taxa from threatened habitats close to Cape Town and on the intrinsic conservation value of each collection. Priority is given to the most threatened taxa and those that lend themselves for restoration projects. The prime goal is to preserve the genetic integrity of these collections by storing them in the Millennium Seed Bank in addition to holding live living collections in our Botanical Garden. Equally important is the restoration of these key conservation areas, many of which are degraded. Partnerships have been established with Conservation Organisations to secure these habitats from further degradation so that they remain viable for restoration projects. There are major challenges in establishing viable ex situ conservation collections in the Cape Floristic Kingdom. These include taxonomic and horticultural problems, fragmentation and loss of genetic reserves, limited resources and conflicting priorities within a burgeoning city environment.

8.16.1. Alpine flora and ethnobotany in Nepal: Resources vs conservation measures

K. Shrestha;
Central Department of Botany, Tribhuvan University, Kirtipur, Kathmandu, Nepal.

The high hills of Nepal, above 3000 m elevation, comprise 35.2 percent of the land area. Major part of its landscape is covered by high mountains and Himalayas. Approximately one third species of the flowering plants of Nepal are recorded from the sub-alpine to nival zone, of which 80% species are endemic to the Himalaya. About 64% endemic species of Nepal occur in this region. Similarly, 7.3% of the people living in this fragile habitat belong to indigenous ethnic groups of Tibetan or Mongoloid origin. Plant resources are the major source of basic commodities for the livelihood of the indigenous people residing in the remote areas. Overexploitation and hapahazard harvesting of plant resources for timber, firewood, and medicinal herbs, for trade and local uses lead to deforestation and vulnerable natural habitats. Threats to plant resources are alarming where natural regeneration of commercially threatened species is extremely poor. Integrated efforts of local, national and international organizations are commendable in the conservation, sustainable harvesting and domestication of few high demand traded species in some protected and buffer zone areas of Nepal.

8.16.2. Chinese and Russian medicinal plants and their folk use.

T. V. Dikareva;
Moscow State University, Geographical faculty, Moscow, Russian Federation.

Ever since the first contact with the Far East, the Western world has been irresistibly fascinated by the mysterious pharmacology of China, by its promise of health, longevity, increased sexual potency, fertility, and rejuvenation. On the other hand, Western medical science continues to discover important constituents in botanicals employed in so-called "folk" medicines of various countries. As far as the folk medicine of China is concerned, the difficult and ambiguous language barrier has kelp this area from being extensively studied. Many contacts in the Far East culture between Russia and China appeared to reveal a lot of similarities in pharmacology and use of various plants. We compared the medicinal plants of Russian and Chinese Far East and found many similarities as well as differences in their usage. For example, while in Russia and China *Tussilago farfara* is used as antitussive, *Inula britannica* in China is used as expectorant and stomachic, while in Russia it is mostly used for curing of skin diseases. We analyzed the use of more than 200 herbs. It is obvious that further contacts will promote to enrichment of both Russian and Chinese pharmacology.

8.16.3. Medicinal plants of Hezar Masjed Mountain chain

S. C. Hojjat[1], G. Normohamadi[2];
[1]Research Center for Plant Science, Mashhad, Islamic Republic of Iran, [2]Azad University of Tehran, Tehran, Islamic Republic of Iran.

Hezar Masjed, one of the two main mountain chains parallel to the direction of (Northwestern -Eastwestern) the north of Khorasan, consists of several single mountains.These sediments consist of lime, bug lime,Chile, marl, and occasionally, conglomerate and evaporative sands which each, based on the rate of hardness and other existing conditions, forms various soils. On the other hand, different height, temperature, the rain and dispersion rate, have created several ecology so that at the margin of piedmont mountain of Hezar Masjed, there is an ecology with ultra cold semiarid, at the submountain it is Mediterranean ultra cold, altitudes are with subhumid climate and at the top of mountain there is ultra cold humid climate. Generally it creates a considerable diversity in the plant cover. The medicinal plants of this area have been collected during the past years, by me and my cooperators and after detection have been stored in the herbarium of botanical research center of Ferdowsi University.

8.16.4. Native plants from the arid zones of Mexico with medicinal and pesticide potential

H. Lira[1], M. Hernández[1], R. Gamboa[1], L. Angeles[1], J. Santiago[1], G. Lopez[1], L. Villarreal[1], D. Hernandez[2];
[1]CIQA, Saltillo, Mexico, [2]UAAAN, Saltillo, Mexico.

Plant extracts particularly medicinal plants, are becoming increasingly important in pharmacy and have great popularity as alternative therapy. The use of synthetic pesticides creates several problems like pests resistance, resurgence, and detrimental effect on non-target organisms. Therefore, the aim of this study was to evaluate the effect of 4 plants extracts (*Larrea tridentata*, *Flourensia cernua*, *Origanum majorana* and *Bouvardia ternifolia*) from the Mexican desert on 12 phytopatogenic fungi. Also, 7 bacteria were tested for antibacterial activity, these include 5 gram-negative and 2 gram-positive bacteria. Fungi cultures were grown in potato dextrose agar (PDA) into Petri plates (Pp). Pp were incubated at 25°C. Mycelia growth was monitored by measuring the plates area covered by the fungi. Antibacterial activity of plants extracts was assayed by mixing them with Muller Hinton agar (MHA). Bacteria cultures were incubated at 36°C into 3-divided Pp. Each test was replicated at least 2 times. The four extracts analyzed showed antimicrobial activity against all organisms studied, but the *L. tridentata* extract was more active against all microorganisms.

8.16.5. Ethnobotanical studies in Ethiopia: the case of medicinal plants

W. Teshome B.;
Institute for Anthropology, Vienna, Austria.

In this paper, I attempt to provide a picture of the past and current ethnobotanical studies in Ethiopia by using studies on medicinal plants as a case study. Until recently, the gathering of medicinal plants in Ethiopia was the responsibility of traditional medical practitioners. In the gathering process, spiritual, ritual, taboos, seasonal and social restrictions get high considerations. According to a recent study, Ethiopia is one the six countries of the world where about 60% of its plants are indigenous and have a healing potential. It is believed that about 1000 types of medicinal plants are found in Ethiopia. The objectives of this paper are to identify the causes for the depletion of wild populations of medicinal plants in Ethiopia, and to explore ways for the effective conservation of all medicinal plants species in the country. It is found out that at present, the existence of medicinal plants is threatened due to the expansion of agriculture, over exploitation, deforestation, destructive harvesting and habitat alteration. The paper suggests that cultivation could be used as an alternative to over exploitation of traditional medicinal plants by gatherers.

8.16.6. Innovation and tradition in Mediterranean diet: gathered food plants

D. N. Rivera[1], C. D. Obón[2];
[1]Universidad de Murcia, Murcia, Spain, [2]Universidad Miguel Hernández, Orihuela (Alicante), Spain.

Wild plants and weeds have been a substantial part of the diet in rural Mediterranean areas during centuries. Although it has been assumed that these types of gathered local food are the remnants of the hunter-gatherers cultures anteceding the Neolithic revolution, the ethnobotanical research brings evidence of adaptive changes in the lists of plants consumed. Recent replacements in the Mediterranean points to a resilient mechanism that allowed Mediterranean people to introduce in their diets new cultivated taxa but also weeds and invasive species. These replacements supposed changes, amongst others, in the ingest of secondary metabolites and fatty acids in the Mediterranean diet. The tender perennial ornamental *Gazania rigens* (L.) Gaertn., native from South Africa is naturalized in Mediterranean Spain. In the lower Segura basin it is now part of the gathered food plants species complex, locally known as “rampetes”. The character in common to this group is the basal whorl of pinnate leaves that are collected and consumed in salads after a short boiling. Examples of “rampetes” are *Plantago coronopus* L., *Coronopus didymus* (L.) Sm. (native from South America).

8.16.7. Local food in the Mediterranean and its antioxidant effects

M. Heinrich, S. Nebel;
School of Pharacy, London, United Kingdom.

Very little is known about the current role of local used food plants in the Mediterranean (‘local food’). An EU-funded consortium of six academic institutions and one company (coordinated by M.H.) investigated the role of such resources in the local diets of selected regions in of the Mediterranean. For example, in the Graecanic community Gallicianò (Southern Italy) about 40 wild food taxa have been identified, for example *Reichardia picroides* (used raw as a snack or cooked with other wild greens). As part of this project the broader public a booklet for usage in the region of origin has been developed. A total of 120 food species have been investigated for anti-oxidant activity using a variety of *in vitro* assays (incl. guaiacol oxidation, xanthine oxidase inhibition, HOCl scavenging, eNOS activity), and against a variety of other targets. An example is *Cynara cardunculus ssp. cardunculus* which shows one of the highest anti-oxidants effects in the guaiacol assay (about 95% at 0.2µg/ml).
Acknoweldgements: The Consortium 'Local Food-Nutraceuticals', EU ('Food, Nutrition and Health' - FP5 - QLRT-2001-00173; 2002 - 2004).

8.17.1. The first Eastern Central European herbals and early botanical monographs on CD-ROM and Internet

A. T. Szabo[1], I. Szabo[2], Z. Biro[3];
[1]Institute of Biology, Veszprém, Hungary, [2]University of Veszprém, Georgikon Faculty of Agriculture, Keszthely, Hungary, [3]GrammaSoft Bt., Szombathely, Hungary.

Case studies are presented, based on E-ditions of first Eastern Central European botanical monographs, (mostly herbals): Váradi Lencsés György (1530-1593) - *Ars Medica Electronica* vol. I-VI (Budapest-Kolozsvár-Szombathely-Veszprém; 2000); Melius P. - *Herbarium about the names, nature and use of plants* (1578, Colosvar); C. Clusius - *Rariorum aliquot stirpium per Pannoniam, Austriam etc⁎ ,* (1583, Antwerpen); Beythe A. - *Fíves Könüv (a Hungarian Herbal,* Nemetujwar 1595) . The influence of different pharmacobotanical schools form, Sárvár (HU), Güssing/Németújvár (AU), and Kolozsvár/Cluj (RO) and the role of I. Sylvester, P. Melius, G. Lencsés, St. and A. Beythe - and first of all - by C. Clusius in developpment of botany is analysed using the new databases, including the role of Clusius in the study of Central European plant diversity and the advance of pre-Linnaean botany. An EU-7 project for botanists working in “Clusius-cities” from Austria, Belgium, England, France, Germany, Hungary, Italy, Poland, Spain and The Netherlands is outlined for education and research, to reveal hidden values of European botany by electronic methods.

8.17.2. Toward an Eastern Central European „Electronic ethnobotanical database”

L. G. Szabo[1], **I. L. Szabo**[2], T. Grynaeus[3], E. Nyeki[2];
[1]Faculty of Sciences, Pecs University, Hungary, [2]Georgikon Faculty, Keszthely, Hungary, [3]no, Budapest, Hungary.

The first records about the knowledge of plants are as old as the first written relics. The diversion of vernacular and official use of plant names began in the 16th century. A lot of new plant names given by neologists of the 19th century has been drawn from traditional country use of words. The upcoming industrialisation, the extension of cultivated landscape and the changing structure of settlements caused irreversible alteration and detriment of the nature and the relation of humans to the nature were also basically changed by the new disciplines The recent flow of population ageing process and globalization caused elementary social and economical changes of way of life. The maintenace of traditional plant varieties and land-races came to be at the end by disappearing of country life. The process described above has been demonstrated by the results of a great number of local and regional ethnobotanical studies. It is necessary to build detailed databases for the versatile landscape structure of Eastern Central Europe adjoining to world ethno- and econom-botanical databases.

8.17.3. Information literacy and botany

R. A. Cowan;
Library / School of Biological Sciences & Biotechnology, Murdoch, WA, Australia.

We have all heard of the information explosion and the anxiety that can accompany this phenomenon. Today students at university are expected to be computer literate. They may not be information literate. The lecturers and research supervisors may not be information literate. A manual aimed at the undergraduate biology level has been written as an information literacy tool. We need to equip new botanists with the skills to be able to *identify*, *access* and *locate* information as well as *evaluate* and *apply* information. The principles of developing a search strategy, understanding the different types of reference materials and subject materials, and being able to find information in catalogues or databases, are discussed in the manual. What changes have occurred in the information literacy level since this manual has been in use? Should information literacy be a core part of an undergraduate curriculum?

8.17.4. The study of genotype, cold pretreatment, low-dose gamma irradiation and 2,4-D concentration effect on wheat doubled haploid production

B. Naserian, C. Vedadi, S. Karbalaii;
Nuclear Research Center for Agriculture and Medicine, Karaj, Islamic Republic of Iran.

In this study, response of a cultivar (Atrak) and two lines (F3 2005 and F3 2104) of wheat , and effect of cold pretreatment, low dose gamma irradiation and 2,4-D (2,4 mgl^{-1}) were investigated to anther culture response. Donar plants were grown under field conditions in early spring. Anthers were plated on modified CHB medium containing 2, 4-D (2, 4 mgl^{-1}), 0.5mgl^{-1} Kinetin and 90 gl^{-1} Sucrose. Persent of Callus formation in 100 anther and persent of plantelt in 100 calli were measured. Results indicated that genotype, cold pretreatment and 2,4-D concentrations had significant effect on anther culture response. F3 2005 showed highest callus induction and plantlet production and F_3 2104 had lowest response. This experiment indicated that androgenic traits are controlled by genotype and environmental factors. Further more these traits are controlled indepently.

9.1.1. Plants have effective non-host resistance against the great majority of pathogens

H. Thordal-Christensen;
Dept. of Agricultural Sciences, The Royal Veterinary and Agricultural University, Frederiksberg C, Denmark.

All individuals of a plant species resist attack by most pathogens due to their “non-host resistance”. Only a limited number of microbes are able to overcome this resistance, and can be seen as pathogens of the species. In this way non-host resistance is extremely broad-range and durable. On the other hand, host resistance, where only a subset of plant of a species exhibits resistance towards a pathogen, is often narrow in range and vulnerable for breakdown. Therefore non-host resistance is predicted to have a potential in plant disease control, provided we understand the mechanisms behind. It is conceivable that understanding non-host resistance will go hand-in-hand with understanding host resistance and the process of pathogen attack. As such it becomes clear that non-host resistance can be the combined action of a number of defence components functioning along the steps of pathogen ingress towards establishing disease. This is also true for host resistance, and it has been documented that several of these defence components are shared between the two types of resistance. But still it is unknown what in fact determines the difference between them.

9.1.2. RLKS and innate immunity in plants

T. Boller;
Botanisches Institut der Universität Basel, Basel, Switzerland.

Recent studies highlight the importance of "pathogen-associated molecular patterns (PAMPs)" or "general elicitors" in basal disease resistance. One prominent PAMP is bacterial flagellin. FLS2, the receptor-like protein kinase (RLK) encoded by *FLS2* in *Arabidopsis thaliana*, functions as the receptor for flagellin. Homozygous *fls2* mutants are completely insensitive to flagellin. They are also more susceptible to *Pseudomonas syringae* DC3000 than wildtype plants, demonstrating the functional importance of this PAMP receptor in disease resistance. Another PAMP recognized by *A. thaliana is* EF-Tu, one of the most abundant proteins present in bacteria. A mutant in the *EFR* gene, which encodes an RLK as well, lacks both EF-Tu responses and binding sites for EF-Tu derived elicitors, indicating that EFR represents the functional EF-Tu receptor. A comparison of the responses of *Arabidopsis* to flagellin and EF-Tu will provide insights into the similarities and differences among the PAMP perception systems in plants.

9.1.3. Mechanisms of induced resistance against pathogens and insect attack

L. C. Van Loon, P. A. H. Bakker, J. Ton, C. M. J. Pieterse;
Utrecht University, Utrecht, The Netherlands.

After limited attack by pathogens or herbivorous insects, plants develop an enhanced capacity to defend themselves against subsequent attacks, which often occurs throughout the entire plant. Several types of systemically induced resistance have been recognized: pathogen-induced systemic acquired resistance (SAR), rhizobacteria-induced systemic resistance (ISR), and wound-induced resistance (WIR). Whereas SAR is regulated by salicylic acid, ISR and WIR are dependent on jasmonic acid; all three types also require responsiveness to ethylene. Activation of more than one type of induced resistance causes cross-talk between the different signalling pathways, allowing the plant to prioritize its defensive mechanisms. Associated with SAR and WIR additional defenses are induced, but ISR depends entirely on an enhancement of extant mechanisms to counter the invader. This “priming” phenomenon relies on the activation of either pre-existing or newly induced transcriptional regulators.

9.1.4. Conservation of disease resistance systems in two plant families

L. E. Ong, T. Ashfield, R. W. Innes;
Indiana University, Department of Biology, USA, Bloomington, IN, United States.

Arabidopsis Rpm1 and soybean Rpg1b are resistance genes that mediate recognition of the AvrB protein from the plant pathogen *Pseudomonas syringae*, thereby establishing defense responses and resulting in disease resistance for the host plant. Recognition also requires the Rin4 protein in *Arabidopsis*, which interacts with both Rpm1 and AvrB and is required for Rpm1-mediated disease resistance. Recent cloning of Rpg1b has allowed phylogenetic comparison of these two functionally analogous resistance genes, which appear to have evolved independently. We aim to discover the molecular level of conservation between these two disease resistance systems from different plant families. We transformed *rpm1* mutants with Rpg1b, assayed for AvrB recognition, and recovered plants that showed resistance against *P. syringae* strains carrying AvrB. However, plants that respond to AvrB also exhibit dwarfing phenotypes. We have also identified three Rin4 homologs in soybean, and are currently assaying for their physical interaction with AvrB and their ability to functionally replace *Arabidopsis* Rin4.

9.1.5. An *Arabidopsis* glutaredoxin interacts with central components the signal transduction pathway responding to salicylic acid

I. Ndamukong, A. Al Abdallat, **C. Gatz**;
Albrecht von Haller Institute for Plant Sciences, Göttingen, Germany.

Salicylic acid (SA) and jasmonic acid are crucial internal signaling molecules needed for the induction of defense responses upon attack of pathogens. Basic leucine zipper (bZIP) transcription factors of the TGA family bind to activating sequence-1 (as-1)- like elements found in promoters of SA- and JA-inducible genes. Using a modified yeast-two-hybrid screen using AtTGA2 as a bait we have isolated a glutaredoxin (GRX28480) which is able to form a ternary complex with TGA factors and NPR1, a redox-regulated protein essential for SA-inducible gene expression. Expression of GRX28480 is induced by SA and infection with virulent and avirulent bacteria. Lines overexpressing GRX28480 exhibit reduced expression of the truncated CaMV 35S promoter, which contains an as-1 element as the only regulatory sequence. As jasmonic acid responsive genes can be repressed by SA in an NPR1-dependent manner, we are currently investigating whether GRX28480 is involved in this response.

9.1.6. Early effects of *Pseudomonas syringae* infection on primary metabolism and defence response of *Arabidopsis thaliana*

K. Bonfig, U. Schreiber, S. Berger, T. Roitsch;
Universität Würzburg, Würzburg, Germany.

To elucidate the effect of pathogen infection on primary metabolism and defence responses, Arabidpsis thaliana plants have been challenged by the bacterial pathogen Pseudomonas syringae pv. Tomato. Infection by a virulent and an avirulent strain of P. syringae resulted in a differential and complex regulation of defence gene expression and photosynthesis. The non-invasive technique of cholorophyll fluorescence imaging revealed specific spatial and temporal effects on photosynthetic activity around the infection sites. Impairment of the photosynthetic apparatus after pathogen infection was limited to the infected tissue and could be detected prior the development of visible symptoms. Both the maximum and the effective quantum yield of the photosystem II were inhibited. The non-photochemical quenching showed a complex pattern. Northern blot analyses of representative marker genes also showed a differential response. Defence related genes were induced both by the virulent and avirulent stains although with a different time course. In contrast, the expression of the Calvin cycle gene Rubisco was only repressed in the virulent interaction.

9.2.1. Plant proteomics: Mass spectrometry driven strategies and applications

O. N. Jensen;
Univ. Southern Denmark, Odense M, Denmark.

Proteomic technologies facilitate analysis of very complex protein mixtures derived from plant cells and tissues. In this lecture, I will highlight some of the mass spectrometry driven strategies that have been employed for the study of plant proteins in our laboratory, including the analysis of membrane proteins, phosphoproteins, and quantitative studies of protein expression and interactions. Proteomic tecnologies, including 2D electrophoresis, multidimensional chromatography, peptide sequencing by mass spectrometry and stable isotope labeling will be discussed. Applications include proteomic analysis of GPI-anchored proteins, determination of phosphorylation sites in membrane proteins and the use of stable isotope labeling of amino acids in cell culture (SILAC) for relative quantitation of plant proteins. Approaches for de novo sequencing of peptides by tandem mass spectrometry are presented and applied to the detailed analysis of plant proteins.

9.2.2. Proteome and transcriptome characterization of *Medicago truncatula* seed development. The switch from embryogenesis to storage functions.

K. Gallardo[1], C. Firnhaber[2], D. Hericher[1], J. Burstin[1], H. Küster[2], R. Thompson[1];
[1]URLEG-INRA Dijon, 21000 Dijon, France, [2]Lehrstuhl für Genetik, Universität Bielefeld, D-33501 Bielefeld, Germany.

Seed development is a multi-stage process requiring the coordinated expression of many genes. It starts with the conversion of the integuments into a resistant seed coat and by the formation of the endosperm and embryo. Once the embryo is differentiated, storage compounds accumulate and metabolic activities switch towards a quiescent state. As the majority of storage materials that constitute the value of seed crops are deposited during seed filling, we have investigated this period by using proteomics with M. truncatula adopted as a model for legumes. In this presentation, we will highlight the roles of diverse metabolic processes during seed filling. Using protein maps, we will present differential proteomics comparing embryo, endosperm and seed coat at the onset of reserve deposition. Finally, we will show data comparing proteome and transcriptome during embryogenesis, seed filling, maturation and desiccation, and also in comparisons of the seed tissues. These studies clearly identify marker genes for characteristic stages of seed development and tissue differentiation and highlight the role of various genes in the switch towards reserve accumulation.

9.2.3. Beyond big lists: building networks of interaction in the proteome of plant mitochondria for functional interpretation of a cellular organelle

A. H. Millar, J. L. Heazlewood, J. Ito, J. Whelan;
The University of Western Australia, Perth, Australia.

Combining isolation of mitochondria with separation techniques and peptide mass spectrometry has provided lists of >600 non-redundant genes encoding proteins that are targeted to these respiratory organelles in plants. Many challenges lie in interpreting these lists and defining the relationship between them in the operation of mitochondria. We have been determining the subset of contaminants in these sets using overlays with protein sets located elsewhere in the cell. We have been linking these protein lists on the basis of physical interactions in complexes and functional similarities by ligand affinity and also clustering their expression during development and stress response using microarray data interpreted on the basis of proteome sets. Lastly we have been mapping, by similarity, the plant mitochondrial proteome onto the mitochondria proteomes from mammals and fungi. In this manner we learn about the evolutionary divergence of mitochondrial function, identify plant-specific classes of mitochondrial proteins and link genes of unknown function with those of known function that encode a relatively low complexity proteome set.

9.2.4. The plastid proteomes of *A. thaliana* and maize; quantitative expression profiling, protein interaction networks, functions and a plastid proteome database

K. J. van Wijk, J. B. Peltier, J. Ytterberg, W. Majeran, G. Friso, Y. Cai, L. Giacomelli, A. Rudella, V. Zabrouskov, Q. Sun;
Cornell University, Ithaca, NY, United States.

Plastids are predicted to contain several thousands of proteins, forming an interacting network of proteins. A semi-quantitative overview of stromal, as well as thylakoid-associated proteins and protein complexes in Arabidopsis thaliana chloroplasts and cell specific Bundle sheath (BS) and Mesophyll (M) chloroplasts will be shown. Quantitative comparative proteome analysis of purified BS and M chloroplasts was carried out by stable isotope labeling techniques, as well as 2-DE gels. Protein spots were analyzed by mass spectrometry and emphasis was placed on distinguishing between different members of gene families. Proteins were assigned to molecular functions and metabolic pathways. A Plastid Proteome Database, PPDB (http://pdb.tc.cornell.edu/) was created to all experimental, as well as curated and predicted plastid proteomics data, currently holding experimental data on more than 1000 plastid proteins. The database also facilitates comparison between different plastid types in maize and Arabidopsis. Acknowledgements: Financially supported by the NSF, the USDA and NYSTAR.

9.2.5. Membrane proteomics: Identification and subcellular localization of new transport systems

S. Miras[1], C. Ramus[2], M. Ferro[2], D. Berny[1], D. Salvi[1], J. Garin[2], J. Joyard[1], **N. Rolland**[1];
[1]Laboratoire de Physiologie Cellulaire Végétale, UMR5168 CNRS INRA UJF CEA, Grenoble, France, [2]Laboratoire de Chimie des Protéines, INSERM CEA, Grenoble, France.

Plastids, and especially chloroplasts, conduct vital biosynthetic functions, and many reactions are located exclusively within these unique organelles (photosynthesis, amino acids biosynthesis, fatty acids and vitamins biosynthesis...). A two-membrane system, the envelope, surrounds all plastid types and separates the plastid stroma from the cytosol. As a consequence, the envelope is involved in the controlled exchange of a variety of ions and metabolites between these two subcellular compartments. Chloroplasts also import cytoplasmically synthesized precursor proteins from the cytosol. However, only few proteins involved in these transport processes have been already identified at the molecular level. In order to identify new envelope transporters, a targeted hydrophobic and subcellular specific proteomic approach was developed to identify components of the hydrophobic core of the chloroplast envelope. We demonstrated that the development of such studies may help to reveal the hydrophobic protein composition of a particular membrane system in a given tissue, thus enhancing our understanding of the plant transport systems.

9.2.6. Proteomics of *Fagus sylvatica* L. seeds dormancy breaking and germination.

T. Pawğowski, Z. Szczotka;
Institute of Dendrology PAN, Kórnik, Poland.

Investigation of proteins, product of genes activated during a complex developmental process as is dormancy breakage was the aim of presented research. With seed dormancy breaking the plant hormones are associated: GA_3 responsible for stimulation of dormancy breaking and germination, and ABA responsible for maintenance of dormancy and inhibition of germination. These studies were carried out on *Fagus sylvatica* seeds during their stratification and germination. After imbibition in water (control) and in solution of GA_3 or ABA, beechnuts were subjected to cold stratification, which breaks dormancy. Regarding the proteomic approach, proteins of the seeds were separated by 2D-gel electrophoresis and were analyzed by mass spectrometry. The influence of hormones was investigated and main protein variations were pointed out. Analysis of the proteins specific only for the GA_3 or ABA was done. The link between the variation of proteins, hormones and dormancy breaking was established.

9.2.7. Proteome analysis of differentially displayed proteins as a tool for investigating copper stress in mycorrhizal and non-mycorrhizal hemp (*Cannabis sativa*) roots.

E. Bona, F. Marsano, M. Cavaletto, **G. Berta**;
Dipartimento di Scienze dell'Ambiente e della Vita, Alessandria, Italy.

Due to its fast growth and capability to accumulate high amounts of metals (cadmium and chromium), *Cannabis sativa* has a role, improved by arbuscular-mycorrhizal (AM) symbiosis, in phytoremediation of metal polluted soils. A metal which is often found in polluted soils is copper, a plant micronutrient toxic at high concentrations, whose effects have not yet been investigated in hemp. The aim of this work was to investigate the response mechanisms to Cu in *C. sativa* plants grown in absence and in presence of 150 ppm of $CuSO_4$ and of the AM fungus *Glomus intraradices*. To evaluate protein expression pattern, analytical two-dimensional electrophoresis (2-DE) was performed on IPG strips 3-10 and 4-7 and by vertical slab 12% SDS-PAGE; 2-DE gels were Coomassie stained and analysed with the image analysis PDQuest software for qualitative and quantitative evaluation of differentially expressed proteins. For the first time we showed the 2D maps of hemp soluble root proteins and the first draft of proteins identification by nano-LC (ESI Q-TOF) MS/MS peptide sequencing of *C. sativa*, a species with unsequenced genome.

9.3.1. Pollen characteristics - achieving their potential in plant systematics and phylogeny

M. M. Harley;
Royal Botanic Gardens, Kew, Richmond, United Kingdom.

By the mid 1960's light microscopy had provided a rich pollen literature, and scanning electron microscopy was becoming available commercially. Serious pollen morphologists soon appreciated its potential, because the data it produced complemented both light microscopy and transmission electron microscopy. Pioneering pollen research during the late 1960's and the 1970's saw rapid development in the application of pollen morphological data to plant systematics, phylogenetics and evolution. Many remarkable insights into pollen, as well as more routine taxonomic and systematic pollen papers, have been published, demonstrating and establishing the importance of pollen data - and some key examples are highlighted. However, as more integrated approaches to plant phylogeny take hold few institutes any longer support pollen morphology as a discipline. Therefore, if pollen data are to provide maximum value, botanists not well-acquainted with pollen morphology must acquire a better understanding, within their research projects, of the quality of previously published pollen data, as well as the appropriateness of planned pollen preparation techniques.

9.3.2. Pollen morphology and development in aquatic angiosperms

J. M. Osborn, M. L. Taylor;
Truman State University, Kirksville, MO, United States.

In the history of angiosperm evolution there have been numerous transitions from the terrestrial environment to the aquatic habitat. While there are many examples of aquatic genera and species nested within terrestrial families and genera, respectively, there are only about 28 families of angiosperms that primarily comprise aquatic taxa. The majority of these occur in freshwater environments, but several groups have colonized the marine habitat. Although the biology and systematic relationships of these predominately aquatic families are becoming better understood, relatively little is known about the pollen biology of these interesting plants. In this presentation, we review pollen morphology, ultrastructure, and ontogeny from the families of aquatic flowering plants for which detailed data are available, with emphasis on Cabombaceae, Nymphaeaceae, Nelumbonaceae, Callitrichaceae, and Podostemaceae. Pollen studies of aquatic angiosperms provide the opportunity to address fundamental questions about reproductive biology, ecology and evolution of pollination syndromes, evolution of key pollen characters, and phylogeny.

9.3.3. Pollen and anther ontogeny in *Brasenia* (Cabombaceae, Nymphaeales)

M. L. Taylor, J. M. Osborn;
Truman State University, Kirksville, MO, United States.

Brasenia is a monotypic water lily sporadically distributed throughout the Americas, Asia, Australia, and Africa. Evidence from a range of studies indicates that Nymphaeales are among the most primitive angiosperms. Despite their phylogenetic utility, pollen developmental characters are not well known in *Brasenia*. In this presentation, pollen and anther ontogeny will be described for *Brasenia*. Anthers at all stages of development have been studied using scanning electron, transmission electron, and light microscopy. The tetrad stage proceeds rapidly and variation in tetrad geometry has been identified. Formation of the infratectal collumellae and the tectum begins during the tetrad stage, with the tectum forming discontinuously. The endexine lamellae and foot layer form during the free microspore and early grain stages, and their development varies in the apertural and non-apertural regions of the pollen wall. *Brasenia* is wind-pollinated, and several pollen characters appear to be correlated with this pollination syndrome. The adaptive significance of these characters, in contrast to those of the fly-pollinated genus *Cabomba*, will be discussed.

9.3.4. Post-meiotic cytokinesis and pollen aperture pattern ontogeny: comparison of development in four species differing in aperture pattern

S. Nadot;
Université Paris-Sud, Orsay, France.

The pollen grains of angiosperms display a wide range of variation in aperture patterns. An increasing number of studies indicate that aperture pattern ontogeny is correlated with the way in which cytokinesis that follows male meiosis is completed. To investigate this hypothesis and the nature of the mechanisms involved in pattern ontogeny, the formation of the intersporal callose walls that are formed to isolate the microspores after meiosis was studied in four species that all display different aperture patterns. Two species belong to the monocots (*Phormium tenax* and *Asphodelus albus),* the two other species belong to the eudicots (*Helleborus foetidus* and *Protea lepidocarpodendron*). The way in which post-meiotic cytokinesis is performed differs between all four species. The variation in callose deposition could be linked to aperture pattern definition, providing new data to support the hypothesis that post-meiotic cytokinesis is involved in aperture pattern ontogeny.

9.3.5. The role of micelle self-assembly in exine development

N. I. Gabarayeva[1], V. V. Grigorjeva[1], A. R. Hemsley[2];
[1]Komarov Botanical Institute RAS, St.Petersburg, Russian Federation, [2]Cardiff University, Cardiff, United Kingdom.

Exine ontogeny in *Chamaedorea microspandix* and *Trevesia spirocarpa* has been ultrastructurally studied. Our interpretation in the light of knowledge of colloidal chemistry allows to explain many steps of exine ontogeny as self-assembly of micelles, or liquid crystals. Liquid crystal systems, depending on the concentration of a dispersion, have several mesophases: spherical micelles, cylinder ones, layers of hexagonally packed cylinders (middle micelles), bilayers with water-contained gap (neat micelles), transforming one to another spontaneously. All these micelle mesophases are seen in the periplasmic space during exine development. In both species at early tetrad stage portions of the glycocalyx - glycoproteins - are seen as spherical micelles. At middle tetrad stage spherical micelles turn to cylinder ones, and then to middle micelles, corresponding to J. Rowley's tufts. The first step of the endexine lamellae development is the formation of neat micelles with water-gap (well-known white lines). In apertural oncus in *Trevesia* microspores both spherical and neat micelles are observed as granular and lamellate parts of the endexine.

9.3.6. The enigmatic pollen morphology of *Duparquetia* (Leguminosae: Caesalpinioideae)

H. Banks[1], S. Feist-Burkhardt[2], B. Klitgaard[2];
[1]Royal Botanic Gardens Kew, Richmond, United Kingdom, [2]Natural History Museum, London, United Kingdom.

Phylogenetic affinities of the monotypic genus *Duparquetia* are currently poorly resolved; preliminary molecular analyses suggest a basal, isolated position among legumes. Understanding the development of *Duparquetia* pollen is necessary to deduce the orientation of the apertures and contribute pollen characters to multi-dataset analyses. For examination of microspores within developing tetrads, we used confocal microscopy to clarify the position of the ectoapertures, and light microscopy of microspores stained with Alcian blue to locate the pores. *Duparquetia* pollen develops in a pattern similar to that of other eudicots. However, mature grains are asymmetrical with one equatorial (latitudinal) encircling ectoaperture and two circular endoapertures (pores), a feature unique in legumes and eudicots. This autapomorphic character is consistent with a pattern of greater pollen morphological diversity in basal caesalpinioid legume groups than in more derived clades.

9.3.7. Importance of pollen morphology for *Cistus* and *Halimium* (Cistaceae) systematics.

L. Civeyrel[1], J. Leclercq[2], J. Demoly[3];
[1]Laboratoire de Dynamique de la Biodiversite, Toulouse, France, [2]CIRAD, Montpellier, France, [3]APBF, Paris, France.

The two genera Cistus and Halimium are shrub-like members of the family Cistaceae and occur only around the Mediterranean Sea and the Canary Islands. For this study, palynological characters have been examined for almost all species of Cistus and Halimium using light and scanning electron microscopy. Some other reproductive characters have also been investigated and are presented here. Pollen morphology is compared to a molecular phylogeny built with the plastid spacers trnS-trnG and trnL-trnF. Palynological characters as well as flower colour appear to be highly phylogenetically informative. For example, the pink flowered Cistus species, which share interesting microreticulate pollen exines, form a monophyletic group radiating to the Canary Islands. In the genus Halimium, three well defined and well supported monophyletic groups share interesting pollen characters and also biogeographical patterns of distribution.

9.4.1. Self-incompatibility and the evolution of mating systems in the Brassicaceae

J. Nasrallah;
Department of Plant Biology, Cornell University, Ithaca, NY, United States.

Inhibition of self-related pollen in the self-incompatibility response of the Brassicaceae is effected by allele-specific interactions between two highly polymorphic proteins, the stigma-localized S-locus receptor kinase SRK and its pollen coat-localized ligand, the S-locus cysteine-rich protein SCR. SRK and SCR variants are highly polymorphic, making it difficult to identify potential specificity determinants by sequence alignment. Modeling of 3D structures is used to identify potential specificity determinants and to understand the processes that underlie the generation of novel self-incompatibility specificities. In parallel, transgenic *A. thaliana* plants that express the self-incompatibility trait as a result of transfer of an *SRK/SCR* gene pair from *A. lyrata* are used for genetic screens aimed at identifying signaling intermediates and the loci required for expression of the self-incompatibility trait. Results pertaining to the diversification of the recognition repertoire and to the molecular bases of evolutionary switches from out-crossing to self-fertilizing mating system will be presented.

9.4.2. The *S* locus and global pollination responses among *Arabidopsis* species

M. E. Nasrallah;
Department of Plant Biology, Cornell University, Ithaca, NY, United States.

Reciprocal pollinations between self-incompatible (SI) species and self-compatible (SC) often exhibit unilateral incompatibility, whereby pollinations in which the SI species is the pistillate parent are typically incompatible, while the reciprocal pollinations are compatible. Based on these observations, which were generalized into the so-called SI X SC rule, a role for the self-incompatibility (*S*) locus in inter-species pollen recognition and consequently in species isolation, has been proposed. In crucifers, the SI X SC rule is applicable to the majority of inter-specific and inter-generic pollinations, including those between *A. thaliana* and its close relative *A. lyrata.* Our successful transfer of the self-incompatibility trait into *A. thaliana* by transformation with the two *S*-locus genes that determine self-incompatibility specificity in stigma and pollen provides new opportunities to investigate the possible contribution of the *S* locus to inter-specific pollen-stigma barriers. Our observations of pollen tube growth and guidance and the ultimate outcome of these inter-specific pollinations will be presented.

9.4.3. DNA polymorphism in and around the *A. lyrata* self-incompatibility loci

D. Charlesworth;
University of Edinburgh, Edinburgh, United Kingdom.

The self-incompatibility genes are highly polymorphic, both in terms of allele numbers maintained by rare-allele advantage, and in levels of diversity per nucleotide, at both synonymous and non-synonymous sites. The observations can be interpreted in the light of population genetic models for situations where selection maintains variation for certain amino acids (giving high non-synonymous site diversity), and linkage ensures high variability at nearby sites because variants arising in one allele will only slowly recombine with other alleles. This effect of balancing selection on regions of genome linked to the S-loci themselves extends to several linked loci at considerable distances away. This linkage disequilibrium is expected if recombination is suppressed in the S-locus region, as is predicted because preservation of incompatible allele combinations is necessary at the pistil recognition gene (SRK) and the gene encoding the pollen ligand.

9.4.4. Natural variation in outcrossing rates in North American populations of *Arabidopsis lyrata* (Brassicaceae)

B. K. Mable;
University of Glasgow, Glasgow, United Kingdom.

The genetic basis for breakdown in self-incompatibility (SI) systems is known for some groups but few studies have examined variation in selfing rates in species for which the molecular basis of SI is known. We surveyed such variation in *Arabidopsis lyrata* (Brassicaceae) in order to examine the causes and genetic consequences of changes in its breeding system. In the Great Lakes region of North America we found a surprising dichotomy in strength of SI among populations sampled from a limited geographic region. Out of 12 populations surveyed, 5 showed a preponderance of SC individuals, high levels of inbreeding (based on progeny arrays using multilocus microsatellite markers), and substantially reduced genetic diversity and observed heterozygosity compared to outcrossing populations. Geographic distributions of outcrossing and inbreeding populations are currently disjunct, suggesting that they could have originated from different source populations. Results will be discussed in terms of implications of flexibility in mating systems for adaptation in species such as this that are restricted to threatened habitats (sand dunes, alvars, cliff edges).

9.4.5. Molecular population genetics of pollen-coat genes in the self-fertilizing *Arabidopsis thaliana* and the outcrossing *Arabidopsis lyrata*

K. J. Schmid, N. Odat;
MPI of Chemical Ecology, Jena, Germany.

Pollen-pistil interactions are species-specific. Genes involved in species recognition can be expected to be highly divergent between species, but have a reduced level of polymorphism within species. Levels of sequence variation in species-recognition genes should be reduced in an outcrossing as compared to selfing or apomictic species. Oleopollenin proteins are family of seven proteins that are expressed in the pollen coat of *Arabidosis thaliana*. They may be involved in species-recognition of the male gametophyte. They evolve rapidly by gene birth and death processes and by sequence divergence. To test whether these genes are involved in species recognition, we compared levels of polymorphism and divergence in the self-fertilizing species *A. thaliana* and the self incompatible species *A. lyrata*. Sequence polymorphisms in these genes are reduced in both species relative to genome-wide levels of variation. Oleopollenins are repetitive proteins and we found a high level of variation in the number of amino acid repeats in both species. We will discuss whether observed patterns of polymorphism are consistent with a role in species recognition.

9.4.6. Reproductive and genetic consequences of diploid hybrid speciation in *Senecio.*

A. C. E. Brennan[1], M. J. Hegarty[1], J. M. Jones[1], G. Liu[2], R. J. Abbott[2], K. J. Edwards[1], **S. J. Hiscock**[1];

[1]University of Bristol, Bristol, United Kingdom, [2]University of St. Andrews, St. Andrews, United Kingdom.

Senecio squalidus (Oxford ragwort) represents an example of a recently formed homoploid hybrid species for which the parental taxa are known. The parental taxa, *S. aethnensis* and *S. chrysanthemifolius*, native to Sicily, hybridize on Mt. Etna where they have produced an extensive hybrid zone, from which the original material that gave rise to *S. squalidus* was collected and introduced to the UK approximately 300 years ago. The well-characterized hybrid history of *S. squalidus* makes it a valuable 'model' for studying the reproductive and genetic effects of homoploid speciation. We are investigating the inheritance of sporophytic self-incompatibility (SI) in wild and synthetic hybrids of *S. aethnesis* and *S. chrysanthemifolius* (both of which are strongly SI) for comparison with UK *S. squalidus* (also strongly SI). In addition, we are using anonymous cDNA microarrays to study patterns of floral gene expression in these wild and synthetic hybrids, their parental taxa and UK *S. squalidus*.

9.5.1. The green algal ancestry of land plants as revealed by the chloroplast genome

M. Turmel, C. Otis, C. Lemieux;
Universite Laval, Quebec, PQ, Canada.

About 500 millions years ago, freshwater green algae belonging to the class Charophyceae emerged from their aquatic environment to colonize the land. This important event in the history of our planet ultimately gave rise to all the land plant species, yet little is known about the nature of the immediate algal ancestor of land plants. We have recently undertaken the sequencing of chloroplast genomes from representatives of all five recognized lineages of the Charophyceae to elucidate the branching order of these lineages and to study the evolution of chloroplast DNA within the Streptophyta (the phylum containing the Charophyceae and land plants). We have determined thus far the complete chloroplast genome sequences of *Chaetosphaeridium* (Coleochaetales), *Chara* (Charales), *Chlorokybus* (Chlorokybales), *Mesostigma* (Mesostigmatales), *Staurastrum* (Zygnematales) and *Zygnema* (Zygnematales). We will present the streptophyte phylogenies we have inferred from multiple chloroplast gene and protein sequences as well as our comparative analyses of the gene partitioning pattern, gene content, gene structure, gene order, and intron content.

9.5.2. The mitochondrial perspective on early land plant evolution

V. Knoop;
IZMB - Institut für Zelluläre und Molekulare Botanik, 53115 Bonn, Germany.

Most molecular studies find bryophytes paraphyletic at the base of land plants while confirming the individual monophylies of liverworts, mosses and hornworts. Mitochondrial data, notably the occurrence of introns, suggest liverworts as sister to all other embryophytes. This early dichotomy was apparently followed by differential intron invasion into the chondriomes. Further introns appear to be gained, and occasionally lost, along the backbone phylogeny of non-liverworts in genes such as *nad2, nad4, nad5* and *nad7* and include the ancestors of trans-splicing group II introns in angiosperms. Intron occurrence is congruent with a model that places hornworts as the sister group to tracheophytes. The idiosyncratic phenomenon of frequent pyrimidine exchange RNA editing in plant mitochondria is phylogenetically less conclusive. Intergenic regions, frequently investigated in chloroplast and nuclear DNA, have so far not been analysed in plant mitochondria due to a lack of conserved gene arrangements. We now find at least two gene clusters widely conserved in bryophytes as further phylogenetically informative loci.

9.5.3. Inference of land plant phylogeny from genomic chloroplast data

D. G. Kelch[1], K. G. Karol[2], B. D. Mishler[1], P. G. Wolf[3];
[1]University and Jepson Herbaria, Berkeley, CA, United States, [2]University of Washington, Seattle, WA, United States, [3]Utah State University, Logan, UT, United States.

The large influx of comparative DNA sequence data has led to many new inferences regarding the land plant tree of life. Early branches in the phylogenetic history of major clades are particularly hard to reconstruct due to the phenomena of long branch attraction. Several analyses spanning land plants have used data from different genetic markers. Nevertheless, there is disagreement about the order of branching among the major clades. We have used available data from complete chloroplast DNA sequences from the plastome of 19 taxa with exemplars of charophytes, liverworts, mosses, hornworts, lycophytes, moniliforms, conifers, and angiosperms. We present several analyses of evolutionary relationships among land plants by using full nucleotide data, amino acid sequences, and by comparing gene arrangements from chloroplast genomes. The results, while still tentative pending the large number of chloroplast genomes from other key lineages that are soon to be sequenced, are intriguing in themselves, and contribute to a growing comparative database of genomic and morphological data across the green plants.

9.5.4. Phylogenetic significance and diversification of the Bryophyta sensu lato

B. Goffinet[1], J. A. Shaw[2];
[1]University of Connecticut, Storrs, CT, United States, [2]Duke University, Durham, NC, United States.

The earliest forms of plants on land are represented among extant lineages by the bryophytes (i.e., Anthocerotophya, Marchantiophyta and Bryophyta). The sequence of cladogenesis following the transition to land is still fairly unresolved due to a) discrepancies in outgroup selection, b) inconsistencies in selection of ingroup exemplars as of the main lineages, c) difficulties in uncovering character sources suitable for reconstructing ancient radiations and d) recovering a phylogenetic signal that dates back nearly 500 my. Significant progress has been made in identifying the root of the mosses and the hornworts, but early divergences among the liverworts remain controversial. Character sampling has greatly expanded to multigenic and genomic data sets, but despite such intensive character samplings, inferences remain incongruent with regard to the monophyly of the bryophyta and in the case of their paraphyly, which lineage marks the earliest divergence.

9.5.5. Evolutionary history of ferns: Ancient origins and recent radiations

K. M. Pryer, E. Schuettpelz;
Department of Biology, Durham, NC, United States.

By integrating molecular phylogenetic data with fossil constraints we show that by the end of the Carboniferous, all five extant fern lineages - ophioglossoids, whisk ferns, marattioids, horsetails, and leptosporangiates - were present, and the earliest divergence within crown-group leptosporangiate ferns had also occurred. The Permian witnessed the establishment of four additional leptosporangiate lineages - gleichenioids, filmy ferns, schizaeoids, and core leptosporangiates. A subsequent Triassic diversification of the core leptosporangiates gave rise to the heterosporous ferns, tree ferns, and polypods. Despite the ancient origins of all the major extant fern lineages, the bulk of the diversification within these lineages is more recent; several successive radiations since the Cretaceous generated most of modern fern diversity. Although much of the diversification occurred within polypods, which now account for more than 80% of ferns, the more recent radiations were not confined to this group. Concurrent diversifications in several other fern lineages raise important questions about the evolutionary processes underlying fern diversity.

9.5.6. Seed plant phylogenomics: Insights from multicharacter analysis and partitioning

J. E. B. De la Torre[1], M. Egan[2], M. Katari[3], E. Lee[2], E. Brenner[4], R. Martienssen[3], R. McCombie[3], D. W. Stevenson[4], G. M. Coruzzi[1], R. DeSalle[2];
[1]New York University, NY, NY, United States, [2]American Museum of Natural History, NY, NY, United States, [3]Cold Spring Harbor Labs, NY, NY, United States, [4]New York Botanical Garden, NY, NY, United States.

Phylogenetic relationships among Seed Plant groups remain controversial, even after numerous individual character sources have been used to resolve them. It is now clear that phylogenies based on single or a few molecules tend to reflect their histories, rather than that of the taxa analysed. Recent studies have supported the simultaneous analysis of multiple data partitions to overcome the effect of conflicting phylogenetic signals. A recent surge in sequencing projects (such as ours) has significantly increased the availability of molecular characters. Using a concatenation of orthologous genomic and EST sequences, with novel bioinformatics tools and phylogenetic methods, we are addressing the issue of Seed Plant phylogeny at a multigene scale. Our aim is a fully resolved and well-supported species tree, for which individual character support can still be identified and evaluated. Results of preliminary analyses using data from several genes will be shown. Approaches to determine the extent and probable consequences of character changes, and potential implications of these analyses in expression, functional, and evo-devo studies, will be discussed.

9.5.7. Phylogenetic reconstruction and age estimation of land plants and their subclades using DNA sequences

Y. Qiu;
University of Michigan, Ann Arbor, MI, United States.

Origin and subsequent diversification of land plants (embryophytes) had a significant impact on evolution of life on Earth by fundamentally altering the terrestrial ecosystem. Despite a large number of morphological, paleontological, and molecular studies, several issues on land plant phylogeny remain controversial. These include: the deepest-diverging lineage of land plants, the sister group of tracheophytes, relationships among basal moniliformopses, and phylogenetic affinity of Gnetales. We have assembled a data set of eight chloroplast (atpB, rbcL, cpSSU, cpLSU), mitochondrial (atp1, mtLSU), and nuclear (18S, 26S) genes from over 180 land plants and green algae. We have also gathered information on distribution of several mitochondrial group II introns and gene content in the chloroplast DNA inverted repeat. Analyses of these three data sets indicate that the evolutionary history of land plants can be reconstructed with a high level of confidence. We also use the DNA sequences to estimate the ages of land plants and their subclades.

9.6.1. Plant parasitic microfungi and their host plants in temperate and tropical areas - a comparison

M. Piepenbring;
Botanical Institute, Frankfurt am Main, Germany.

During evolution, fungi belonging to different systematic groups (mainly different orders of Asco- and Basidiomycota) adopted a plant parasitic life style. Apparently any plant can be infected by plant parasitic microfungi, but a single fungal species usually can only infect a limited range of host species. Different systematic groups of plant parasitic microfungi show primarily temperate or tropical centres of distribution according to geographical distribution centres of their host plants. Life cycles and morphological characteristics of fungi differ according to different climatic and ecological conditions. While fungi in higher latitudes are adapted to overcome winter, fungi in tropical regions have to deal with high light intensities and often quickly and drastically changing humidity and temperature values. Observations on different characteristics are presented and compared based on plant parasitic microfungi in Europe and in the Neotropics. A lack of basic morphological and systematical investigation as well as long term ecological observation and experiments on tropical plant parasitic microfungi is evident.

9.6.2. Evolution of the Proteaceae and their pathogens

J. E. Taylor;
University of Botswana, Gaborone, Botswana.

The Proteaceae are distributed predominantly in the Southern Hemisphere occurring in Australia and the South Pacific, Mexico, Central and Southern America, Africa, India and South East Asia. The foliicolous pathogens tend to be unique to these Proteaceae hosts. However, it appears that pathogens associated with Proteaceae in the various regions where members of the family occur differ, and it is possible that the divisions in the family are reflected in the host and geographic range of the foliar pathogens. In this study an attempt is made to investigate this observation using specimens collected from the field, and herbarium specimens. Pathogens of southern African Proteaceae are well understood and are observed on Australian hosts (e.g. unusual Rhyncostomatoid fungi, *Vizella interrupta* and *Verrucisporota proteacearum*). However, *Phyllachora* and other biotrophic and epiphytic taxa are common to Australian and South American Proteaceae, but noticeably lacking from southern African Proteaceae. Although patterns are emerging, more collections are necessary in Australia and South America to further elucidate fungus/host relationships.

9.6.3. Evolution of host-parasite patterns within selected Peronosporales

H. Voglmayr[1], A. Riethmüller[2], M. Göker[3];
[1]Department für Botanische Systematik und Evolutionsforschung, Universität Wien, 1030 Wien, Austria, [2]Fachbereich 18 Naturwissenschaften, Fachgebiet Ökologie, Universität Kassel, Heinrich-Plett-Str. 40, 34132 Kassel, Germany, [3]Universität Tübingen, Botanisches Institut, Lehrstuhl Spezielle Botanik und Mykologie, Auf der Morgenstelle 1, 72076 Tübingen, Germany.

In an exemplary manner, ecology, morphology, systematics and coevolution within the genus Plasmopara and its closest relatives is presented in the light of recent molecular and morphological investigations. Data on phylogeny, distribution, morphology and ecology of both hosts and parasites are combined to elucidate evolutionary host-parasite connections. In addition, the influence of climatic and ecological constraints (habitats) on species diversification will be debated. By comparison of host range and molecular phylogeny, the evolutionary importance of host jumps versus cospeciation is evaluated and their contribution to the currently observed biodiversity is discussed. The available molecular and morphological data on evolutive radiation of Plasmopara are shortly presented for the parasites of selected host families (e.g. Ranunculaceae, Apiaceae, Geraniaceae), and the importance of host specificity is evaluated. The resulting problems of species concepts (morphological versus molecular) will be briefly discussed on the basis of selected Plasmopara species groups.

9.6.4. Patterns and processes of host-parasite relationships in rust fungi and wild roses: integrating ecology and evolution

W. F. A. Maier[1], C. M. Ritz[2], F. Oberwinkler[3], V. Wissemann[2];
[1]University of Pretoria, Pretoria, South Africa, [2]Universität Jena, Jena, Germany, [3]Universität Tübingen, Tübingen, Germany.

Rust fungi in the genus Phragmidium are frequent pathogens of both wild and cultivated roses. We investigated the occurrence and relationships of rusts on dog roses, Rosa. sect. Caninae (Rosa canina, R. corymbifera and R. rubiginosa) in Germany. Two Phragmidium species, P. mucronatum and P. tuberculatum, were found and they were able to infect each of the three dog rose species. However, the overall infection of R. rubiginosa was significantly lower. Despite overlapping host ranges, the evolutionary background of P. tuberculatum and P. mucronatum is quite distinct. Phylogenetic analyses of nuclear ribosomal DNA sequences suggest that P. mucronatum shares a common ancestor with other rose rusts, whereas P. tuberculatum evolved from a Rubus-Sanguisorba rust clade and must have undergone a host shift to Rosa spp.

The above results will be discussed in the light of recent findings concerning the evolution of dog roses and larger scale relationships of Phragmidiaceae and Rosaceae in general.

9.6.5. How can phylogenetic data contribute to the understanding of Microbotryales?

D. Begerow, M. Kemler, M. Lutz, M. Göker, R. Bauer, F. Oberwinkler;
Spezielle Botanik/Mykologie, Tübingen, Germany.

Although the convergence of smut-like appearance of several fungal plant parasites was discussed for a long time, molecular phylogeny revealed the Microbotryales as a second independent smut group not related to the Ustilaginomycetes, but as a subgroup of the Urediniomycetes. Within the Microbotryales, characters like morphology and host species are as diverse as they are in the Ustilaginomycetes. Phylogenetic analyses of LSU rDNA sequences support a separation of Ustilentylomataceae and Microbotryaceae as predicted from ultrastructural markers. The Microbotryaceae are infectious to several plant families with a focus on Polygonaceae. The anther smuts on Caryophyllaceae represent a smaller monophyletic group. Recent data give insight into the distribution of morphological characters, the role of host specificity and joined evolution with their hosts. A comparison of the convergent Ustilaginomycetes and Microbotryales reveals differences in their host-parasite relationships through time.

9.6.6. Coevolutionary aspects in smut fungi (Ustilaginaceae) on grasses (Poaceae)

M. Stoll, M. Göker, D. Begerow, F. Oberwinkler;
Botanisches Institut, Tübingen, Germany.

The basidiomycete family Ustilaginaceae (Basidiomycota: Ustilaginales) encompasses about 15 genera and more than 750 species of phytopathogenic fungi. The majority of these species belong to the genera Ustilago and Sporisorium. Both genera parasitize exclusively on grasses (Poaceae) where they induce a variety of symptoms on different host organs.

Due to the highly specific occurrence of Ustilago and Sporisorium species on certain grass genera or species, the outcome of certain co-evolutionary host-parasite interaction seems to be very likely.

In order to detect nature and extent of these evolutionary interactions, we used molecular sequence data (internal transcribed spacer and large subunit ribosomal DNA) of about 50 parasite species and their hosts. Reconciliation analyses, Brooks Parsimony analyses and randomization tests of the resulting topologies will be used to discuss cospeciation events versus host jumps. These results will be compared with data from other parasitic basidiomycete genera.

9.6.7. Parasitism of rust spores by *Ramularia* species

A. Plachecka;
Warsaw Agricultural University, Warsaw, Poland.

Three *Ramularia* species have been known as hyperparasites of rust fungi in Poland. *Ramularia coleosporii* is quite frequently found on uredial sori of *Coleosporium tussilaginis*; *Ramularia uredinis* parasitizes uredial sori of many species belonging to *Melampsora* and *Cronartium* genera, whereas *Ramularia uredinearum* is a parasite of various sori of *Puccinia* species.

Uredial and telial sori of different species of rust fungi infected with *Ramularia coleosporii*, *Ramularia uredinis* and *Ramularia uredinearum* were examined using light, scanning and transmission microscopes to determine the parasite-hyperparasite contact. The microscopical examination clearly showed that mycelium of *Ramularia* species grows on the surface of the uredial and telial sori of rust fungi and it is observed as a white coating of hyphae and conidiophores with spores. Hyphae of the hyperparasite directly penetrate rust spores causing gradually their complete destruction.

9.7.1. Progress in systematics and evolution of Bromeliaceae

W. G. Till;
Institute of Botany, Wien, Austria.

Evidence from molecular studies of the chloroplast genome is rapidly growing and demonstrating the unreliable classification of the family. While all results corroborate the monophyly of Bromelioideae and Tillandsioideae subfamilies, the opposite is true for Pitcairnioideae which disintegrates into numerous clades. However, these phylogenies have not yet been compared with data from mitochondrial and nuclear genomes. At the generic level many groups need to be reclassified. This is most obvious in the large and inhomogeneous „genera“ *Aechmea* and *Tillandsia*. Morphology of flowers, pollen, stigmata, septal nectaries, and seeds as well as anatomical characters also are in conflict with current classifications but are still insufficiently known. They do not unequivocally support the molecular data. Analyses of selected characters like CAM photosynthesis and succulence reveal numerous homoplasies reflecting extensive and rapid adaptive radiation in Bromeliaceae.

9.7.2. Phylogeny of Bromeliaceae - implications for origin, adaptive radiation, and geographic diversification

T. J. Givnish;
University of Wisconsin, Madison, WI, United States.

We provide a new classification for Bromeliaceae with eight subfamilies, based on a cladistic analysis of *ndh*F sequences. Brocchinioideae is basalmost, followed by Lindmanioideae, and an unresolved trichotomy involving Hechtioideae, Tillandsioideae, and the remaining bromeliads in Navioideae, Pitcairnioideae, Puyoideae, and Bromelioideae. Bromeliads arose as C_3 terrestrials on moist infertile sites in the Guayana Shield 70 Mya, spread centripetally in the New World, and dispersed to West Africa less than 10 Mya. Modern lineages began to diverge 20 Mya and invaded drier regions beginning 15 Mya, coincident with a “bromeliad revolution” involving the repeated evolution of epiphytism, CAM photosynthesis, impounding leaves, several features of leaf/trichome anatomy, and accelerated diversification at the generic level. Epiphytism may have accelerated speciation by allowing colonization along the length of the Andes, while favoring the occupation of a dissected cloud-forest landscape. *Hechtia, Abromeitiella-Deuterocohnia-Dyckia-Encholirium,* and *Puya* show a remarkable pattern of concerted convergence in six leaf traits adapted to drought.

9.7.3. Phylogenetics of subfamily Tillandsioideae (Bromeliaceae): a comparison of plastid and nuclear DNA sequence with morphological data

M. H. J. Barfuss, W. Till, R. Samuel;
Department of Systematic and Evolutionary Botany, University of Vienna, Vienna, Austria.

Part of the low-copy nuclear gene phosphoribulokinase (PRK) and a multicopy nuclear rDNA spacer region (ITS) were used to clarify relationships of subfamily Tillandsioideae (Bromeliaceae). These data are compared with the available cpDNA sequences of coding *rbcL* and *matK* and noncoding *trnL* intron*, trnL-F* intergenic spacer, *atpB-rbcL* intergenic spacer, *rps16* intron, and partial 5' and 3' *trnK* intron. We added taxa of *Tillandsia, Guzmania* and *Vriesea* to get better resolution within these genetically convergent genera. Molecular phylogenetic data is compared with various morphological characters to test their usefulness for a new classification of Tillandsioideae. These characters are optimised onto a strict consensus tree of the combined matrices of plastid and nuclear DNA sequences. Preference has been given to characters likely to be little affected by adaptive constraints, i. e., pollen, stigma, ovules, anther, seed, and nectary morphology.

9.7.4. Improving taxa and character sampling to support generic and subgeneric units in Bromeliaceae: the example of *Alcantarea* and *Vriesea goniorachis* complex (Tillandsioideae)

E. M. C. Leme;
Herbarium Bradeanum, Rio de Janeiro, Brazil.

Historical difficulties encountered in defining species and generic units in Bromeliaceae have been documented on the basis of sampling related problems: loss or modification of some important structures in herbarium specimens in post-collection preparation steps and under collection and the consequent poor documentation of morphological variation in wild populations. However, recent studies using improved data mainly based on living specimens demonstrate that better taxon sampling combined with careful attention to character sampling can result in a much clearer understanding of taxonomic and phylogenetic relationships within Bromeliaceae. In Tillandsioideae, the careful selection and documentation of subutilized characters provided by living specimens strengthened the generic status of the recently resurrected *Alcantarea* and allowed a consistent delineation of the species complex headed by *Vriesea goniorachis.* Thus, besides the itensification of field activities, the establishment of well-documented living collections has a strategic importance in the conduction of new taxonomic investigation in Bromeliaceae.

9.7.5. Evolution of the inflorescence in *Puya* (Bromeliaceae): a phylogenetic point of view

C. T. Hornung-Leoni, V. Sosa;
Instituto de Ecologia, A.C., Xalapa, Veracruz, Mexico.

Several hypothesis can be performed about the relationship between species in Bromeliaceae. *Puya* is a predominantly South American genus subdivided in two subgenera: *Puya* (8 spp) and *Puyopsis* (187 spp). In this work, phylogenetic analyses are carried out based on morphological characters to determine if the subgenus *Puya* is monophyletic and to explore if the character-sterile branch apex of the inflorescence- is a significant character for the subgenus. We also study the evolution of other characters and their relation to pollination systems, and discuss the evolution of the inflorescence in this genus, as to shape, size and floral characters, from a phylogenetic point of view. Results indicate that petals spiraled together after anthesis and the presence of the sterile apex are synapomorphic of the genus and the subgenus *Puya* respectively, and that they are related to pollination systems.

9.7.6. Evolution of Bromelioideae (Bromeliaceae)

K. Schulte, **R. Horres**, G. Zizka;
Research Institute Senckenberg and J.W. Goethe-University, Frankfurt am Main, Germany.

We focus on subfamily Bromelioideae including 29 genera/58 species (of 40 genera and 81 species of Bromeliaceae investigated). Phylogenetic analyses of three chloroplast markers, matK, trnL-intron and trnL-trnF intergenic spacer, improve

resolution in Bromelioideae. Greigia is putative sister to the remainder of the subfamily.
The latter displays an unresolved trichotomy with branches formed by (a) Bromelia, (b) Ochagavia, Fascicularia and Deinacanthon, and (c) the remaining "core Bromelioideae".
Based on comparison of molecular phylogeny and photosynthetic pathway, life-form and biogeography, we conclude that early Bromelioideae probably had an Andean distribution, were terrestrials with C3 photosynthesis, and lacked water-impounding phytotelmata. The most derived "core Bromelioideae" are almost exclusively CAM. Additionally, the sequence data from atpB-rbcL IGS are presently included into the phylogenetic reconstruction.

9.7.7. A phylogenetic analysis of Bromelioideae (Bromeliaceae) based on molecular and morphological data

T. M. Evans[1], **G. K. Brown**[2], T. Wendt[3], S. L. Kortering[1], J. E. Drake[1];
[1]Hope College, Holland, MI, United States, [2]University of Wyoming, Laramie, WY, United States, [3]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

Of the three traditionally defined subfamilies of Bromeliaceae, the systematics of Bromelioideae are perhaps the most poorly understood. A low rate of molecular evolution has made it difficult to produce a well-resolved molecular phylogeny. Likewise, morphological data have proved difficult to apply due to a high degree of morphological variation, lack of preserved floral and fruit material, and the difficulty of obtaining field-collected materials. Bayesian and parsimony analyses of morphological and molecular (*trn*L-*trn*F, *psb*A-*trn*H, and *mat*K sequence) data were conducted to resolve intra- and intergeneric relationships within the subfamily. An emphasis on floral and fruit characters has yielded numerous new phylogenetically informative characters. Analysis of each data set (morphological and molecular) separately generated large numbers of trees (> 10,000) with moderate resolution and support. Combining the data sets, however, yielded far fewer trees and greatly increased resolution and internal support. Numerous genera (e.g. *Aechmea*, *Portea*, *Araeococcus*) are highly polyphyletic, and a restructuring of generic circumscriptions is needed.

9.8.1. Dispersal and establishment of ground layer mosses and Lichens: dynamics at the local scale

D. H. Vitt, R. E. Mooneyhan;
Southern Illinois University, Carbondale, IL, United States.

Bryophytes and lichens dominate the ground layer in conifer-dominated forests. The dominant lichens, *Cladina mitis* and *C. rangiferina*, form a mosaic of extensive patches intermixed with the feather mosses *Pleurozium schreberi* and *Hylocomium splendens*. We studied lichen/moss responses to canopy opening 7 years post-thinning. Our 4 questions were posed around determining the responses to canopy opening of 1) vegetation, 2) diversity, 3) diaspores, and 4) establishment. Conclusions are that canopy opening has effected ground layer vegetation, but has had little effect on overall species richness. Both lichen and moss diaspores are abundant. Moss vegetation has decreased, yet lichens have not yet recolonized the resulting non-vegetated space. We conclude that lichens are generalists and with time are able to establish under a variety of environmental conditions, however they are inhibited by pre-existing substrates. Feather mosses are specialists and they are limited by environmental conditions inhibiting their establishment, except in local areas where pre-existing substrates and canopy conditions have precluded lichen establishment.

9.8.2. Local scale genetic structure of bryophytes

B. Shaw, J. Shaw;
Duke University, Durham, NC, United States.

Genetic variation in nature is structured at multiple scales. We describe the structure of genetic variation and phylogenetic relationships in mosses and liverworts at relatively local scales ranging from among-individuals within populations to among-populations within a particular geographic region. In contrast to traditional views of bryophytes as being largely clonal, genetic analyses over the last 25 years have revealed high levels of genetic diversity at local scales. Genetic/phylogenetic analyses at these scales provide insights into the relative importance of sexual and asexual reproduction in natural populations, gene flow patterns, natural selection, and interspecific hybridization. We also compare insights from different molecular approaches and evaluate the strengths and weaknesses of alternative methods. The applications of genetic and phylogenetic studies to conservation biology of bryophytes are reviewed. Finally, we suggest directions that should be given priority in future research.

9.8.3. Influence of forest modification on epiphytic bryophyte diversity in the tropics

I. Holz[1], N. Nöske[2], **R. Gradstein**[2];
[1]University of Greifswald, Greifswald, Germany, [2]University of Göttingen, Göttingen, Germany.

The dynamics of epiphytic bryophyte assemblages along disturbance gradients have rarely been investigated in the tropics. We sampled epiphytic bryophytes in primary and recovering secondary montane forests and on remnant trees in Costa Rica and Ecuador. Species richness values in primary and secondary forests did not differ significantly, showing that old-growth primary forests are not necessarily more diverse than secondary ones. Diversity on remnant trees, however, was significantly reduced. Canopy closure and atmospheric humidity were important parameters influencing bryophyte diversity along the disturbance gradient. Shade epiphytes and projecting life forms were most strongly affected by the environmental changes. Similarity in species composition of secondary and primary forests increased with forest age, but after 40 years of succession about one fourth to one third of the primary forest species had not re-established in secondary forest. Community composition in primary and secondary forests also differed markedly, indicating that long time is needed for re-establishment of bryophyte species and communities in the regenerating niches.

9.8.4. How does life history attributes shape local scale genetic structure?

U. Gunnarsson[1], K. Hassel[2];
[1]Dept of Biology, NTNU, Trondheim, Norway, [2]Dept of Natural History, NTNU, Trondheim, Norway.

In this study three dioicous species are compared; *Sphagnum angermanicum*, *S. fuscum* and *Pogonatum dentatum*, to see how differences in life history and ecology can be reflected in genetic structure within populations. The difference is mainly in frequency of sexual reproduction; *S. angermanicum* rarely sporulates, *S. fuscum* often have sporophytes and in *P. dentatum* sporophytes are common and numerous. This will affect the rate of recombination and together with differences in establishment rates shape the genetic structure. None of the species have specialised asexual reproduction but they occupy habitats of different longevity. Asexually formed clones may grow large in stable environments, reducing the risk of being eliminated by stochastic events and increasing sexual reproduction by formation of contact zones between sexes. In contrast, unstable environments rarely host large clones. Population level genetic structure data supports a trend from large uniform clones in the rarely reproducing species *S. angermanicum* to many small clones in the frequently reproducing *P. dentatum*.

9.8.5. Matrix population models - an unused tool among the bryologists

K. Rydgren;
Sogn og Fjordane University College, Faculty of Science, Sogndal, Norway.

Matrix population models have been used as an important tool in vascular plant and animal population biology for more than 20 years, addressing questions that otherwise are hard or impossible to analyse in a quantitative way, e.g. the lifetime impacts of herbivory and the effects of various kinds of disturbance. Matrix population models are also used in population viability analyses and is an important tool in population management studies. Bryologist have however been very slow to adopt these models, probably because of the general small size of bryophytes making tagging and tracking of individuals/ramets for following their fate hard or even impossible. In this presentation I will give a short introduction to the life cycle graph, linking the individual and the population, and the simplest matrix population model, the deterministic linear model. I will then go into the particular challenges associated with application on bryophytes before I exemplify the potential matrix models may have for bryologists.

9.8.6. Sexual reproduction in unisexual bryophytes - novel insights and implications

I. Bisang;
Swedish Museum of Natural History, Stockholm, Sweden.

Fifty to 60% of mosses and a slightly higher fraction of liverworts are unisexual. Despite an expected 1 female: 1 male progeny sex ratio at meiosis, female-dominated sex expression is the general pattern. More than $^{2}/_{3}$ of 103 taxa scored exhibit a female-biased sex ratio. Spatial segregation of sexes and skewed sex ratios affect the chance for sexual reproduction. Fertilization success in two pleurocarpous mosses is shown to be distance-dependent and limited by mate availability. Maximum fertilization ranges are several times larger than previous estimates. In *Dicranum polysetum* sporophyte formation incurs a cost in terms of reduced future growth and sex induction frequency. In the female-biased and rarely sporophytes bearing *Pseudocalliergon trifarium*, annual gametangial investment is larger in females than males, and gametangia formation does not affect vegetative growth. Thus, higher reproductive costs in males than in females cannot generally account for male rarity in unisexual mosses.

9.8.7. The role of sexual and asexual reproduction for local dynamics and rarity

L. Söderström;
Department of Biology, NTNU, Trondheim, Norway.

Formation of propagules is important for the survival of any species. Sexually produced propagules (spores) have a dual role as they also contribute to genetic diversification in addition to being able to disperse efficiently. Asexually produced diaspores do not contribute to the genetic differentiation (except for somatic mutations) but are important for the dispersal. As asexual diaspores are generally larger than spores they are assumed to contribute more to local dispersal and survival of populations while the smaller spores are assumed to be more important for distance dispersal.The frequency and size of spores and propagules in the liverwort family Lophoziaceae is analyzed in relation to rarity (distribution ranges and local population sizes) and the local dynamics. The latter is related to habitat persistence, i.e. how often a species need to move to a new locality/substrate patch due to disappearance of suitable substrate.

9.9.1. Phylogeny and biogeography of the angiosperm family Rubiaceae

E. Robbrecht[1], J. F. Manen[2];
[1]National Botanic Garden, Meise, Belgium, [2]Conservatoire et Jardin Botaniques, Chambésy/Genève, Switzerland.

Robbrecht's world survey, using trends to define subfamilies, was the last of an era. Simultaneously the first molecular analysis saw the light. The numerous such contributions are reviewed. Only Antirheoideae proved to be polyphyletic; the other subfamilies and many tribal concepts ± withstood the test of molecular phylogeny. Rubioideae were confirmed almost unchanged. Ixoroideae (s.lat.) and Cinchonoideae (s.str.) needed mutual re-delimitation, but can no longer be defined morphologically. At lower levels too, (partial) answers to long-standing disputes were given, e.g. on the question if Psychotria needs splitting.

(1) The position of Luculia and Coptosapelta, isolated at basal position in most of the former results, is re-analysed based on five chloroplast and three nuclear genes in order to examine the root of the Rubiaceae tree. (2) Published plastid phylogenies allow the construction of a supertree for more than 500 species in 300 genera, based on rbcL, atpB-rbcL spacer, rps16 and trnL-F. (3) A DIVA analysis of the geographical distribution of extant terminal taxa allows to reconstruct potential ancestral distributions.

9.9.2. Diversity and biogeography of the Mesoamerican Rubiaceae

C. M. Taylor[1], D. H. Lorence[2];
[1]Missouri Botanical Garden, Saint Louis, MO, United States, [2]National Tropical Botanical Garden, Kalaheo, HI, United States.

For study of origins of diversity in Rubiaceae, the native Mesoamerican Rubiaceae present a well documented case. Mesoamerica, the region comprising Chiapas, Mexico through Panama, is varied ecologically and physiographically with a complex geological history. Many highlands originated as islands, and the varying ages of these and adjacent regions require a more complex interpretation than areas of strictly continental origin. The Mesoamerican Rubiaceae comprise 804 species in 109 genera. 96 genera belong to 25 tribes; 13 genera are incertae sedis as to tribe. 8 genera are endemic to the region: of these 5 belong to Hamelieae, 1 to Sipaneeae, 1 to Hillieae and 2 incertae sedis for tribe. 351 species (44%) are endemic to this region, indicating significant diversification within it. Most of the endemic genera are from geologically older areas and habitats, while most of the endemic species are from younger ones. The continental Guianas have 60% as much area, 64% as many genera (77% shared), 2 endemic genera, and 50% as many species. High diversity of Rubiaceae is expected in other geologically complex regions, e.g. southeastern Asia and the Pacific Islands.

9.9.3. Evolution of myrmecophytism in Naucleeae s.l. (Cinchonoideae, Rubiaceae)

S. G. Razafimandimbison[1], J. Moog[2], H. Lantz[3], U. Maschwitz[2], B. Bremer[1];
[1]The Bergius Foundation at the Royal Swedish Academy of Sciences, Stockholm, Sweden, [2]Department of Zoology, University of Frankfurt, Frankfurt, Germany, [3]Deapartment of Systematic Botany, Uppsala University, Uppsala, Sweden.

Myrmecophytism occurs in 140 of the 11 000 species, 22 of the 630 genera, and 11 tribes of Rubiaceae. These rubiaceous myrmecophytic species are predominantly distributed in Southeast Asia, with comparatively few species in mainland Africa and the Neotropics. They produce different types of myrmecophytic traits that provide nesting space exploited by distantly related ant species. Evolution of myrmecophytism within the mostly paleotropical tribe Naucleeae s.l. and its most speciose genus Neonauclea s.s. is tested using molecular-based phylogenies. Our analyses strongly show that myrmecophytism has evolved independently at least two or three times within Naucleeae. They also support multiple origins of the Bornean myrmecophytic Neonauclea but perceive no support for either the hypothesis of a single origin of the Bornean myrmecophytic Neonauclea or that of monophyletic origin of the non-myrmecophytic Neonauclea. We conclude that the uniform myrmecophytic traits in the Bornean myrmecophytic Neonauclea have evolved through parallel evolution and therefore are likely to mislead morphological-based phylogenies if included in analyses.

9.9.4. Dating the Rubiaceae phylogeny

B. Bremer, T. Eriksson;
Royal Swedish Academy of Sciences, Stockholm, Sweden.

Rubiaceae is the fifth largest angiosperm family with over 10,000 species. We present a phylogeny with molecular dating of the family, including the three subfamilies, Rubioideae, Cinchonoideae, and Ixoroideae and a majority of the tribes. To get the underlying tree for dating, we performed different phylogenetic analyses of a maximum of 540 taxa and five different molecular markers (two protein-coding genes and three from non-coding regions). Branch lengths were estimated using maximum likelihood (GTR+G model), and dating used Bayesian and penalized likelihood methods. We used two different approaches when calibrating the tree. In the first, we accepted an estimate of 78 MYR for the stem lineage of Rubiaceae from an earlier analysis of the asterids as a whole. The second approach used available fossil evidence from within the Rubiaceae for calibration. All three subfamilies are of Palaeocene origin. The Ixoroideae tribes mainly diversified during Eocene and Oligocene and the Cinchonoideae and Rubioideae tribes diversified also during Miocene.

9.9.5. The circumscription of the Coffeeae (Rubiaceae) based on nuclear and plastid sequence data

A. P. Davis, M. Chester, O. Maurin, M. F. Fay;
Royal Botanic Gardens, Kew, Surrey, United Kingdom.

The tribe Coffeeae (Rubiaceae) was formerly restricted to two genera: *Coffea* and *Psilanthus*. Recent molecular studies (Andreasen & Bremer 2000, Amer. J. Bot. 87: 1731-1748; Persoon 2000, Nordic J. Bot. 20: 257-269.) infer that members of tribe Gardenieae subtribe Diplosporinae (viz. *Bertiera*, *Diplospora*, *Tricalysia*) should be removed from Gardenieae and placed in Coffeeae. Plastid sequences (*trnL* intron, *trnL-F* IGS, RPL 16 and *accD-psa1* regions) and nuclear sequences (ITS region) of the above genera and four other members of Gardenieae subtribe Diplosporinae (viz. *Argocoffeopsis*, *Calycosiphonia*, *Discospermum*, *Sericanthe*) support an enlarged concept for the

Coffeeae. *Belonophora*, a genus unplaced within the Rubiaceae tribal system, is also considered to a member of the Coffeeae. On the basis of the molecular and morphological evidence *Bertiera* is excluded from the Coffeeae.

9.9.6. Phylogenetic analysis of the subfamily Ixoroideae (Rubiaceae), with a focus on the controversial systematic position of some genera

R. Cortés-B.[1], P. G. Delprete[2], T. J. Motley[3];
[1]Herbario Forestal, Universidad Distrital, Bogota, Colombia, [2]Instituto de Ciencias Biologicas, Universidade Federal de Goias, Goiania, Brazil, [3]Lewis B. & Dorothy Cullman Program for Molecular Systematics Studies, The New York Botanical Garden, Bronx, NY, United States.

The subfamily Ixoroideae (Rubiaceae) includes many genera that exhibit secondary pollen presentation. Recent phylogenetic studies have resolved three major clades within the subfamily. One clade includes mainly the Ixoroideae sensu Bremekamp, the other two clades include genera that were traditionally placed in the subfamily Cinchonoideae. We have expanded the sampling to include more Paleotropical members of the subfamily and tested the unresolved placement of *Dialypetalanthus*, *Platycarpum, Posoqueria*, and *Retiniphyllum*. A phylogenetic analysis of the *trn*L-F spacer and *rps*16 intron confirmed the recent delimitation of the tribes Mussaendeae, Pavetteae, and Octotropideae and reject the inclusion of *Scyphiphora* in the Ixoreae. *Dialypetalanthus* is in a clade of subfamily Cinchonoideae genera. The other clade containing Cinchonoideae genera also includes *Platycarpum* and *Posoqueria*. *Retiniphyllum*, the single member of the tribe Retiniphylleae, is sister to a clade that comprises the Ixoroideae sensu Bremekamp. We are continuing to expand the sampling inside the tribes Sipaneeae, Henriquezieae, Posoquerieae, and Retiniphylleae.

9.9.7. Phylogenetic signal in morphological data

H. Ochoterena[1], S. Dessein[2], P. De Block[3], S. Jansen[4];
[1]Instituto de Biologia, Mexico, Mexico, [2]Laboratory of Plant Systematics, Institute of Botany and Microbiology, K.U.Leuven, B-3001 Leuven, Belgium, [3]National Botanic Garden of Belgium, Domein van Bouchout, B-1860 Meise, Belgium, [4]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey, TW9 3DS, United Kingdom.

Molecular revolution has markedly increased the number of systematic DNA-based phylogenetic studies. In contrast, morphological systematic studies have diminished and have even been discarded with the arguments that those matrices contain a high degree of homoplasy and are unreliable. We re-examine the value of organismic data even though it may contain homoplasy, using the Rubiaceae family as example. Parsimony analyses of more than 450 terminals with representatives of the main lineages of the Rubiaceae were performed. Analyses based on single DNA regions or on combined datasets yielded similar results at higher hierarchic levels, retaining three main clades. Organismic data, such as crystals, aluminum inclusions, pollen, flower and fruit characters corroborate these clades and others less inclusive. Combined analyses of molecular and morphological datasets show that morphology contains significant phylogenetic signal. Morphology facilitates the circumscription of diagnosable groups and allows the use of reciprocal illumination to (re-) examine cases of homoplasy.

9.10.1. Asexuality, polyploidy and the male function

M. Mogie, N. F. Britton, J. A. Stewart-Cox;
University of Bath, Bath, United Kingdom.

Polyploidy influences many aspects of asexuality in cosexual plants. These include: the expression of asexuality; the potential for reproducing sexually via the male function; the extent to which asexuals can coexist with related sexuals; and the geographic range over which asexuals are distributed. These influences will be examined. Detailed consideration will be given to the interaction between polyploidy and the male function in apomictic flowering plants and in asexual ferns. In apomictic flowering plants, polyploidy can cause disturbances during the reductional male meiosis. This can profoundly reduce the efficiency of the male function, which can increase the length of time apomicts and their sexual relatives coexist. In asexual ferns, male gametes are produced by processes that retain the full (sporophytic) chromosome number. As a result, crosses between related sexuals and asexuals result in offspring having a higher ploidy level than their asexual parent. This polyploidisation effect of the male function of asexuals can decrease the length of time asexuals and their sexual relatives coexist.

9.10.2. Apomixis may evolve by reticulate evolution and appears to be stabilized by asexuality or structural heterozygosity

J. G. Carman, T. Naumova, M. Jamison, B. Kowallis, J. Bradley;
Utah State University, Logan, UT, United States.

Gametophytic apomixis involves destabilizations of the megasporocyte or nucellar cells, the egg, and the central cell or polar nuclei. This is accompanied by the heterochronic elements of apomixis: unreduced embryo sac formation, parthenogenesis, and autonomous or pseudogamous endosperm formation. We discovered that onset timing of each major germline sequence (GS) stage is independently regulated by heterochrony gene(s) and that apomixis can be induced by uncoupling GS stages through reticulation-based breeding. Apomixis may have evolved in nature in a similar manner. In coadapted sexual ecotypes, systems of heterochrony genes responsible for timing of GS stages function harmoniously; but in certain reticulation-derived derivatives of hybridization, these gene systems compete causing intermediacy between sexuality and sterility with apomictic embryo sac formation, parthenogenesis, and autonomous or pseudogamous endosperm formation arising. For apomixis to persist in nature, the causal allelic combinations, from multiple loci, must be genetically stabilized. This is accomplished through sexual sterility or karyotypic heterozygosity.

9.10.3. Genetic diversity and reproductive biology in Italian populations of the facultative apomict *Hypericum perforatum* L.

G. Barcaccia;
Faculty of Agriculture, Legnaro, Padova, Italy.

Fingerprinting methods based on multi-locus DNA markers were used to determine the genetic diversity within and relatedness among landraces of St. John's wort. Five out of 15 sampled populations were grouped apart from the main cluster of populations revealing substantial levels of genetic differentiation. All populations resulted polyclonal and characterised by distinct rates of multi-locus genotypes. Flow cytometric analysis of both bulked and single seeds revealed variation in ploidy and suggested facultative apomixis for all populations. Cyto-embryological analysis showed that sexual and aposporic processes can initiate within the same ovule but only rarely sexual and aposporic embryo sacs are present together. Moreover, the egg cell is in an active metabolic state before pollination and likely its parthenogenetic activation to form an embryo occurs before fertilization and endosperm initiation. Comparison of cyto-histological and molecular data leads to the conclusion that natural selection effectively acts in favouring genotypes with an prevalent apomictic mode of reproduction so preserving the most locally adapted gene combinations.

9.10.4. Genetic diversity within and among Kentucky bluegrass (*Poa pratensis* L.) worldwide accessions

E. Albertini[1], L. Pallottini[1], T. F. Sharbel[2], G. Marconi[1], M. Falcinelli[1];
[1]Plant Biology and Agro-environmental and Animal Biotechnology Department, Perugia, Italy, [2]Institut für Pflanzengenetik und Kulturpflanzenforschung (IPK), Gatersleben, Germany.

Kentucky bluegrass (*Poa pratensis*) is a hardy, persistent, attractive forage and turf grass adapted to a wide range of soils and climate. Its mode of reproduction is extremely versatile and ranges from naturally obligate apomixis to complete sexuality. Because different plants may have contrasting modes of reproduction, *P. pratensis* could serve as a model species for investigating apomixis and its inheritance. We are currently investigating both candidate genes for apomixis and the evolution of the apomictic trait. Here we report the characterization of 33 accessions of Kentucky bluegrass collected in 24 countries. Most of the accessions (25) represent wild material whereas the other 8 are either the most cultivated varieties (such as, Banff, Midnight, and Princeton) or the most used for Kentucky bluegrass breeding (e.g. Nugget). Thirty plants per accession were grown and are maintained to study both morphological traits over a period of three years and the ploidy level through evaluation of DNA content. DNA was extracted from each genotype and analyzed by SSR markers, chloroplast SNPs and by a candidate gene-derived SCAR marker.

9.10.5. Genetic diversity and the dynamic nature of facultative apomictic complexes: the case of *Ranunculus auricomus*

E. Hörandl, O. Paun;
Department of Systematic and Evolutionary Botany, Faculty of Life Sciences, Vienna, Austria.

Sources and effects of genetic diversity in agamic complexes remain largely unexplained. The *Ranunculus auricomus* complex, comprising c. 600 allopolyploid, aposporous and pseudogamous agamospecies plus four di- to hexaploid sexual species, provides a model system for study. Isozyme, AFLP and SSR analyses revealed a high genetic diversity and divergence of sexual taxa; agamospecies harbour considerable genotypic variation within and among populations, which usually consist of predominant clones and a few deviating genotypes. Character compatibility analyses showed that genetic variation within apomicts is caused to a high extent by facultative recombination. Backcrossing of apomicts to sexual species, and hybridization between agamospecies contributes only locally to genetic variation of apomicts because of spatial and ecological differentiation. Apomicts occupy a broader range of habitats and a much larger distribution area than sexuals. The complex originated probably from wide crosses resulting in an initial pool of diverse asexual genotypes, and expanded via facultative sexuality and ecological differentiation of lineages.

9.10.6. Non-random patterns of hybridization, polyploidy, and B chromosomes in the *Boechera holboellii* complex: possible insights into apomixis origins?

T. F. Sharbel[1], T. Mitchell-Olds[2];
[1]IPK Gatersleben, Gatersleben, Germany, [2]MPI for Chemical Ecology, Jena, Germany.

The *Boechera holboellii* complex comprises *B. holboellii, B. divaricarpa* and *B. stricta*, members of which can reproduce through sex or apomixis. Sexuals are diploid, whereas apomictic individuals can be diploid or triploid, with or without B and aneuploid chromosomes. B chromosome carriers and triploids have originated via hybridization events between genetically and geographically divergent members of this group. Diploid plants containing the Bs reproduce apomictically, suggesting that the supernumerary elements are associated with apomixis. Repeated origins of B chromosomes and polyploidy imply that the apomictic phenotype has been expressed multiple times during the evolution of this complex. Analyses of single nucleotide polymorphisms (SNP) and microsatellites show that apomictic *Boechera* are characterized by similar levels of genetic variability compared to sexuals. The nature and genomic distribution of this variability will be discussed in light of the possible mechanisms which may have led to apomixis expression.

9.10.7. The costs and benefits of sexual and asexual reproduction in *Taraxacum.*

P. J. Van Dijk;
Netherlands Institute of Ecology (NIOO-KNAW), Heteren, The Netherlands.

In this paper I review studies of the cost of sex in natural dandelion populations (*Taraxacum officinale*). The cost of sex is largely a theoretical concept. The real costs of sex in nature depend basically on the biology of the system and its natural context. Over the last couple of years we have measured gene flow in mixed sexual-apomictic dandelion populations. We also have studied the heritability of apomixis. This allows us to estimate the cost of meiosis in the field. To evaluate these data for the long-term stability of mixed populations, we have integrated these data in computer models. Low triploid pollen fertility and non-transmission apomixis genes via haploid pollen transmission facilitate the coexistence of diploid sexuals and triploid apomicts dramatically. It is shown that tetraploids can play an important role in the generation of new asexuals, even although they are rare in mixed populations. Data show that sexuals experience an important cost of non-fertilized ovules in certain years with bad weather conditions during flowering period. Other costs of sex are discussed.

9.11.1. Aquatic primary production in artificial environments

C. Wilhelm;
Institute of Biology I, Leipzig, Germany.

Artificial aquatic environments are of growing importance. Water management measures in rivers and lakes have tremendous impact on the availability of light and nutrients for the primary producers. Eutrophicated lakes are often restored by means of destratification via bubbling plums which change nearly all environmental parameter like temperature, light climate and biological networks. Additionally, artificial new environments have been formed by flooding mining areas in different areas in the world. In some cases the resulting lakes contain extremely acidic water bodies up to values of 1.5. The efficiency of photosynthesis is of great importance in all these different ecotypes. In nutrient rich manipulated waters the efficiency of biomass formation should be as low as possible, whereas in new lakes from former coal mining photosynthesis should be contribute as much as possible to the alkalinisation. The symposium gives an overview on the conditions for primary production in these artificial waters and reports how the basic processes of biomass synthesis can be regulated on a physiological level.

9.11.2. Acidic Lakes: a challenge for aquatic botany and bioremediation.

W. Geller, J. Tittel, B. Zippel;
UFZ Centre for Environmental Research Ltd., Magdeburg, Germany.

Acidic waters show a very broad range of acidity and pH, from rain-acidified soft water lakes (pH 4-5.5) to geogenically acidic mining waters (pH 2.5-3) and extremely acidic volcanic lakes and rivers (till pH 0). The numbers of species living in these extreme systems decrease with lower pH. In the extremely acidic waters the algal species found were largely identical: Chlamydomonas acidophila, Keratococcus (Chlorella) raphidioides, Euglena mutabilis, and Ochromonas sp.. Biomass maxima were found as high as in eutrophic neutral lakes. In a nutrient rich acidic lake, growth rates and biomasses of a nearly monospecific phytoplankton community were measured continuously by automatic sampling, and growth reached rates as determined under laboratory conditions. Mixotrophy was important in these species to different degrees, showing both types, osmotrophy and phagotrophy. The phototrophic and mixotrophic algae, both grazed by Heliozoa (Actinophrys sol) as the top carnivore of the food chain, showed a stratification of physiological types, explaining the deep chlorophyll maxima (DCM) found in different pit lakes and in volcanic lakes.

9.11.3. Interactions between photosynthesis, respiration and nutrient acquisition in algae

J. Beardall[1], S. C. Roberts[1], E. B. Young[2];
[1]Monash University, Clayton, Australia, [2]University of Wisconsin-Milwaukee, Milwaukee, WI, United States.

Inorganic nutrient acquisition by algae usually occurs against a concentration gradient so is an energy demanding process, often with direct involvement of photosynthetic energy pathways. Assimilation of inorganic nutrients, particularly nitrogen, also requires the supply of C skeletons from photosynthesis or from intermediates of respiratory pathways. Conversely, inorganic nutrients are essential for maintenance of energy transduction systems. This interdependence results in complex interactions between nutrient uptake and assimilation processes and photosynthetic and respiratory energy metabolism. In this paper, we review 1) the basic processes by which algae take up nutrients such as C, N and P, 2) the energy requirements for the uptake and assimilation of these nutrients and 3) what is known about the biochemical interactions between energy metabolism and nutrient acquisition. We will discuss the consequences of nutrient uptake and assimilation to rates of respiration and photosynthesis and how these can be investigated. We also show how these interactions can be exploited in assessing nutrient status of algal cells in the environment.

9.11.4. A possible phosphorus limitation in *Chlamydomonas acidophila* Negoro living in a low pH environment

E. Spijkerman[1], V. Bissinger[1], A. Meister[2], U. Gaedke[1];
[1]Biochemistry and Biology, Potsdam, Germany, [2]Institute of Plant Genetics and Crop Plant Research, Gatersleben, Germany.

Chlamydomonas acidophila, a dominant phytoplankton species in the very acidic Lake 111 (pH 2.65) faces low concentrations of inorganic carbon (C_i), phosphate (P_i) and potassium (K^+). In an integrated laboratory and field investigation, the potential (co-)limiting factors operating within this lake were explored. Measurements of phosphatase activity, threshold concentrations of soluble reactive phosphorus (SRP_t) and C:P ratios all suggested that the growth of this alga was potentially limited by P_i. Analysis of field samples suggested that phosphatase activity did not result from a complexation of P_i with either metals or organic carbon. Furthermore, the cellular P_i demand in *C. acidophila* was similar to those in other *Chlamydomonas* species. Low K^+ concentrations resulted in higher minimum phosphorus quotas (Q_0) and higher SRP_t than in P_i-limiting medium. Moreover, low K^+ concentrations decreased the cellular chlorophyll a content and possibly explain the low primary productivity rates measured in Lake 111. A relationship between CO_2 concentration and Q_0 was observed under K^+/P_i-limited conditions, but not under P_i-limited growth.

9.11.5. Photoprotection in phytoplankton: regulation and ecophysiology

J. Lavaud, P. Kroth;
University Konstanz, Konstanz, Germany.

The photosynthetic efficiency and productivity of phytoplankton depend on the light environment which can be highly variable in aquatic ecosystems. Fluctuating irradiances due to water motions and especially excessive light exposure can be harmful for the photosynthetic apparatus. In order to cope with fluctuating light intensities, phytoplankton organisms have developed various mechanisms for their photoprotection. They safely dissipate, ‘deviate’, store and recycle excess energy from light absorption. Among theses mechanisms, the dissipation of excess energy (or NPQ, non-photochemical chlorophyll fluorescence quenching) is considered as one of the most important mechanisms on the short time scale (seconds and minutes). New results will be presented : 1) on the regulation of NPQ in diatoms and cyanobacteria, and compared to land plants, 2) on the potential involvement of photoprotection in the spatial distribution (coastal, open ocean, etc) of species in relation to the turbulence of waters, and consequently the range and rapidity of light fluctuations they are submitted to.

9.11.6. Photoacclimation processes in phytoplankton: Mechanisms, consequences and applications

Z. Dubinsky;
Faculty of Life Sciences, Bar Ilan University, Ramat Gan, Israel.

In nature and bioreactors phytoplankton are exposed to fluctuations in light intensity. These include seasonal and diel changes in irradiance, and those stemming from vertical mixing over the light field. In algal mass cultures and photobioreactors similar changes take place as cultures grow denser, and as cells are mixed in the system. In order to survive supraoptimal, free radical generating irradiance levels as well as exposure to dim light phytoplankton species are capable of photoacclimation. Light harvesting pigments increase under low light, decreasing under high light, resulting in cells being rather transparent under strong light all the way to optically black under limiting irradiance levels. These processes are complemented up to five fold changes in Rubisco per PSU levels, resulting in parallel changes in light-saturated photosynthetic rates. Photoacclimation can be used to optimise biomass and target product yields in biotechnological applications.

9.11.7. Photoautotrophic growth under acidic conditions: A physiological comparison of two *Chlamydomonas* species

U. Langner, T. Jakob, C. Wilhelm;
University, Leipzig, Germany.

Mining lakes in central Germany are characterized by low pH-values (2.6 - 3) and high cFetot (3 µM). Chlamydomonas acidophila (C. a.) isolated from an acidic lake was physiologically compared to the wild type strain Chlamydomonas reinhardtii (C. r.). Growth rates of C. a. at pH 2.65 were similar to those of C. r. at pH 7. Both algae showed almost the same carotenoid composition, whereas Chl a/b ratio is twice as high in C. a. as in C. r.. The photosynthetic performance was investigated with PAM-, fast fluorescence and oxygen evolution measurements. Both species have similar quantum yield and photosynthetic capacities under growth conditions. Fluorescence induction curves indicate an increased reduction state of the PQ-pool in the dark, fast transitions from state 2 to state 1 at low light and a stable state 2 at high light. These effects were more pronounced in C. a.. In both strains the fluorescence based electron transport rates do not match the oxygen evolution rates on the basis of absorbed quanta. As a conclusion, we propose that both species operate with alternative electron cycling and that it is an adaptive mechanism in an acidic environment for C. a..

9.12.1. New perspectives on the role of Plasmodesmata and Raffinose-family Oligosaccharides in phloem loading

R. Turgeon;
Cornell University, Ithaca, NY, United States.

The extremely high hydrostatic pressure in the phloem of most higher plants results from an energetic concentration of soluble carbohydrates in the sieve elements and companion cells (phloem loading). Loading in the minor veins of leaves occurs by two species-specific mechanisms. One involves plasma membrane transporters (apoplastic loading) while the other involves plasmodesmata (symplastic loading). It has been postulated that plants using these alternate mechanisms can be distinguished on the basis of plasmodesmatal frequencies. However, studies on several species with abundant minor vein plasmodesmata indicate that they load via the apoplast. Symplastic loading appears to be associated exclusively with the transport of raffinose-family oligosaccharides (RFOs) by polymer trapping. Species that do not translocate these sugars load via the apoplast, no matter how abundant their minor vein plasmodesmata. We suggest that the adaptive significance of RFOs in phloem transport lies exclusively in their role as polymer trapping agents. Symplastic loading will be discussed from ecological and evolutionary perspectives.

9.12.2. Reduction in nucleotide-sugar supply for cell wall polymers cause changes during seedling development

R. Tenhaken, M. Klinghammer, U. Kanter;
Biocenter, Frankfurt, Germany.

Arabidopsis primary cell walls contain large amounts of hemicelluloses and pectic polymers. Roughly 50% of the cell wall biomass is synthesized from the nucleotide sugar UDP-glucuronic acid, the precursor for arabinose, xylose and galacturonic acid. Two pathways contribute to the synthesis of UDP-glucuronic acid from photosynthesis assimilates, each being controlled by a small gene family in Arabidopsis. The entry key enzymes are UDP-glucose dehydrogenase or inositol oxygenase in the second pathway, respectively. Both reactions lead to an irreversible oxidation of their substrates. Thereby the nucleotide sugar pool used for the synthesis of storage compounds is separated from the pool for cell wall polymers. Knock-out mutants in single genes lead to viable plants with almost normal phenotype. However, a more detailed analysis revealed changes in individual mutants, effecting root growth, cotyledons or flower development. The changes are specific for particular isoforms indicating an individual role for each member of the gene family. The phenotypes of knock-out mutants and aspect of pathway cross-talk will be discussed.

9.12.3. Soluble sugars and starch in leaves of congeneric savanna and gallery forest trees

I. Nunes Cornelio[1], A. A. Richter[2], A. C. Franco[1];
[1]University of Brasília, Brasília, Brazil, [2]University of Vienna, Vienna, Austria.

The central plains of Brazil are occupied by a complex of seasonal savannas and gallery forests, known locally as “cerrado”. In the cerrado, the radiation of woody plants into savanna and forest species has occurred independently in a large number of genera. In this study, we compared the soluble sugars and starch concentrations in leaves of eight congeneric pairs of savanna and gallery forest trees in the wet and dry season. Forest species showed higher concentrations of both starch and soluble sugars. However, starch concentrations were significantly higher in the wet season while soluble sugars were higher in the dry period. This result suggests a reduction of starch by low water availability and therefore to a drop in the supply of carbon compounds in the leaves during the dry season. Sucrose was the most abundant soluble sugar. Pinitol was detected only in five out of the 16 species and had higher amounts in the dry season, when light interception by evergreen trees is much higher. In leaves, pinitol is considered to play a role as an antioxidant. Thus, this increase in the dry season may be related to photoprotection. CAPES, CNPq, FINATEC.

9.12.4. Phloem loading in two Scrophulariaceae species: what can drive symplastic flow via plasmodesmata?

O. V. Voitsekhovskaja[1,2], O. A. Koroleva[3], D. R. Batashev[2], C. Knop[1], D. Tomos[3], Y. V. Gamalei[2], H. Heldt[1], G. Lohaus[1];
[1]A.-von-Haller Institute for Plant Sciences, Goettingen, Germany, [2]V.L. Komarov Botanical Institute RAS, Saint-Petersburg, Russian

Federation, [3]School of Biological Sciences, University of Wales, Bangor, United Kingdom.

In order to determine the driving forces for symplastic sugar flux between mesophyll and phloem, gradients of carbohydrate concentrations and of osmotic pressure were studied in leaf tissues of *Alonsoa meridionalis* and *Asarina barclaiana*. In *A.meridionalis*, phloem loading is symplastic as indicated by intermediary companion cells in the minor vein phloem. In *A.barclaiana,* two types of companion cells, modified intermediary cells and transfer cells, occur in minor vein phloem, indicating a complex loading. We identified all phloem-transported carbohydrates in both species and analyzed the levels of carbohydrates in chloroplasts, vacuoles and cytoplasm of mesophyll cells. Osmotic pressures in single cells, whole leaves and phloem saps were compared. The data show that diffusion of sugars along their concentration gradients cannot be the major mechanism for symplastic phloem loading in these species. We conclude that in both plants, apoplastic phloem loading is an indispensable mechanism, and symplastic entrance of solutes into the phloem may occur by mass flow. The conditions favoring symplastic mass flow from mesophyll into the phloem are discussed.

9.12.5. Import of glucose 6-phosphate into amyloplasts and its impact on potato tuber starch content

L. Zhang[1], C. Greiten[1], S. Haghnazarian[1], I. Haferkamp[2], J. Tjaden[2], H. E. Neuhaus[2], R. E. Häusler[1], U. I. Flügge[1], **F. Ludewig**[1];
[1]Department of Botany II, Cologne, Germany, [2]Department of Plant Physiology, Kaiserslautern, Germany.

Amyloplasts depend on the import of carbon and energy to synthesize starch. Carbon enters the amyloplasts in form of glucose 6-phosphate via the glucose 6-phosphate/phosphate translocator (GPT), and energy is imported as ATP via the adenylate translocator (NTT). We analyzed the impact of decreasing or increasing glucose 6-phosphate import into amyloplasts of potato tubers on starch synthesis and composition as well as tuber yield. Following an RNAi strategy GPT activity was decreased, on the other hand plants were created that simultaneously overexpressed pea GPT and Arabidopsis NTT to increase the corresponding transport activities. Whereas an increase of both carbon and energy import into tuber amyloplasts led to increased tuber starch content and yield, decreasing carbon (and also energy) import led to opposite effects. These findings suggest that carbon and energy import into tuber amyloplasts co-limit starch production and tuber yield of potato plants.

9.12.6. Role of quercitol in drought stress adaptation of eucalypts

S. K. Arndt, A. Merchant, S. J. Livesley;
School of Forest and Ecosystem Science, Creswick, Australia.

The occurrence of the cyclic polyol quercitol among certain eucalypt species correlates strongly with the distribution of these eucalypts in arid environments. Yet, the function of quercitol in stress adaptation to low internal and external water potentials is unknown. We investigated the role of quercitol as a stress metabolite in a glasshouse experiment containing 13 eucalyptus species and a field study with *Eucalyptus astringens*. Seedlings of all species investigated contained quercitol and it occurred in leaves, branches, stems and roots of these species. Quercitol concentration decreased during the growth of well-watered plants and drought stressed plants of “mesic” species, whereas it was maintained or increased in droughted “xeric” species in the glasshouse experiment. In “xeric” species in the glasshouse and in *E. astringens* in the field tissue concentrations of quercitol increased after drought exposure (up to 300 mmol kg DW) and contributed to an overall increase in leaf osmolality. Quercitol played a vital role in the osmotic adjustment and contributed to around 20% of the total osmotic potential of *E. astringens* in all plant organs.

9.12.7. Leaf metabolites provide functional links between physiology and evolution in the genus *Eucalyptus*

A. Merchant[1], M. A. Adams[2];
[1]School of Forest and Ecosystem Science, Creswick, Australia, [2]Centre of Excellence in Natural Resource Management, Nedlands, Australia.

Increasing aridity is universally regarded as a major factor in the evolution of the Australian vegetation. The genus *Eucalyptus* contains more than 700 species that collectively represent a broad ecological spectrum. *Eucalyptus* spp. constitute the dominant stratum among a range of ecological types, from the wet sclerophyll forests characteristic of the south east of the continent, to the woodlands of the dry interior where rainfall may be as little as 250 mm per annum. Targeted metabolite profiling has, for the first time, uncovered a quantitative yet discrete biochemical link with eucalypt taxonomy and evolution. Here I present a broad, metabolite-based analysis of the genus, targeting soluble carbohydrates and polyols, that is then discussed in relation to adaptation of *Eucalyptus* spp. to aridity. In particular, the distribution of cyclic polyols (cyclitols) among *Eucalyptus* species, and their proposed functions in plant tissues, provides putative links with the acclimation of trees to arid environments.

9.13.1. Metabolomics: a key technology for systems biology

R. Verpoorte, Y. H. Choi, H. K. Kim;
IBL, Leiden, The Netherlands.

What is the function of a gene? For all approaches to this question the characterization of the phenotype is the key. A phenotype can be characterized morphologically, chemically (metabolomics) and biochemically (proteomics). Metabolomics aims at the identification and quantification of all metabolites (metabolome) in an organism, proteomics gives a view of the proteins.

One can use a targeted approach for selected compounds, or a non-targeted approach in which as many as possible compounds are measured. In both cases one can aim at the identification of all compounds or only those that show variation. Methods applied are: chromatography (LC, GC), mass- (MS) and NMR-spectrometry. Each has limitations. Chromatographic methods and MS are most sensitive, in NMR all compounds can be quantified with a single internal standard. Reproducibility of NMR is best. Chromatographic methods are dependent on the columns. No methods fulfills all demands for the ultimate goal: measure all metabolites. NMR gives a macroscopic view of the metabolome, the other methods may be used for specific groups of metabolites. Metabolomics is a major tool for systems biology.

9.13.2. Metabolic Characterization of Phytochemicals and their Metabolic Effects

E. Holmes;
Imperial College, London, South Kensington, London, United Kingdom.

Metabonomics combines sophisticated analytical tools such as NMR spectroscopy and mass spectrometry with multivariate statistical analysis to generate complex metabolic profiles of plant and animal tissues, fluids and cell extracts. The technology provides a systems approach to measuring dynamic biochemical responses of organisms to biological stimuli and operates by profiling the metabolic responses of key intermediary biochemical pathways. Such analysis generates information regarding the metabolic status of organisms, metabolic phenotypes of genetically modified organisms and enables prediction of a range of pathological conditions. Various chemometric strategies for optimizing the characterization and interpretation of complex spectra can be adopted to increase the sensitivity of metabonomic analysis and to accommodate the dynamic nature of living systems. Applications in plant biology include quality control of plant products and characterization of growth/ageing, stress responses, geographical origin and growth conditions. In addition the technology is explored as a tool for profiling metabolic consequences of phytochemicals.

9.13.3. Multidisciplinary pattern recognition: a tool to find proper medicinal plants within the genus Achillea

J. Saukel[1], R. Mittermayr[1], R. Hiessböck[1], G. Galla[1], Y. Guo[2], S. Glasl[1], F. Ehrendorfer[2];
[1]Pharmakognosie, Vienna, Austria, [2]Systematic and Evolutionary Botany, Vienna, Austria.

The genus Achillea includes about 130 species, i. a. “A.millefolium L.”, which is the required source of “Millefolii Herba” in the European Pharmacopoeia. A content of not less than 0.02% chamazulene is requested. This is confusing, as A. millefolium L. s.str. is now more narrowly defined as a hexaploid species which lacks proazulenes, the precursors of chamazulene. Therefore, we searched for pharmaceutically more appropriate members within the species group of A.millefolium agg. which includes about 20-30 different, diploid (2x) to polyploid (4x, 6x and 8x) taxa throughout the N. Hemisphere. For this purpose, many populations (each with 5-50 individuals) from about 30 taxa from Achillea and A.

millefolium agg. were screened with multidisciplinary methods: morphometrics, anatomy, phytochemistry (GC, GC-MS, TLC), cytogenetics and DNA-analyses (ITS and trnL-F sequences, AFLP, plastid haplotypes). Our results show that the A. millefolium agg. is the hybrid linked crown group of the genus. As a polyploid complex it exhibits an enormous spectrum of diversity which is recombined in various ways in its species, of which some correspond to medicinal requirements.

9.13.4. Correlative GC/TOF/MS based metabolite profiling and LC/MS based protein profiling reveal time-related systemic regulation of metabolite-protein networks and improve pattern recognition for multiple biomarker selection

W. Weckwerth, K. Morgenthal, S. Wienkoop, M. Scholz, J. Selbig;
Max-Planck-Institut für Molekulare Pflanzenphysiologie, 14424 Potsdam, Germany.

A novel approach is presented combining quantitative metabolite and protein data and multivariate statistics for the analysis of time-related regulatory effects of plant metabolism at a systems level. For comparison, leaves of wild type plants and starchless mutant plants deficient in phosphoglucomutase activity (PGM) were sampled at intervals throughout the day/night cycle. Using principal and independent component analysis, each data set (metabolites and proteins) displayed discrete characteristics. The integrated metabolite/protein data set resulted in an improved ability to distinguish between WT and PGM plants (first independent component) and, in parallel, to see diurnal variations in both plants (second independent component). The described method is applicable to all kinds of biological systems and enables the unbiased identification of biomarkers embedded in correlative metabolite-protein networks [1, 2]. [1] Weckwerth, W., Wenzel, K., Fiehn, O., *Proteomics* 2004. [2] Morgenthal, Wienkoop, S., Scholz, M., Selbig, J., Weckwerth, W., *Metabolomics* 2005.

9.13.5. Metabolic profiling of root and shoot-induced changes in *Brassica nigra* (Brassicaceae).

R. Galiart[1], Y. H. Choi[2], K. Rani[3], H. J. Bouwmeester[3], **N. M. van Dam**[1];
[1]NIOO-KNAW, Heteren, The Netherlands, [2]Institute of Biology, Leiden, The Netherlands, [3]Plant Research International, Wageningen, The Netherlands.

Plants produce a wide variety of chemical compounds as defences against the many phytophages in their natural environment. Many of these compounds are inducible and their levels will change after the plant has been damaged. Interactions between induced defences have been studied extensively for aboveground (AG) herbivores, but there is increasing evidence that root feeders (BG) induce systemic responses that affect aboveground phytophages, and *vice versa*. These AG-BG interactions may have a significant impact on how induced defences function and evolve in natural environments.We used GC MS and 2D NMR analyses to study the metabolic state of *Brassica nigra* plants after shoot or root induction with jasmonic acid (JA). Our data show that JA-application induces changes in both primary and secondary metabolite levels. Furthermore, plants induced with JA to the roots show a different metabolic profile than shoot-induced plants. We will discuss metabolic profiling as a technique to help us unravel interactions between root and shoot-induced defences. Eventually, we will link these interactions to plant and phytophage performance in both lab and field conditions.

9.13.6. Analysis of of *Hypericum perforatum* (St. John's Wort) lots by NMR based metabonomics

C. Seger[1], S. Sturm[1], E. Humpfer[2], H. Schäfer[2], M. Spraul[2], H. Stuppner[1];
[1]University of Innsbruck, Institute of Pharmacy, Department of Pharmacognosy, A-6020 Innsbruck, Austria, [2]Bruker-Biospin GmbH, D-76287 Rheinstetten, Germany.

Hypericum perforatum L. (Clusiaceae), also known as St. John’s wort, is one of the best characterized phytotherapeuticals on the market. A broad variety of secondary metabolites (e.g. phloroglucinols, flavonoids, naphtodianthrones) have been characterized and their pharmacological activities have been evaluated. Within the last years, addressing biological diversity and metabolic time courses have become major topics of NMR based metabonomics. This methodological approach does combine 1D proton NMR spectroscopy with chemometrical data processing. We applied this methodology to *H. perforatum* drug batches of different origin serving as test case sample for investigating secondary metabolite profiles of phytopharmaceuticals. A principal component analysis (PCA) carried out with 600 MHz 1D ^{1}H-NMR spectra allowed to discriminate the lots unambiguously. The correlation of the obtained differentiation with specific spectral regions was facilitated by the loading plots. The obtained results are compared to HPLC-DAD/MS derived metabolic profiles obtained from the identical samples.

9.14.1. Vegetation survey: moving to larger scales

M. Chytry;
Masaryk University, Brno, Czech Republic.

Survey research of plant community diversity across landscapes has a long tradition, particularly in continental Europe where phytosociological vegetation classification has been a popular occupation of plant ecologists throughout the past century. Currently there is an increasing demand in many parts of the world for vegetation surveys over large areas to be used for habitat inventory, monitoring and setting conservation priorities. With the increasing availability of information technologies such as database management software, multivariate statistical methods and geographic information systems, the focus of vegetation survey is shifting from local to large scales. Two major trends can be recognized. In the countries with a long tradition of vegetation sampling, many thousands of vegetation plot records were stored in electronic databases and revisions of previous vegetation typologies, using formalized methods, were prepared. In other countries, where survey research is newly introduced, stratified sampling plans designed with GIS are used, which minimize the sampling effort in the field and maximize the representativeness of the data.

9.14.2. Constancy values depend on plot size - a problem for vegetation classification and how it can be solved

J. Dengler;
University of Lüneburg, Lüneburg, Germany.

Most approaches to vegetation classification are based on the comparison of constancy values between different units. As species richness is a function of plot size, constancy values must be, too. In phytosociology, nevertheless, most authors use varying plot sizes as long as these exceed the so-called ‘minimal area’. However, from a statistical point-of-view it is not correct either to calculate constancies for plots with varying size or to compare these between units sampled on different areas. Moreover, classification results crucially depend on the used plot sizes (‘spatial grain’). Thus, recently several proposals have been made to standardise relevé areas for future studies. However, the question remains how to make use of the millions of ‘old’ data. Based on literature and own data from different vegetation types, I analysed whether the increase of constancies with increasing plot size follows a certain ‘law’. It can well be described by a function of the form $C (A) = 1 - (1 - C [A_0])^{(A/A0)\ \hat{}k}$ with C being the constancy, A the area and k a parameter. I present values of k for several plant communities and test the validity of extrapolations by use of this function.

9.14.3. Vegetation inventory and mapping of Taiwan

C. Chiou[1], M. Chen[2], T. Chen[3], K. Fang[4], C. Hsieh[1], H. Liu[5], C. Yu[6];
[1]National Taiwan University, Taipei, Taiwan Republic of China, [2]National Chung-Hsing University, Taichung, Taiwan Republic of China, [3]National Ilan University, Ilan, Taiwan Republic of China, [4]Forestry Bureau, Taipei, Taiwan Republic of China, [5]National Sun Yat-sen University, Kaohsiung, Taiwan Republic of China, [6]Council of Agriculture, Taipei, Taiwan Republic of China.

Taiwan has a great diversity in natural forests ranging from subalpine thickets to tropical rain forests. Although the flora, vegetation formations and principal forest types are well known, there is no detailed vegetation classification based on floristic composition available. It is determined to map the natural vegetation in five years to the scale 1:5000 even the accessibility in many regions is difficult and the orthophotos are the only available images. The classical approach is modified with GIS technology. The delineating polygons are classified based on the corresponding environmental types, which are created by GIS. Sampling sites then chosen according to the combined analyses of vegetation polygons and environmental types. Finally aero and ground surveys are taken to evaluate polygon homogeneity, to make releve sampling, and to refine the polygon attributes. All survey data, including old vegetation survey data, are stored in Taiwan Vegetation Information System, which will be used to establish a national vegetation classification system based on sampling data analyses, and to map the distribution of community types.

9.14.4. The U.S. national park system vegetation characterization and mapping program

G. S. Waggoner[1], K. Brown[2];
[1]U. S. Geological Survey (Retired), Englewood, CO, United States, [2]U. S. Geological Survey, Lakewood, CO, United States.

This paper describes the origins, protocols, standards, and status of the 10 year old USGS/NPS Vegetation Characterization and Mapping Program (http://biology.usgs.gov/npsveg/). Experiences in using the U.S. National Vegetation Classification System developed through cooperative efforts of the Federal Geographic Data Committee, The Ecological Society of America, NatureServe, and the National Park Service and U.S. Geological Survey will be described. Currently under review and revision, the NVCS, classifying existing vegetation, is a 7 tier hierarchical schema nesting general physiognomic types with detailed floristic types. The Program has thus far identified, described, quantified, classified and mapped hundreds of distinct plant association types within the 24 parks completed. Over 100 more parks widely distributed across the nation’s biomes and ecosystems are currently under study. Many applications of the digital vegetation data have been developed to support park management. Three new protocols dealing with small parks, sparse vegetation types, and fire fuels data collection for fire behavior models are also presented.

9.14.5. 'Synthetic floras' - a flexible tool in large scale vegetation analysis

V. Mosbrugger, C. Traiser, S. Klotz;
IFG Institute of Geosciences, University of Tuebingen, Tuebingen, Germany.

The concept of synthetic floras offers a wide range of applications in large scale vegetation sciences. A synthetic flora comprises all species occurring at a given locality or grid cell and is derived from overlapping species distribution maps. Consequently, a synthetic flora list reflects rather the potential than the real vegetation of a locality. The compilation of large grid data sets of synthetic floras allows to analyse large scale spatial (e.g. continental) patterns of biodiversity, of vegetation composition and of the respective controlling environmental factors. Furthermore, these grid based synthetic floras can be used to classify vegetation with regard to a multitude of characteristics such as morphologic, physiologic and ecologic traits. The concept and use of synthetic floras is illustrated for an European data set of woody angiosperms covering 108 species and 5166 (0.5° x 0.5° lat./long.) terrestrial grid cells.

9.14.6. Is vegetation classification a natural or an artificial classification?

G. Kuhn;
Bavarian State Research Center for Agriculture, Freising, Germany.

So-called artificial classifications generally use only few attributes of the objects to be classified, are designed for pragmatic purposes and are directly applicable, e.g. separating eatable from poisonous plants.

In contrast to this 'natural' classifications (including vegetation classification) are general-purpose classifications of high predictive value, which are destinated to represent causal relationships between the objects. They shall arrange objects so that a maximum of correlation can be found in each class. Furtheron generation of hypotheses shall be facilitated and, after all, the classification should allow scientific progress. The criterion for a 'good' natural classification is not to approach 'reality' but to produce useful classes for defined purposes (such as just mentioned) which can be proved by being widely used in scientific communities or in everyday life.In my contribution the logical relationship of phytosociological classification to artificial and natural classifications and the resulting consequences for syntaxonomy shall be explained.

9.15.1. Narrow endemism as a top priority in taxonomy and conservation (a crimean example)

A. V. Yena;
Crimean Agrotechnological University – Southern Branch of National Agrarian University, Simferopol, Ukraine.

The vascular flora of the Crimean peninsula (Ukraine) was a model for studying endemism during 150 years, with assessments varying from 12 to 279 species endemic to Crimea. I reconsidered Crimean endemism to 127 species, and it fits well the phytogeographical gradients. The study showed again a pressing need to overcome disagreements and parochialism for making data on endemism more realistic and comparable. Defining endemism, I recognize chorionomic and scaled approaches. When combining them, narrow endemics can be referred to areas not exceeding e. g. Sicily, Peloponnesus, or Crimea. Such areas correspond to one of the IUCN criteria for endangered and vulnerable taxa so that wider ranges refer to lower risk taxa. Each country is primarily responsible for preserving its narrow endemics, even those yet to be reconsidered taxonomically and phytogeographically. This will help avoiding the "agony of choice", misselected taxa, resource dispersing, and overfilling of Red Lists. Because of their monotopic origin, all species were sometime narrow endemics. That is why the latter should be considered as a key but fragile potential for further plant cover evolution.

9.15.2. Endemism, rarity, and reintroduction: A case study in *Silene* (Caryophyllaceae)

S. R. Kephart, D. Lofflin;
Willamette University, Salem, OR, United States.

Endemism arises for multiple reasons, from anthropogenic habitat alteration to range extension into newly created landscapes. Today botanists are increasingly faced with enhancing native populations at risk for extinction. Thus, reintroduction of rare species into historically-occupied habitats is a tactic growing in popularity: it simultaneously increases population size and diversifies gene pools. A 20-yr case study of rare vs common *Silene douglasii* (Caryophyllaceae) illustrates the factors affecting rarity in herbaceous perennials and the potential means of population recovery. Demographic analysis shows that inbreeding, seedling establishment, and loss of pollinators all contribute to rarity and recovery in rare var *oraria*, extant only in 3 sites. Despite similar ex situ germination, seed reintroduction produced significantly fewer juveniles of *oraria* than common var *douglasii*, and outbred transplants had higher survival and reproduction. Nocturnal moth pollinators also visit only common vars *douglasii* and *rupinae* indicating key roles for pollination and genetics in crafting effective restoration strategies for endemic plants.

9.15.3. *Allium* L. sect. *Codonoprasum reichenb*. (Alliaceae), a taxonomic and chorological study: what is a taxonomic value of narrow endemics?

A. P. Seregin;
M. V. Lomonosov Moscow State University, Moscow, Russian Federation.

Allium subgen. *Allium* (*Alliaceae*) is evolutionary the youngest subgenus of the genus. Taxonomy of *A.* sect. *Codonoprasum* Reichenb. is complicated, because species limits are not consistent, a lot of infraspecific taxa unsuitable for modern *Allium* taxonomy were described, and identification of herbarium specimens is unreliable. Some widely spread species of the section form local derivates, which are being described as narrow endemics: about 10 new species were described during past 15 years, though the revision of the whole section was not submitted. According our revision the section includes 68 species (and 7 subspecies) of total 750 species in the genus. Species of the section are widely spread in Europe, North Africa and Middle East. Territory of Greece and Turkey is the main centre of species diversity with high level of endemics. The species of the section look rather uniformly, though there are some species, which are intermediate in habit between *A.* sect. *Codonoprasum* and *A.* sect. *Scorodon* C. Koch. The following evolutionary trends were determined provisionally: spring blooming Ÿ autumn blooming, umbels without bulbils Ÿ umbels with bulbils.

9.15.4. Distribution patterns and conservation measures of local endemic Centaurea species In Turkey

T. Ekim[1], M. Vural[2], Z. Aytaç[2], H. Duman[2], N. Adigüzel[2];
[1]Istanbul University, Science Faculty, Istanbul, Turkey, [2]Gazi University, Faculty of Art and Science, Ankara, Turkey.

Compositae represented by the highest number of species and subspecies is the largest family within Turkey. *Centaurea* genus of this family has an exceptional position among the other genera and also in Flora of Turkey. It is the third richest genus in terms of the number of species and the endemic species, following *Astragalus* and *Verbascum* genera. According to the Turkish Flora *Centaurea* genus comprises 184 species, 111 of which are endemic. The endemism ratio is 62 % with 142 endemic taxa. Besides some widespreaded endemic species, some are only restricted to a few localities. In this presentation, distribution patterns of narrow endemics in CR and EN categories of Red Data Book and their relation with the ecological factors were explained. Additionally, the conservation measures taken for the threatened or endangered endemic species were also stated.

9.15.5. Narrow endemism and its bearing on conservation in the floras of Madagascar and New Caledonia

P. P. Lowry II, G. E. Schatz;
Missouri Botanical Garden, St. Louis, MO, United States.

The exceptionally diverse floras of Madagascar (c. 12-13,000 spp.) and New Caledonia (c. 3,300 spp.) are renowned for their high rates of endemism at the species level (c. 90% and c. 76%, respectively) and also at higher ranks. A large portion of the endemic species on both of these ancient continental islands have highly restricted geographic distributions and/or occur at a limited number of sites, and thus qualify as narrow endemics. Recent studies have shown that species ranges on both islands are strongly correlated with physical and eco-geographic parameters (e.g., bioclimate, substrate, elevation) whose complex spatial distribution largely accounts for the high proportion of narrow endemics. We examine some of these correlations, provide examples of factors that may have generated local centers of endemism, and discuss the concepts of Extent of Occurrence, Area of Occupancy, range-size rarity (endemism richness), and irreplaceability in relation to narrow endemism, and the critical role narrow endemics must play in conservation planning.

9.15.6. Recovering narrow endemic plant populations on Trindade Island, Brazil

R. J. V. Alves[1,2], L. S. G. Martins[1,2];
[1]Alves, R. J. V., Rio de Janeiro, Brazil, [2]Museu Nacional, Rio de Janeiro, Brazil.

Vegetation recovery on Trindade, a Brazilian oceanic Island, was monitored from 1994 to 2004, during and immediately after the deliberate eradication of feral goats. The colonization of entirely barren volcanic tuffs by the narrow endemic sedges *Cyperus atlanticus* Hemsl and *Bulbostylis nesiotis* (Helmsl.) C.B.Clarke, and the native fern *Pityrogramma calomelanos* (L.) Link measured on ten permanent quadrats, achieved 80% cover in 3 years. Another narrow endemic, currently with thousands of individuals regenerating from a seed bank, *Plantago trinitatis* Rahn was considered extinct until goat populations were considerably reduced by 1998. Known only from the type collection in 1965 and described as extinct, *Peperomia beckeri* E. F. Guimarães & R. J. V. Alves is yet to be rediscovered. The status of endemic plant populations and vegetation cover of Trindade Island is correlated to the estimated populations of feral goats. All interventions which lead to this successful recovery are explained and commented in a historical perspective.

9.16.1. Beyond the tower of babylon: Taxonomy and ethnobotany in Central Asia

B. Dickoré;
A. v. Haller Institute of Plant Sciences, Göttingen, Germany.

The mountains of Central Asia, Tibet and the Himalayas are of great significance to the evolution and diversity of the northern temperate flora. Indigenous knowledge of plants and their uses, in great depth and detail, has a long tradition in Asia and is alive in many communities. However, this cultural heritage is endangered by recent developments and assessing the biological diversity of Central Asia remains a huge task. This paper presents results of taxonomic work in the genera *Codonopsis* (*Campanulaceae*), *Leontopodium* (*Asteraceae*), *Oxytropis* (*Fabaceae*) and *Rhodiola* (*Crassulaceae*), which challenge some issues connecting basic and applied research. Botanical taxonomy and nomenclature are important means of communication and remain the basis for various fields of research including phylogeny, vegetation sciences and ethnobotany. Collaborative and integrative studies may help to conserve and sustainably develop natural and cultural resources, while also maintaining inter-cultural exchange in a globalizing world.

9.16.2. Medicinal plants of Mongolia

E. Ganbold;
Institute of Botany, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia.

A brief overview over the history of research on the Mongolian flora is given. The large Mongolian territory is mostly mountainous and covers different geographical zones characterised by an extreme continental climate and by a unique vegetation. Three main vegetation zones - forest-taiga, steppe and desert - as well as transitional zones, such as mountain forest steppe and semi-desert, are developed. In Mongolia, around 3000 species of vascular plants, belonging to 662 genera and 128 families are registered. During the last 30 years expeditions to all areas of the country were made, and by studying about 25000 specimens, 584 species were newly detected. The Mongolian flora is rich in medicinal plants and about 1000 species are effectively used in traditional Mongolian medicine. As a result of my studies on the resources and distribution of medicinal plants, a monograph including photos of 227 species of widely used medicinal plants was published in 2003.

9.16.3. Medicinal plants in Tibetan botanical treatises and medical works

O. Czaja;
Institute for Indology and Central Asian Studies, Leipzig, Germany.

This paper will give a brief survey from a tibetological perspective of the botanical treatises by Tibetan authors that until now was not done yet. They will be compared with Western publications that make use of some of these sources. It will be shown that surprisingly the latter employ a monolithical concept of Tibetan medicine. They give statements that are actually stripped of any data that reflect the historical, regional and sectarian variance as found in Tibetan written sources. These data are, however, indispensable to a serious assessment of the curing potentials of medicinal plants in as far as they are the opinion of Tibetan doctors. Moreover it will be emphasized that it is necessary to recheck statements given in Tibetan botanical treatises with regard to medical works. It will be illustrated by several case studies of medicinal plants that the curing potentials as stated by Tibetan botanical works (and henceforth Western authors who made use of a limited number of them) do not match the Tibetan medical treatises. By this it will be underlined that an interdisciplinary approach that includes tibetological research can significantly add to botanical studies.

9.16.4. Ritual plants for healing, medicinal plants for trade - Ethnobotany among the Nanman-Xumu (Hengduan Mountains, SW China)

C. S. Weckerle, F. K. Huber, Y. P. Yang, W. B. Sun;
Kunming Institute of Botany, Kunming, China.

The Hengduan Mountains are remarkable for both their biological diversity and their cultural richness. They are spanning SW Sichuan, NW Yunnan and part of eastern Tibet. For several thousands of years, the area has been inhabited by a large number of ethnic groups with distinct and different languages, customs, and land management practices. The area is also a rich source of traditional Chinese and Tibetan medicinal plants, the bulk of which is still harvested from the wild. The Nanman-Xumu are a Tibeto-Burman ethnic group living exclusively in the Shuiluo Valley, a distinct geographical region in the south of Hengduan Mountains. They do collect medicinal plants for trade but mainly use ritual plants for healing purposes. Results from eight months of ethnobotanical field research among the Nanman-Xumu are presented. The use of ritual healing plants both in daily life and by ritual specialists versus the use of medicinal plants are emphasized. The relationship between rituals, landscape and environment is discussed.

9.16.5. Variation in use and knowledge of the medicinal moss HuiXinCao

E. S. J. Harris;
Department of Integrative Biology, University of California, Berkeley, Berkeley, CA, United States.

HuiXinCao (Rhodobryum giganteum) is a common medicinal plant in Yunnan, China used to treat heart ailments. It can be purchased in many different places, ranging from airport souvenir shops to herb dealers in the village market. This medicinal is a moss, which is interesting because mosses generally do not play an important role in the affairs of people. HuiXinCao is also interesting because it is used in different cultural contexts. It is collected, sold, and used by minority groups of Yunnan as well as Han. In addition, it has been studied for its pharmaceutical properties in pharmaceutical factories in Shanghai. The examination of this moss across these different cultural contexts indicates the ways that the ethnobotanical knowledge about a particular plant can vary, and the possible ways that this knowledge might change over time as a result of cultural interaction. Here I discuss peculiarities of HuiXinCao that arise because it is a moss, some of the ways that knowledge about HuiXinCao varies, and how studies of ethnobotanical variation can contribute to studies of ethnobotany in general.

9.16.6. Seabuckthorn-programme for mustang, Nepal: Safeguarding medicinal plants and the biodiversity of Nepal

S. V. D. Heide;
Institute for Technology in the Tropics, University of Applied Sciences Cologne, Germany – HimalAsia Institute for Intercultural Communication and Documentation, Kathmandu, Nepal.

As one measure to safeguard medicinal plants and the biodiversity of Nepal and as a sustainable income source for local people,HimalAsia has started in Mustang, Nepal, to establish four seabuckthorn-nurseries. This programme was initiated in cooperation with two community based cooperatives and with two *Amchi* families (doctors of Tibetan medicine). It was as well planned to begin to harvest the wild growing seabuckthorn forests that are found in certain areas of Mustang in a sustainable way : The collection from wild forests for the species of seabuckthorn *Hippophae tibetana* and *Hippophae salicifolia* in Mustang has started in autumn 2004 by forming women biodiversity forest consumer groups, mainly from low income groups, who were trained by HimalAsia to carry out this work without overharvesting the wild forest. The basic idea is to establish more seabuckthorn nurseries/seabuckthorn forests in different communities of Upper and Southern Mustang in Nepal to use it as an income source for the locally involved actors, and to show that this approach could serve as a model that can be replicated in other areas of Nepal.

9.16.7. Conservation issues of Paanchaunle (*Dactylorhiza hatagirea*) Plant in Nepal: An experience from the Annapurna Conservation Area, Lamjung

D. P. Parajuli;
Ministry of Forests and Soil Conservation, Kathmandu, Nepal.

Paanchaunle *(Dactylorhiza hatagirea)* is one of banned species of high altitude with high market demand and values. Due to its ban on harvest and transport the local inhabitants are in the opinion that its conservation will not be economic incentives to them. A study was carried out at Annapurna Conservation Area of Lamjung district, Nepal between 1997-1998 focusing mostly on socio-economic and biophysical aspects, in justifying the further need of its ban. Information was also collected on existing market prices, marketing channels, etc. from primary and secondary sources. The study concludes that both seeds and vegetative methods between 2500-5000m altitude could propagate it. Root tubers mature after two years in natural conditions and plantations that are best collected during Sept-October. These tubers get decay if they do not harvest by two growing seasons. The study area could produce annually as much as 100.00 kg. of air dry tuber worth of value US$ 70 000 in a sustainable way that could contribute a lot in reducing the poverty at resource available sites. Local inhabitants are expected to motivate from such income for long-term conservation of the resources.

10.1.1. Interrelationship of amphimixis and apomixis

U. Grossniklaus, A. Johnston, H. Wallace, P. Barrell, J. Gheyselinck, M. Federer, R. Baskar, J. M. Moore;
Institute of Plant Biology & Zürich-Basel Plant Science Center, Zürich, Switzerland.

Apomixis and sexual reproduction (amphimixis) are closely interrelated. A better understanding of the genetic and molecular basis of sexual reproduction will provide new tools towards the engineering of apomixis in sexual crops. We have used *Arabidopsis* and maize as model systems to identify genes that play a role in key steps of sexual reproduction, which may also function during apomixis. We concentrate on three developmental processes that are highly relevant to the engineering of apomixis: (1) megasporogenesis (apomeiosis), (2) fertilization (parthenogenesis), and (3) endosperm initiation (functional endosperm). By screening through a few thousand enhancer detector lines we identified genes expressed in specific cell types such as the nucellar region where for instance aposporic initials form in apomictic species, the megaspore mother cell, the egg cell and central cell. The use of these genes and their promoters for mis-expression studies and comparative analyses will be discussed.

10.1.2. The discovery of parthenogenesis: a long journey to the truth!

G. A. Nogler;
Institute of Plant Biology & Zürich-Basel Plant Science Center, Zürich, Switzerland.

1839/41, a voucher of John Smith, Kew, says ,,Notice of a plant which produces perfect seeds without any apparent action of pollenâ€œ. This plant, *Coelebogyne ilicifolia*, and the phenomenon of parthenogenesis in general, were strongly debated in the following years. According to Strasburger (1877), parthenogenesis did not exist at all in angiosperms. Only Juel (1898/1900) increased the insights into the subject, especially by showing the relationship between the changes of the haploid and diploid phases of the life cycle, thereby laying the basis of present day apomixis research. The discovery of parthenogenesis was made obstructed by many preconceived ideas and a lot of work was required to demonstrate this fascinating phenomenon. This talk will review the history of early apomixis research and explore the long and arduous journey it took to make parthenogenesis in plants an accepted fact.

10.1.3. Apomixis- preliminary lessons from *Poa*, *Hypericum* and wheat

F. Matzk[1], S. Prodanovic[1], A. Czihal[1], F. Arzenton[2], J. Kumlehn[1], L. Altschmied[1], I. Schubert[1], A. Johnston[3], U. Grossniklaus[3], **H. Baumlein**[1];
[1]Institute of Plant Genetics and Crop Plant Research (IPK), Gatersleben, Germany, [2]University of Padua, Padua, Italy, [3]University of Zurich, Zurich, Switzerland.

Poa pratensis has been used to study the inheritance of apomixis. The data support a model with five major genes required to control asexual seed formation: apospory initiator and preventer, parthenogenesis initiator and preventer and a megaspore development gene. Differences in expressivity and interactions of these genes are responsible for the wide variation of the mode of reproduction. Apospory and parthenogenesis segregated independently. In *Hypericum* controlled crosses between a completely sexual diploid and an obligate apomictic tetraploid plant led to the isolation of a putative apospory-related AFLP-marker. A first characterisation of putative *Arabidopsis* homologs will be reported. The Salmon system of wheat comprises three isogenic alloplasmic lines with either zygotic or autonomous, fertilisation independent embryo development. cDNA libraries of sexual and parthenogenetic egg cells have been used for molecular subtraction and EST sequencing. Egg cell specific candidate genes have been isolated. Putative *Arabidopsis* homologs have been identified and will be discussed.

10.1.4. Genes linked with apomixis: identification and characterization

P. Ozias-Akins, J. A. Conner, S. Goel, Y. Akiyama, W. W. Hanna;
University of Georgia Tifton Campus, Tifton, GA, United States.

Pennisetum squamulatum Fresen and *Cenchrus ciliaris* L. are two related apomicts in the grass family. They reproduce primarily by apospory where four-nucleate embryo sacs are formed from nucellar cells. The unreduced egg develops by parthenogenesis while endosperm development requires fertilization of the central cell. Although apomixis in these two species segregates in

Mendelian fashion, a large, non-recombining portion of a chromosome is transmitted implying that multiple genes necessary for apomixis could reside in this linkage block. Physical mapping of parts of the chromosomal region transmitted with apomixis has been conducted and has shown that considerable macrosynteny exists between the two apomictic species throughout the region. Genes contained within bacterial artificial chromosome (BAC) clones have been identified and their DNA sequences have been used to determine the extent of macro- and micro-synteny with rice. Although the apomixis-associated region appears highly heterochromatic, several of the genes from this region are transcribed when tested by RT-PCR for apomict-specific transcripts.

10.1.5. Physical mapping of apomixis in *Paspalum simplex* and candidate gene discovery

O. Calderini[1], I. Donnison[2], H. deJong[3], S. Arcioni[1], F. Pupilli[1];
[1]IGV-CNR Perugia, Perugia, Italy, [2]IGER, Aberystwyth, United Kingdom, [3]Wageningen University, Wageningen, The Netherlands.

Apomixis is a natural mode of reproduction that would allow fixation on seeds of a desired genotype if introgressed in valuable crops. Several efforts are underway to reveal the genetic control of the character. In our model *Paspalum simplex*, as in other aposporous species, genetic mapping via molecular markers (AFLPs, RFLPs) revealed a block of recombination, a partial hemizigosity and a strong synteny of EST markers with the telomeric end of the long arm of rice chromosome 12. Physical mapping was undertaken through the construction of a BAC library with a 9x approximate genome coverage. BAC clones from the apo-locus were obtained and used for FISH experiments confirming the hemizigosity and monosomic inheritance of the dominant marker as signals were obtained on a distal euchromatic region of one chromosome. Partial sequencing of BAC clones enabled the discovery of coding sequences at a low density and confirmed the synteny with rice chromosome 12. The functional characterization of candidate genes is underway via expression studies and mutant analysis in model plants.

10.1.6. Dissecting the control of diplosporous apomixis in *Tripsacum*, a wild relative of maize

D. Grimanelli, O. Leblanc;
Institut de Recherche pour le Développement, Montpellier, France.

Apomixis refers to a group of highly variable developmental processes in angiosperms, leading to the formation of progenies that are genetically identical to their mother plants. Little is known about the molecular bases of apomixis. The current consensus is that apomixis results from the temporal or spatial alteration of the developmental pathways that in sexual plants lead to the development of the embryo, rather than the establishment of a novel function. We are using maize and its wild apomictic relative, Tripsacum dactyloides, to compare apomictic and sexual developments at the cellular and molecular levels in two closely related species. Our data indicate that both reproductive modes differ in the timing of expression of complete developmental pathways. We are using mutant analysis and specific genetic screens in maize to identify genes that regulate the temporal expression of genes during female reproduction and mimic aspects of the apomictic mode of reproduction. The results suggest that a surprising diversity of mutations can lead to apomictic-like features.

10.1.7. Genetic linkage mapping of an apomixis locus in *Taraxacum* (common dandelion; Asteraceae)

K. Vijverberg, R. J. Va ut, S. Ivanoviĺ , P. J. van Dijk;
Netherlands Institute of Ecology (NIOO-KNAW), Heteren, The Netherlands.

In *Taraxacum*, the apomixis elements: diplospory (first division restitution meiosis), parthenogenesis, and autonomous endosperm formation, inherit independently, indicating control by different loci. Diplospory inherits as a dominant, monogenic trait: *DIPLOSPOROUS* (*DIP*). We mapped *DIP* by (1) bulked segregant analysis, followed by analysing 73 plants for 34 AFLP- and 2 SSR markers that co-segregate with diplospory, (2) screening of a total of 2229 plants for two markers close to, and spanning, *DIP*, followed by analysing the 24 recombinants found for the 6 AFLPs in this region, and (3) FISH experiments, using BACs that are positive for markers closest to *DIP*. The first map measured 18 cM, showing markers in groups at both sides of *DIP* at a minimum distance of 1.4 cM. Recombination is not found in other mapping studies of apomeiosis to date, and allows for map-based cloning of *DIP* in *Taraxacum*. The second map showed the closest markers to *DIP* at a minimum distance of 0.1 cM and spanning 0.6 cM. First FISH results indicated co-hybridisation of BACs originating from both sides of *DIP*. This suggests a short physical length of the *DIP* chromosomal region, but has to be confirmed.

10.2.1. Insertion-tag mutations in *Arabidopsis* that affect tolerance to abiotic stresses

R. A. Bressan;
Department of Horticulture, Purdue University, West Lafayette, IN, United States.

Large-scale genetic screens were performed for stress response mutants using *Arabidopsis* harboring the luciferase reporter (*LUC*) driven by the stress-responsive *RD29A* promoter. These screens revealed lines whose functions describe essential or important components in stress signaling, and transcriptional and metabolic response networks. Selected mutants to be discussed include lines with differential stress responses to osmotic stress, low temperature, exogenous abscisic acid (ABA), or salt stress, or the ability to stress acclimate. Examples are mutants in the category (high expression of osmotically responsive genes). Mutant *hos10-1*, for example, a putative MYB transcription factor, impedes ABA biosynthesis. Additional mutants are those that enhance or repress known mutations in the SOS category (salt overly sensitive). Here, maintenance of ion homeostasis and oxidative stress protection are revealed, the latter connecting sodium-specific pathways to the injury response system.

10.2.2. Transcriptional changes associated with the abiotic stress tolerance of *Thellungiella*

B. A. Moffatt[1], A. Wong[1], C. Diaz-Camino[1], Y. Li[1], A. Labbe[1], P. Nuin[2], B. Whitty[2], B. Golding[2], E. A. Weretilnyk[2], M. Griffith[1];
[1]University of Waterloo, Waterloo, ON, Canada, [2]McMaster University, Hamilton, ON, Canada.

Thellungiella, a wild crucifer and close relative of Arabidopsis, is able to survive the extreme cold, dry and saline environment of the Canadian Yukon. We are investigating the molecular basis of Thellungiella's stress tolerance using a cDNA microarray prepared from transcripts present in chamber-grown plants subjected to high salt, drought or cold conditions. The array of approximately 4000 different sequences was hybridized with probes prepared from plants subjected to each stress state with the objective to identify mRNAs that change in a "stress-specific" fashion. In addition we have harvested tissue from Yukon field sites to evaluate the transcript profile of plants experiencing multiple stresses. The results are being integrated with complementary physiological and metabolic studies. To date we have found surprisingly little overlap in the expression patterns amongst the three stress conditions.

10.2.3. Comparative genomics to identify genes for metal hyperaccumulation and hypertolerance in *Thlaspi caerulescens*

J. van de Mortel[1], D. Rigola[1], S. Talukdar[1], E. Lukasik[1], L. Almar Villanueva[1], Z. El-Bialy[1], H. Schat[2], **M. G. Aarts**[1];
[1]Lab of Genetics, Wageningen University, 6703 BD Wageningen, The Netherlands, [2]Institute of Ecological Sciences, Vrij Universiteit, 1081 HV Amsterdam, The Netherlands.

Thlaspi caerulescens (*Tc*) is a natural Zn, Cd and Ni hyperaccumulator species belonging to the Brassicaceae family. It is a self-fertilizing species, closely related to *Arabidopsis thaliana* (*At*), with about 85-90% DNA identity in coding regions. While the physiology of metal accumulation in plants has received increasing attention in previous years, the molecular genetics is still largely unexplored. We address this by comparing gene expression in *Tc* and *At* exposed to deficient, sufficient and excess zinc concentrations. In addition we have sequenced a set of around 5000 ESTs from a root and a shoot *Tc* cDNA library. Besides several genes previously implicated in metal homeostasis, this comparative micro-array analysis revealed an interesting set of novel genes, which are differentially expressed either within each species or between them. The biological significance of the differentially expressed genes as well as interesting genes identified in the set of ESTs will be further discussed. This work is supported by an NWO-Genomics (050-10-166) grant, the EU-PHYTAC project QLRT-2001-00429 and the EU-RTN-METALHOME project HPRN-2002-00243

10.2.4. Transcriptional analysis of calcium-dependent and calcium-independent signaling pathways induced by oligogalacturonides

R. Moscatiello[1], P. Mariani[1], D. Sanders[2], F. J. M. Maathuis[2];
[1]Department of Biology, University of Padova, Padova, Italy,
[2]Department of Biology, University of York, York, United Kingdom.

Ŭ-1,4-linked oligogalacturonides (OGs) are pectic fragments of plant cell walls, able to induce defense and developmental responses. To understand plant responses to OGs at the transcriptional level, we examined changes in gene expression using microarrays. In suspension-cultured *Arabidopsis thaliana* cells steady-state changes in the abundance of transcripts encoding stress- and disease-related proteins, signalling components, and transcription factors were particularly noteworthy. As in other plant cell types, OGs elicit a rapid - but transient - elevation in cytosolic free Ca^{2+}. The Ca^{2+} transient can be abolished by various inhibitors, thereby facilitating distinction between Ca^{2+}-dependent and Ca^{2+}-independent transcriptional responses. Abolition of the Ca^{2+} transient specifically inhibited transcriptional upregulation of two groups: genes involved in post-pathogen attack cell wall modification and several genes involved in the biosynthesis of jasmonate (AOS and LOX) and of C6 volatile compounds (hydroperoxide lyase). Our data therefore suggest an essential role played by Ca^{2+} in the above processes.

10.2.5. Brassinosteroid mediated stress responses

P. Krishna, S. Kagale;
University of Western Ontario, London, ON, Canada.

A remarkable feature of brassinosteroids (BRs) is their potential to increase stress tolerance in plants, but a good understanding of the molecular mechanism underlying this phenomenon is lacking. We have found that seedlings grown in the presence of 24-epibrassinolide (EBR) are more resistant to a variety of abiotic stresses than untreated seedlings. Investigation into the mechanism of EBR-mediated thermotolerance revealed that heat shock proteins accumulate to higher levels in EBR-treated seedlings, and this correlates with higher protein synthesis and modified translational machinery. Our present approaches to understanding how BR promotes stress tolerance include 1) overexpression of the DWF4 gene that mediates the putative rate-limiting step in BR biosynthesis, in Brassica napus and Arabidopsis thaliana, and analysis of the resulting transgenic plants, as well as of BR-deficient mutants for stress tolerance, and 2) identification of genes differentially expressed in BR-treated seedlings vs. untreated seedlings under non-stress and stress conditions by use of DNA microarrays. The results of these studies will be discussed.

10.2.6. Cold stress in white clover - An integrated view of metabolome and transcriptome responses

S. Rasmussen[1], G. Lane[1], C. Mingshu[1], K. Fraser[1], H. Xue[1], G. Spangenberg[2], B. Ong[2];
[1]AgResearch Grasslands, Palmerston North, New Zealand, [2]Primary Industries Research, Victoria, Australia.

Trifolium repens, with its capability to associate with symbiotic atmospheric N-fixating *Rhizobiaceae*, is the main forage legume in New Zealand pastures. Winter conditions lead to a decline of white clover in mixed pastures, the understanding of cold stress responses of clover is therefore of importance to New Zealand's agriculture. Flavonoids are known to be involved in general stress tolerance of plants and we studied the effects of cold stress on *T. repens* genotypes with low and high base levels of flavonoids. Changes in the transcriptome were analysed by microarray techniques using slides with clover specific cDNA's. Statistical analysis showed a strong cold induced regulation of genes involved in several biosynthetic pathways, including the flavonoid pathway. The metabolome was analysed by various analytical methods including GC-, and LC-MS/MS. Major metabolite classes differentially regulated by cold stress included flavonoids, sugars, sugar alcohols, and amino acids. We will discuss the importance of an integrated metabolome and transcriptome analysis for the unravelling of stress responses and future functional genomics strategies.

10.2.7. Linking physiological and genetic analyses with the modelling of drought tolerance

F. Tardieu[1,2], B. Muller[1], W. Sadok[1,2], C. Welcker[1], T. Simonneau[1];
[1]INRA, Montpellier, France, [2]Ensam, Montpellier, France.

While considerable progress has been achieved in improving plant survival to water stress by manipulating single genes, this has not been the case until now for improving the plant performances under water deficits compatible with agriculture. In this case, several mechanisms are involved, whose respective importances depend on climatic scenarios and whose genetic determinisms are still poorly understood. Thus, tolerance cannot yet be modelled directly from gene action. Another strategy is proposed, where the response of phenotypic variables to environmental conditions are considered *via* mechanisms at the plant level, resulting in models. Those can be tested by using transgenic plants affected on the mechanisms which drive the model. The parameters of models, usually parameters of response curves to environmental conditions, can then be analysed genetically and dissected into QTL effects. Genetic and ecophysiological models can be combined to predict the behaviour of virtual genotypes, as presented for maize leaf growth under water deficit. This opens the way to the simulation of virtual genotypes, known only by their alleles, in any climatic scenario.

10.3.1. Floral nectaries in angiosperms: a review of their distribution, evolution and systematic significance

E. F. Smets, P. L. Caris, F. P. Lens;
Laboratory of Plant Systematics, Leuven, Belgium.

We present an overview of the distribution of floral nectaries in the major clades of the angiosperms using the APG II tree. It is argued that floral nectary types are systematically significant. Our earlier research on nectaries led to the identification of two main types: *(1)* persistent nectaries, grouping receptacular, gynoecial and gynopleural (or septal) nectaries, and *(2)* caducous nectaries, grouping phyllodial nectaries on the ephemeral perianth parts and androphyllominous nectaries which are associated with stamens and staminodes. Gynopleural nectaries and caducous (staminal as well as tepal) nectaries characterise the monocotyledons. Disc-shaped gynoecial or receptacular nectaries never occur in monocotyledons. In eudicots, these disc-like nectaries are dominant. Gynopleural nectaries are excluded from "dicots" with some notable exceptions, which are the result of convergent evolution. It is striking that receptacular nectaries are the dominant type in rosids, while gynoecial nectaries are typical of asterids.

10.3.2. Nectar sugar composition in angiosperm families: phylogeny vs pollination

B. Van Wyk;
Department of Botany and Plant Biotechnology, University of Johannesburg, South Africa.

The sugar composition of nectar in angiosperm flowers is traditionally interpreted as a functional character that relates mainly to pollination and pollinators. A systematic survey of thousands of nectar samples taken from many plant families has shown that the phylogeny of the plants is strongly reflected in the nectar sugar compositions. The relative quantities of fructose, glucose, sucrose and xylose are usually remarkably invariable within taxa, while they often differ markedly between taxa. Each plant family investigated had unique features and the sugar ratios varied from fairly uniform (Amaryllidaceae, Fabaceae, Orchidaceae), to moderately diverse (Acanthaceae, Crassulaceae, Ericaceae, Iridaceae, Proteaceae) to extremely diversified (Asphodelaceae, Geraniaceae). In some cases the nectar ratios are diagnostically different at generic and species level. The data support the idea that nectar sugars reflect the underlying genetic and phylogenetic relationships of the plants.

10.3.3. Nectary structure and nectar production in relation to flower symmetry and spur location in *Linaria genustifolia* (Scrophulariaceae)

A. R. Davis[1], S. Vogel[2];
[1]University of Saskatchewan, Saskatoon, SK, Canada, [2]University of Vienna, Vienna, Austria.

Various flower morphs of *Linaria genustifolia* were studied for their nectar production and floral-nectary structure. Most flowers are bilabiate and possess a single petal spur extending from the lower lip. The non-glandular spur holds nectar secreted by a crescent-shaped nectary that opposes the spur orifice. Nectary morphology of these 1-spurred zygomorphic flowers was compared with that of spurless zygomorphic and 3- to 5-spurred peloric, actinomorphic flowers. Mature nectaries in spurless flowers were slightly smaller. However, each peloric flower had a large, ring-shaped nectary encircling the gynoecium. Stomatal distribution on mature nectaries also differed, being confined ventrally in zygomorphic flowers, but throughout the disk-shaped nectary in peloric flowers. Nectar production by the three flower morphs also differed. Nectar volume was highest in the multi-spurred flowers, intermediate in 1-spurred flowers, and usually nil in the spurless morph. Nectar-solute concentration, however, was reversed. On average, each peloric flower yielded about 3- and 400-fold more nectar sugar than the 1-spurred and spurless flowers, respectively.

10.3.4. On mechanisms of nectar secretion

N. K. Koteyeva[1], A. E. Vassilyev[1], N. Tarlyn[2], V. R. Franceschi[2];
[1]Komarov Botanical Institute, Saint-Petersburg, Russian Federation,
[2]Washington State University, Pullman, WA, United States.

A comparative analysis of composition and ultrastructure including symplasmic connections of nectary vascular system and secretory cells was made in 15 species aimed at gaining an insight in mechanism of nectar transport. Plasmodesmatal frequency drastic reduction was found in symplasmic species. No intermediary cells characteristic of leaf minor veins of these species were differentiated in the nectaries. Thus, unlike leaves, the companion cells of nectary phloem in both apoplasmic and symplasmic plants play a passive role in assimilate transport. The significant proton gradient between apoplasm and symplasm of secretory cells was established in nectaries of three species using Sulphorhodamin G tracer procedure that indicate active secretion. Using gas chromatography the sucrose prevalence in nectar sugars was shown in two of these species and fructose - in one of them. Pathways of nectar discharge from the apoplasm to the nectary surface were the modified (always open) stomata, cuticular pores, and cuticular channels visualized by chemical fixation or by freeze substitution procedure. The apoplasmic mechanism of nectar secretion was proposed.

10.3.5. Secretory structures new to Anacardiaceae in two brazilian species

A. P. S. Lacchia[1,2], S. M. Carmello-Guerreiro[3], M. d. M. Castro[3], L. Ascensão[4];
[1]Pós-graduação em Biologia Vegetal, Universidade Estadual de Campinas, Campinas, Brazil, [2]Bolsista FAPESP, São Paulo, Brazil, [3]Depto. de Botânica, Universidade Estadual de Campinas, Campinas, Brazil, [4]Centro de Biotecnologia Vegetal, Depto. de Biologia Vegetal, Faculdade de Ciências, Universidade de Lisboa, Lisboa, Portugal.

Numerous secretory structures such as trichomes, idioblasts, ducts, extrafloral and floral nectaries have been reported in Anacardiaceae. The aim of this paper is to describe the glands of the vegetative and reproductive organs of *Spondias dulcis* and *Tapirira guianensis* from the anatomical and histochemical point of view. In both species, the shoot apex has colleters, idioblasts with heterogeneous secretion, and ducts associated with phloem and in the pith. The exudates of *T. guianensis* phloem and pith ducts are similar to each other, containing lipids and polysaccharides. In *S. dulcis*, the secretion is predominantly lipidic in the ducts associated with the phloem, and exclusively polysaccharidic in the pith. The flowers of *T. guianensis* have an intrastaminal ring and its epidermis produces lipids. This ring persists and remains secretory in the mature fruit where there is also a glandular endocarp. The two types of ducts producing different secretion compounds, colleters, idioblasts with heterogeneous secretion, intrastaminal ring producing lipophilic substances, and glandular endocarp have not previously been reported for Anacardiaceae.

10.3.6. Nectar carbohydrate sources: facts and hypothesis

M. Nepi, E. Pacini, L. Cresti, M. Guarnieri, D. Artese;
University of Siena, Siena, Italy.

Nectar carbohydrates may be derived from photosynthesis directly or indirectly. In the former case photosynthesis may occur in the parenchyma of the nectary itself (photosynthetic parenchyma, PP) or in any other part of the flower or plant. There is little or no accumulation of starch in the PP. In the latter case the nectary has a storage parenchyma (SP) containing starch in the pre-secretory phase and the starch is hydrolysed in the secretion phase. SP is generally associated with large nectaries and a high rate of nectar secretion characterising short-living flowers visited by large pollinators. Photosynthetic parenchyma, on the other hand, is common in long-living flowers which secrete nectar over a long period and are visited by small pollinators. Defoliation experiments demonstrated that the direct contribution of nectary PP is not sufficient to sustain the whole of nectar carbohydrate production. It derives that the plant must invest, in any case, part of the daily photosynthate in the production of nectar.

10.3.7. Nectar reabsorption and sugar translocation in male and female flowers of *Cucurbita pepo*

M. StpiczyŒska[1], M. Nepi[2];
[1]Agricultural University in Lublin, Dept. of Botany, Lublin, Poland,
[2]Siena University, Dept. of Environmental Biology, Botany Section, Siena, Italy.

The production and secretion of nectar has an energy cost that can be a substantial part of the energy economy of the plant. Plants may therefore recover part of the energy allocated to nectar secretion by reabsorbing nectar not collected by pollinators. This energy-saving strategy has been demonstrated by several authors by different methods. Here we demonstrate nectar reabsorption and sugar translocation in *Cucurbita pepo* by means of micro-autoradiography. Our results confirm that the dynamics of nectar reabsorption is different in male and female flowers. Differences in the dynamics of nectar reabsorption and sugar translocation were also found in pollinated and unpollinated female flowers. Pollinated female flowers reabsorbed sugar very quickly and translocated it to developing fruits in which ovules were the main sugar sink. Sugar translocation was slower and ovules did not label in unpollinated female flowers.

10.4.1. Dynamic genetics: experimental and computational approaches to the *Arabidopsis* shoot apical meristem

E. M. Meyerowitz[1], V. Reddy[1], M. Heisler[1], H. Jönsson[2], B. Shapiro[3], E. Mjolsness[4];
[1]California Institute of Technology, Pasadena, CA, United States, [2]Lund University, Lund, Sweden, [3]Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, United States, [4]University of California, Irvine, Irvine, CA, United States.

The shoot apical meristem (SAM) is a permanent population of stem cells that provides for all of the above-ground tissue in a growing Arabidopsis plant. Despite consisting of only a few hundred cells, the SAM is highly structured, and planes, patterns, and numbers of cell divisions are highly regulated. The cells in the SAM control their division and patterns of gene expression based upon cell-cell communication â€“ the SAM is a network of interacting cells that maintain their states and activities dynamically. We have developed a new set of methods for studying the SAM, and are developing computational methods for modeling it. The new analytic methods allow, via confocal microscopy and image analysis, three-dimensional time-lapse imaging over several days. Use of fluorescent markers allow visualization of gene expression domains and meristematic regions, and gene constructs of various sorts allow real-time manipulation of cell-celll communication. Computational modeling is in its early stages, but already sheds light on the possible mechanisms for primordium localization and meristem patterning.

10.4.2. Modelling genetic regulatory control of pea phenotype

E. Dun[1], **J. Hanan**[1,2], C. A. Beveridge[1];
[1]ARC Centre of Excellence for Integrative Legume Research, Brisbane, Australia, [2]ARC Centre for Complex Systems, Brisbane, Australia.

Ramosus mutants (*rms*) at five loci in garden pea (*Pisum sativum*) display increased branching in comparison to wild-type. The regulatory network of *RMS* genes and signalling processes must be deduced entirely through mutant-based grafting, and phenotypic, hormone and gene expression analyses.

As our biological understanding grows, there is an increasing need for computational modelling as a means to test whether hypotheses of the network are consistent with all data. Models are described as a list of hypotheses and then converted to a simple rule-based, algebraic formulation based on ideas from the mathematics of chemical processes.

We first compared a simple linear description of the process to a model involving feedback as predicted by grafting and hormone experiments and found that feedback was essential. This model led to the design of an unusual experiment to confirm some of its predictions. Testing against more recent *RMS1* gene expression studies resulted in the incorporation of novel ideas about subtle but important differences in the system in operation in the shoot and roots. Ongoing research is taking the developing plant structure into account.

10.4.3. A multiscale model of *Arabidopsis* development: from molecules to plant architecture

P. Prusinkiewicz[1], E. Coen[2];
[1]University of Calgary, Calgary, AB, Canada, [2]John Innes Centre, Norwich, United Kingdom.

A fascinating aim of current research is the understanding of the developmental processes through which multicellular organisms acquire their form. Mathematical models and computer simulations are an emerging methodology assisting in these studies. The talk will describe the work in progress aimed at creating an integrative model of *Arabidopsis thaliana.* The model takes into account the spiral phyllotaxis, apical dominance, flowering sequences, and architecture of wild type and selected mutant *Arabidopsis* plants*.* By combining computational models and simulations operating at different scales, we have begun to synthesize developmental processes from the level of molecules to the level of the whole plant architecture. This makes it possible to appreciate the link between the relatively simple mechanisms operating at the levels of plant modules and tissues and the resulting complex plant structures.

10.4.4. Computational modeling and image processing approaches to understanding the dynamics of the *Arabidopsis thaliana* shoot apical meristem

E. Mjolsness[1], T. Bacarian[1], P. Baldi[1], V. Gor[2], M. Heisler[3], H. Jönsson[4], V. Reddy[3], A. Sadovsky[1], B. Shapiro[2], E. Meyerowitz[3];
[1]Institute for Genomics and Bioinformatics, University of California, Irvine, CA, United States, [2]Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, United States, [3]Division of Biology, California Institute of Technology, Pasadena, CA, United States, [4]Department of Theoretical Physics, Complex Systems Division, Lund University, Lund, Sweden.

An integrated effort to advance the understanding of the shoot apical meristem (SAM) of *Arabidopsis thaliana* through computational modeling of developmental processes, is embodied in the Computable Plant project. Interesting and generic mathematical problems arise at each stage of the computational approach. For example, quantifying the growth of the SAM and the lineages of its cells requires tracking multiple features in 3D imagery, which we approach through nonlinear optimization. Fitting the resulting data to a dynamical model requires a coupled mechanical/regulatory network modeling framework. For both the image processing and dynamic modeling we develop a mathematical foundation based on the use of a dynamical “grammar” capable of representing events such as cell division that change the number of objects present and their relationships, as well as continuous-time processes such as regulatory network dynamics and mechanical processes. The resulting computational algorithms are assisting experimental research on mechanisms of meristem maintenance and phyllotaxis.

10.4.5. Modeling traces 'crooked aspen' architecture to a single biomechanical factor

W. Remphrey[1], J. Taylor-Hell[2], A. Linden[1], B. Lane[2], P. Prusinkiewicz[2];
[1]University of Manitoba, Winnipeg, MB, Canada, [2]University of Calgary, Calgary, AB, Canada.

A clump of trembling aspen (*Populus tremuloides*) located in western Canada exhibits an unusual ‘crooked architecture’, characterized by a shrubby short stature and sharply turning branches. It has been previously hypothesized that this architecture representsnormal gravimorphic response to abnormal bending of current-year shoots. We use 3 models to explore this hypothesis. Model 1 reconstructs the bending of current-year shoots according to a time series of digitized 3D data. The model reveals that an axis bends near the base after growing some length. Model 2 simulates biomechanics of the development of a single axis. It shows that the observed shoot bending may result from the reduced stiffness of the axes, as suggested by anatomical evidence and biomechanical experiments. Model 3 simulates gravimorphic impact of shoot orientation on the development of the whole tree. The model demonstrates that the transition from the wild-type to the crooked morphology may be traced to a single factor, possibly a mutation in one gene, which reduces the stiffness of young shoots.

10.4.6. Towards a dynamic model of the *Arabidopsis* meristem

P. Barbier de Reuille[1], I. Courseau[2], J. Traas[2], **C. Godin**[3];
[1]AMAP, INRA, Montpellier, France, [2]Laboratoire de Biologie Cellulaire, INRA, Versailles, France, [3]AMAP, INRIA, Montpellier, France.

During the last decade an impressive body of knowledge concerning shoot apical meristem function has been generated. This concerns information on the genes involved, their expression patterns, cell differentiation, cell division patterns, etc. The complexity of these data is such, that an integrated view of meristem function is not yet possible. Therefore, adapted mathematical and informatics approaches are now required to integrate the knowledge and to advance the level of understanding in the field. To formulate and test hypotheses on spatial aspects such as flows of signalling molecules between cells, strain within tissues, and the role of gene products in the spatial control of cell proliferation, we are creating a virtual meristem, that will integrate as much spatial, dynamic and quantitative information as possible. Here, we will present the first results obtained on the mathematical modelling of auxin fluxes in the meristem, based on experimental data. This modelling framework, based on local interaction hypotheses between cells, suggests that phyllotaxy patterns may emerge due to auxin overflowing in the meristem centre in growing meristems.

10.4.7. A gene regulatory network model for cell-fate determination during Arabidopsis thaliana flower development that is robust and recovers experimental gene expression profiles

E. R. Alvarez-Buylla[1], C. Espinosa-Soto[1], P. Padilla-Longoria[2];
[1]Institute of Ecology (IE-UNAM), MÃ©xico City, Mexico, [2]Research Institute in Applied Mathematics and Systems (IIMAS-UNAM), MÃ©xico City, Mexico.

The inputs for biologically realistic dynamic models of gene regulatory networks in cell differentiation are accumulating. A gene network model for floral organ cell specification grounded on experimental data shows that all initial conditions converge to few steady gene activity states that match expression profiles observed in primordial cells of sepals, petals, stamens and carpels and it also reproduces mutants patterns. Thus providing a dynamical explanation for the ABC model of floral organ determination, and showing that precise signaling pathways are not required to restrain cell types found in Arabidopsis, but these are rather determined by overall gene network structure and dynamics. This was confirmed by robustness analyses of random perturbations of gene interaction parameters. The network thus constitute a developmental module, and provides an explanation for overall conservation of floral plan among angiosperms. The model formally integrates available information, tests data coherence, predicts novel gene interactions, and enables explorations of evolutionary differences in network architecture between Arabidopsis and Petunia.

10.5.1. Land plant origins: body-building from scratch

P. Kenrick;
The Natural History Museum, London, United Kingdom.

Land plants inherited their biochemistry from the green algae, but their morphology evolved on land. The foundations of the complex and integrated body plans that characterise the group were laid down during the ecological transition from water to land. This is borne out by recent work in molecular phylogenetics, the comparative morphology of the charophycean algae, and evidence from the fossil record. Early body fossils are microscopic, and interpreting this evidence is complicated by its invariably fragmentary nature and the difficulty of distinguishing sporophytic from gametophytic tissues. These findings have implications for our understanding of the origin of form, and they set limits on the extent to which fossils can usefully contribute to the debate on morphological evolution and phylogeny. The fossil record is silent with respect to the early stages of the development of multicellularity in plants, and it is likely to remain so. Despite this limitation, fossils are highly informative with respect to the assembly of other key elements of the plant body, capturing those durable aspects that appeared following terrestrialisation.

10.5.2. Tempo and mode of early land plant evolution: evidence from the dispersed spore fossil record

C. H. Wellman;
University of Sheffield, Sheffield, United Kingdom.

The sporopollenin-walled spore was probably a prerequisite essential for the invasion of the land by plants, and is a character present in all subsequent land plants. Such spores have an excellent fossil record because they are produced in vast numbers, widely dispersed and have high fossilization potential. Thus the dispersed spore record is continuous and provides a unique insight into the timing of the origin of land plants and subsequent patterns of evolution, biodiversity and phytogeography. Intriguingly, following a first appearance in the Mid Ordovician, the spore record indicates a 40 million year period of apparent stasis. This is followed by a major diversification in the Late Silurian. These patterns may be interpreted as an extended period dominated by simple bryophyte-like plants, followed by an adaptive radiation in the Late Silurian coincident with the evolution of vascular plants. The pioneering bryophyte-like plants most likely were generalists with simple reproductive strategy. The later vascular plants had more complex ecologies and reproductive strategies, leading to ecological partitioning and phytogeographical differentiation.

10.5.3. Evolution of shoot development in land plants

T. Nishiyama[1], K. Sakakibara[2], T. Fujita[1], M. Hasebe[1];
[1]National Institute for Basic Biology, Okazaki, Japan, [2]Hiroshima Universitiy, Hiroshima, Japan.

Diversity in form is a hallmark of extant species that was caused by the modifications of gene networks regulating development, and by the generation of novel developmental processes. The basic body plan of land plants, the shoot system, was established in their early stage of evolution. Homologues of the *SHOOTMERISTEM LESS* (*STM*) gene, which is a major regulator of shoot initiation and maintenance in flowering plants, were characterized in the fern *Ceratopteris richardii* and the moss *Physcomitrella patens*. Polar auxin transport was assessed in the moss. Basic functions of *STM* and polar auxin transport are preserved among their diploid generation, although the moss does not form shoot-like structure in its diploid generation. This suggests that basal genetic tools for shoot system were established in the shoot-less common ancestor of land plants. On the other hand, STM expression and polar auxin transport were not detected in the haploid leafy-shoots of the moss, suggesting that diploid shoot systems of the vascular plants and haploid shoot systems of the moss evolved with different molecular mechanisms and that diploid shoots evolved *de novo*.

10.5.4. The fossil record of leaf developmental and physiological evolution

C. K. Boyce;
University of Chicago, Chicago, IL, United States.

The fossil record indicates that the Paleozoic evolution of leaves among vascular plants consists of several independent acquisitions of laminate photosynthetic surfaces in different clades that previously had only axial structures. These independent evolutions of laminate leaves in lineages such as ferns, seed plants, sphenophylls, and archaeopterid progymnosperms follow a highly stereotyped sequence of morphologies. This pattern is hypothesized to result from constraints upon the convergent evolution of leaf development by modification of the mechanisms of axial development shared by all vascular plants. This hypothesis that convergent morphological evolution reflects convergent developmental evolution has been tested with developmental investigations of living tracheophytes. The detailed anatomical information available from plant fossils further allows comparative study of the evolution of hydraulic physiology in the leaves of different lineages.

10.5.5. Evolution of arbuscular mycorrhizal symbioses in early lineages of land plants

J. L. Winther, W. E. Friedman;
University of Colorado, Boulder, CO, United States.

Nearly all vascular plants have mutualistic arbuscular mycorrhizal symbioses where the plant host gains access to essential mineral nutrients through the fungus and the fungal symbiont acquires fixed carbon from the plant. However, the evolution of arbuscular mycorrhizal associations over the nearly 500 million-year course of land plant history has been largely overlooked. Using environmental DNA amplification of 18S and ITS ribosomal DNA, we are the first to report on the identities of the arbuscular mycorrhizal fungal symbionts in a phylogenetically and ecologically diverse set of ferns and lycopods whose life cycles are characterized by a long-lived subterranean gametophyte phase. We have identified the fungal symbionts throughout the life cycle of these taxa including the autotrophic sporophyte and mycoheterotrophic gametophyte. Our data suggest that the evolution of mycoheterotrophic phases in ancient land plant lineages is highly homoplasious,

10.5.6. Do we need more characters or more taxa to resolve the overall pattern of land plant phylogeny?

G. W. Rothwell;
Ohio University, Athens, OH, United States.

Despite theoretical cautions and accumulating empirical evidence to the contrary, there is a growing belief that the overall pattern of land plant phylogeny can be resolved using living species only. Great expectations and the impressive successes of molecular systematics in resolving relationships among relatively closely related species not withstanding, this approach has not led to confident resolution of the deep internal nodes of the tree. As a result, relationships among the four major clades of embryophytes, the pattern of phylogeny for living seed plants, and the overall pattern of phylogeny for embryophyes may be less confidently resolved today than they were a decade ago. To explore the possibility that alternate sets of characters, increased numbers of taxa, and well documented patterns of character development/evolution can provide reliable hypotheses tests, these approaches have been applied to questions about the deep internal nodes of the embryophyte tree. Preliminary results suggest that such approaches may serve as attractive alternatives to statistical assessments of hypothesis strength.

10.5.7. Fern shoot apical meristems (SAMs): structure, morphogenic activity and evolutionary homologies

M. A. Romanova[1,2], O. V. Yakovleva[3], N. K. Koteeva[3], G. M. Borisovskaya[2], J. Jernstedt[1];
[1]University of California, Davis, Davis, CA, United States, [2]St-Petersburg State University, St-Petersburg, Russian Federation, [3]Komarov Botanical Institute of the Russian Academy of Sciences, St-Petersburg, Russian Federation.

Investigation of SAM structure associated with organo- and histogensis in five fern species differing in morphology and growth rhythm showed that: (1) the single apical cell (AC) and its immediate prismatic derivatives share common ultrastructural traits (high vacuolation, accumulation of starch and lipids) which characterize dormant seed plant SAMs; and (2) changes in ultrastructure associated with cell differentiation are correlated with successive unequal (formative) cell divisions of prismatic cells, accompanied by a decrease in plasmodesmata (PD) density. Although multicellular, fern SAMs are composed of clonally related cells, interconnected by primary PDs only (with frequency one order of magnitude higher than in seed plants), and both leaf and root ACs originate simultaneously from the SAM, not by cell proliferation, but with the emergence of the single AC. SAM structure correlates with shoot morphology. Leaf initiation in every prismatic segment of an AC, correlations between changing morphogenetic tempo, leaf shape, and stelar type are described for *Ceratopteris richardii*. Evolutionary homologies of the fern SAM are discussed.

10.6.1. Land plants and their fungi: co-evolutionary trends in symbiotic and parasitic interrelationships

F. C. Oberwinkler;
Spezielle Botanik/Mycologie, Tübingen, Germany.

Mycotropism is a prerequisite for plants to conquer land habitats. Oldest symbiotic Glomeromycota are at least as old as first land plants. The arbuscular type of obligatory plant-fungus association has been established in all newly evolving land plants up to phanerogams. Surprisingly, Asco- and Basidiomycetes were involved in symbiotic interrelationships at a very early stage of plant and fungal evolution. In extant land plants, a distinct pattern of mycorrhizal associations (arbuscular, ericoid, arbutoid, orchid-type, ectomycorrhizae, ectendomycorrhizae) is present that indicates co-evolutionary traits. Only a minor percentage of land plants is considered to be non-mycorrhizal.

Plant life and development requires also decomposition of organic substances, both in living and dead material. There is only one chance for land plants' ecological and evolutionary success: a coordinated interrelationship with symbiotic, parasitic and saprobic organisms. A high diversity of plant parasitic and saprobic fungi is involved in these processes. In many cases, well defined associations occur that indicate co-evolutionary trends.

10.6.2. The role of fungi in shaping the early terrestrial ecosystem

T. N. Taylor[1], H. Kerp[2], H. Hass[2], M. Krings[3];
[1]University of Kansas, Lawrence, KS, United States, [2]Westfälische Wilhelms-Universität, Münster, Germany, [3]Bayerische Staatssammlung für Paläontologie und Geologie, Munich, Germany.

Fungi are critical in the world today. Recent reports place fungi in the Proterozoic. Some may represent fungi referable to modern groups, others examples of ancient lineages now extinct, and others modern contaminants or non fungal. The first fungal remains with structural and morphological features related to modern groups come from the ca 400 million year old Rhynie chert. Preservation provides information about fungi and host responses in this ecosystem. All fungal groups are present except basidiomycetes. Chytrids are common as parasites of algae, macroplants and other fungi. Features are identical to extant representatives, including life history biology. Endomycorrhizae are present in both life cycle phases of land plants, suggesting a strategy to distribute resources within the ecosystem. Endobacteria and a cyanolichen are also present. The Early Devonian is a critical period in the evolution of terrestrial ecosystems, when the first diverse communities appeared. The Rhynie chert provides the opportunity to document biodiversity in a fossil freshwater environment, and reveal community interactions in an ecological and evolutionary context.

10.6.3. Arbuscular mycorrhiza: an ancient symbiosis that can be cheated by plant parasites

D. Redecker;
Botanical Institute, Basel, Switzerland.

Arbuscular mycorrhiza (AM) is an extremely widespread symbiosis between the majority of plants and fungal symbionts from the phylum Glomeromycota. Fossil and molecular phylogenetic evidence suggests that this association has accompanied land plants since their origin. The main benefit provided to the plant by AM is an improved mineral uptake, which is essential under limiting conditions and less important in nutrient-rich soils. AM fungal diversity was shown to have a determining influence on the diversity and productivity of plant communities. Although host specificity in AM has generally been thought to be extremely low, studies using molecular identification methods have recently shown that in many cases there is at least some degree of host preference.

Some non-photosynthetic plants live in association with AM fungi and apparently derive all their nutrients via the fungal symbionts. These parasitic plants are known as mycoheterotrophs. Interestingly, they show a very high degree of host specificity, indicating that there is potential for specific interactions and co-evolution in AM, especially when the association is non-mutualistic.

10.6.4. How plant use fungal carbon: Evolution of orchids toward mycoheterotrophy

M. A. Selosse[1], T. Julou[1], J. Abadie[1], G. Gebauer[2];
[1]Centre d'Ecologie Fonctionelle et Evolutive, Montpellier, France, [2]Lehrstuhl für Pflanzenökologie, Universität Bayreuth, Bayreuth, Germany.

Mycoheterotrophic (MH) plants are achlorophyllous and derive carbon from their associated fungi that are also mycorrhizal on autotrophic plants. MH plants are homoplasic among orchids: e.g. the tribe Neottieae encompasses green forest species and independently arisen MH species. As all MH orchids, MH neottioids shifted from rhizoctonias, the usual orchid mycorrhizal partners, to fungi ectomycorrhizal (ECM) on surrounding trees. To understand the predisposition of green neottioids to become MH, we studied Limodorum, Epipactis and Cephalanthera spp. for: (i) fungal symbionts, using molecular tools, (ii) carbon sources using stable C isotopes, and (iii) in situ gaz exchanges. These neottioids harbour no rhizoctonias, but ECM fungi, and use both fungal carbon and photosynthesis, i.e. are mixotrophic. Achlorophyllous variants found in some green neottioids suggest that loss of photosynthesis may be a critical step in transition to MH states. Among Neottieae, ECM symbionts probably replaced rhizoctonias as neottioids ancestors colonized forest niches, allowing mixotrophy as an adaptation to low-light habitats. It predisposed neottioids to become MH.

10.6.5. Evolution of fungal endophytes of grasses, and the role of host specialization

C. L. Schardl;
University of Kentucky, Lexington, KY, United States.

Grasses of subfamily Poöideae frequently host fungal endophytes of the family Clavicipitaceae, which systemically but asymptomatically colonize aerial plant tissues and are transmitted efficiently to successive generations of host plants. These "epichloë endophytes" include the more pathogenic and obligately sexual *Epichloë* species, and mutualistic but asexual *Neotyphodium* species. Some *Epichloë* species are pleiotropic, i.e., also capable of mutualistic symbiosis. Phylogenetic evidence suggests that most *Epichloë* species and some *Neotyphodium* species have a history of codivergence with their hosts, dating from approximately 40 Myr before present. However, many *Neotyphodium* species are interspecific hybrids, whose ancestral *Epichloë* species are rarely associated with the same or related hosts. Some *Epichloë* species appear to have broad host ranges, but there is almost no detectable gene flow between populations on different host genera. The overall evolutionary pattern indicates host specialization as the overriding factor in speciation for all epichloë endophytes regardless of whether they are pathogenic, pleiotropic or mutualistic.

10.6.6. From local to global patterns of Caryophyllaceae-Microbotryum association: phylogenetic and population studies.

M. E. Hood;
University of Virginia, Charlottesville, VA, United States.

What limits a fungal pathogen's host-range and geographic distribution is an urgent applied question, as well as informing upon the basic ecological processes that govern long-term species interactions. For obligate pathogens, such as the anther-smut fungus Microbotryum, their distribution is entirely constrained by that of the hosts and the ability to transmit between host species to which there may be varying levels of specialization. This study investigates the occurrence of Microbotryum on plant species in the family Caryophyllaceae found in Europe and North America. Phylogenetic analysis and inoculation studies indicate a high level of pathogen specialization to particular host species, but with evidence of historic and recent host-shifts between plant genera. Moreover, the phylo-geography of Microbotryum reveals the presence of the major European clade in northwestern North America, therefore suggesting a route for inter-continental migration of fungal pathogens in association with circum-polar hosts.

10.6.7. Comparing host and parasite phylogenies: Methods, principles, and an example from downy mildews

M. Goeker[1], H. Voglmayr[2], K. Mummenhoff[3], A. Franzke[3], F. Oberwinkler[1];
[1]Botanisches Institut, D-72076 Tübingen, Germany, [2]Department für Botanische Systematik und Evolutionsforschung, 1030 Wien, Austria, [3]Fachbereich 5 Biologie/Chemie, Spezielle Botanik, 49076 Osnabrück, Germany.

Most, if not all, properties of host-parasite systems cannot be properly understood without referring to the respective phylogenies of hosts and parasites. The lecture shortly describes the current methods to reconstruct historical host-parasite associations including statistical tests of significant congruence between host and parasite trees. An important question here is how topological uncertainty related to parasite trees, host trees, or both is coped with. Most recent phylogenetic studies rely on molecular data; depending on the DNA (or protein) sequences the phylogenies are based on, alignment ambiguities may play a role, but may also be accounted for. These principles and methods are illustrated with phylogenetic data concerning *Hyaloperonospora* (downy mildews) and its plant hosts (Brassicaceae). The results are compared with conclusions drawn from other molecular phylogenetic studies in plant-parasitic fungi (mainly smuts) and their hosts as well as with literature data on host-parasite systems in other groups of organisms. Finally, some general hypotheses on host-parasite evolution are proposed.

10.7.1. Phylogenetic relationships and patterns of diversification in Gesneriaceae subfamily Gesnerioideae

J. L. Clark[1], E. H. Roalson[2], L. E. Skog[1], J. K. Boggan[1], E. A. Zimmer[1];
[1]US National Museum of Natural History, Smithsonian Institution, Washington, DC, United States, [2]Washington State University, Pullman, WA, United States.

Gesneriaceae subfamily Gesnerioideae includes more than 1800 species and is currently considered to include six tribes: Beslerieae, Episcieae, Gesnerieae, Gloxinieae, Napeantheae, and Sinningieae. We review the current understanding of phylogenetic relationships and morphological patterns in the subfamily based on combined molecular and morphological data sets. Combined nuclear and chloroplast sequence data and morphological cladistic data sets, suggest that in the Gloxinieae, circumscriptions of *Gloxinia* and *Phinaea* require reorganization. Similarly, in the Episcieae, several genera may require changes to generic circumscriptions, including *Alloplectus*, *Drymonia*, *Nematanthus*, and *Paradrymonia*, among others. Conversely, detailed studies of the Beslerieae suggest that generic definitions and phylogenetic clades are largely congruent. Morphological character variation will be compared with these phylogenetic clade definitions to assess potential morphological synapomorphies.

10.7.2. A molecular phylogenetic analysis of Coronantheroideae (Gesneriaceae).

J. F. Smith, M. M. Funke;
Boise State University, Boise, ID, United States.

Coronantheroideae are unique among Gesneriaceae with nectaries adnate to ovaries, high chromosome counts, and a distribution bridging Old and New World tropics. The relationship of Coronantheroideae to other Gesneriaceae has been difficult due to autapomorphic traits that define it. In the present analysis four of six South Pacific/Australian and all three of the Southern South American genera are included. Analyses are based on four chloroplast loci, ITS and two nuclear low copy genes, glutamine synthetase and G*CYC*. Duplicate copies of both nuclear genes were encountered, probably a result of polyploidy. Phylogenetic analyses place Coronantheroideae with subfamily Gesnerioideae indicating that the ancestor to Coronantheroideae was from the New World tropics and its occurrence in Australia and the South Pacific is the result of two separate dispersal events. Estimates applied to the timing of dispersal allow resolution of whether the event was vicariant or long distance dispersal.

10.7.3. Phylogeny of Old World Gesneriaceae based on molecular and morphological markers

A. Weber[1], M. Pfosser[2], M. Möller[3], C. Jang[4], V. Mayer[1], A. Clark[3], M. Kiehn[1];
[1]Centre of Botany, Vienna, Austria, [2]Bioloy Centre, Linz, Austria, [3]Royal Botanic Garden, Edinburgh, United Kingdom, [4]College of Natural Science, Chungbuk National University, Republic of Korea.

The number of tribes recognised in Old World Gesneriaceae has steadily decreased, numbering presently four. Molecular studies continue this trend: only two major clades can be sharply delimited: (I) the small clade of Epithematoid Gesneriaceae, (II) the large clade of Didymocarpoid Gesneriaceae. While in the former the relationships of the six genera analysed are fairly well understood, the Didymocarpoid Gesneriaceae resist a neat grouping. Roughly, the following succession can be observed: (1) basal Asiatic and European genera, (2) African genera (primariliy with twisted fruits), (3) advanced Asiatic genera, with (3a) genera with mainly twisted fruits, and (3b) genera with straight fruits. In this last group the intergeneric relationships are poorly resolved. This group includes also *Cyrtandra* with indehiscent fruits, while the second genus with indehiscent fruits, *Rhynchotechum*, is in the basal Asiatic group. The evolution of twisted fruits is either a parallelism or a single acquisition prior to the split between African and advanced Asian genera with a consecutive loss in the straight-fruited advanced Asiatic genera.

10.7.4. Cytology in Gesneriaceae after FISH

M. Moeller[1], G. Kokubugata[2], K. Jong[1];
[1]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom, [2]Tsukuba Botanical Garden, National Science Museum, Tokyo, 4 Amakubo, Tsukuba, Ibaraki, Japan.

The current state of cytology in Gesneriaceae is reviewed. While c. 1000 counts have been published, large gaps remain in our cytological knowledge as only 18% of the species have been analysed. There is some pattern in the distribution of basic chromosome numbers across the family. The New World Gesneriaceae show little intrageneric and intratribal variation, whereas the Coronantheroid gesneriads possess high somatic numbers. The Epithematoid gesneriads have low basic numbers and show high variation within some species. The Old World Didymocarpoid gesneriads are cytologically the most diverse. The generally small size of Gesneriaceae chromosomes imposes limitations on genome characterisation. The application of fluorescent *in-situ* hybridisation (FISH) allows fine scale analyses into genome evolution. FISH can reveal differences in number and position of ribosomal DNA sites between closely related species with similar karyotypes (e.g. *Aeschynanthus*, *Streptocarpus*); indicating the power of this cytological tool for plants with small chromosomes.

10.7.5. Historical biogeography of Sinningieae and Nematanthus/Codonanthe lineages (Gesneriaceae): from regional to large scale patterns

M. Perret[1], A. Chautems[1], R. Spichiger[1], B. Loeuille[2], V. Savolainen[2];
[1]Botanical Garden of Geneva, Chambésy, Genève, Switzerland, [2]Royal Botanic Gardens, Kew, United Kingdom.

Distribution history of the tribe Sinningieae and the Nematanthus/Codonanthe group were inferred based on distribution data and molecular phylogenies using Dispersal-Vicariance analyses. Both lineages present their highest species concentration in the Brazilian Atlantic forests. However, biogeographical scenarios reconstructed in these groups are different. The Sinningieae probably arose in the Brazilian coastal rain forest. Dispersal events occurred predominantly into the neighboring inland areas, whereas few recent range expansions through the Andes account for the large peri-Amazonian distribution of the Sinningieae. By contrast, in the Nematanthus/Codonanthe, connections between the Brazilian Atlantic forests and the northern South America occurred early in the group, probably through the Amazon basin. These distinct biogeographic patterns correlate with differences in ecological traits. Our results stress the role of a phylogenetic framework to correctly infer biogeographic scenarios. This approach applied on an extended data set should contribute to better understand patterns of Gesneriaceae diversity in the Neotropics.

10.7.6. Systematics and biogeography of *Cyrtandra*, the largest genus of Gesneriaceae

G. L. C. Bramley[1], H. J. Atkins[2], A. Clark[2], R. Bone[2], Q. C. B. Cronk[3], R. T. Pennington[2];
[1]Royal Botanic Gardens Kew, Richmond, United Kingdom, [2]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom, [3]UBC Botanical Garden and Centre for Plant Research, Vancouver, BC, Canada.

Taxonomic progress in large genera such as *Cyrtandra* (600 spp., Gesneriaceae) is hampered by an inadequate infrageneric classification. Preliminary phylogenetic analysis of ITS and trnL-F sequences for c. 100 species of C*yrtandra* coupled with the identification of key morphological characters shows promise for building a taxonomic framework based upon monophyly. Using this structure, we can identify monophyletic groups of species or geographic areas containing monophyletic species radiations as targets for revisionary taxonomic work. In addition, the phylogeny has potential to address critical biogeographic questions in South East Asia such as the validity of biogeographic boundaries such as Wallace's line. Furthermore, the phylogenetic relatedness and age-structure of *Cyrtandra* species from particular regions gives insight into the evolution of tropical rain forest understorey communities.

10.7.7. Pollinator diversity of Gesneriaceae species from southeastern Brazil

M. Sazima[1], I. SanMartin-Gajardo[2,3];
[1]Depto. Botânica, Universidade Estadual de Campinas, CNPq, Campinas, Brazil, [2]Pós-Graduação em Biologia Vegetal, Universidade Estadual de Campinas, FAPESP, Campinas, Brazil, [3]Universidade Federal de Juiz de Fora, Juiz de Fora, Brazil.

A notable diversity of species is harbored on Gesneriaceae, indicating adaptation to diversified pollinator agents. Pollinators were inferred in many cases, but a few studies have determined the effective pollination system. Here we present field data of pollinator assemblages for 26 Gesneriaceae species. Pollination of these species is carried out by three animal groups: hummingbirds, bees, and bats. Hummingbirds belonging to Trochilinae or Phaethornithinae pollinate most species. Pollination by hummingbirds of each sub-family seems to be determined mostly by the plant habitat instead of floral traits. Four species are pollinated by small or large bees. Flower features (dimension, color, nectar) present marked differences which reflect their pollination by distinct groups of bees. Two species are pollinated by glossophagine bats, being nectar and scent attributes determinant for bat attraction. For most species pollination syndromes coincide with effective pollinators, but for a few species, pollinators belong to other groups than presumed by the syndrome. In the latter the actual pollination systems may be an endpoint or a transitional phase.

10.7.8. Fruit morphology and dispersal strategies in neotropical Gesneriaceae

A. Chautems;
Conservatoire et Jardin botaniques/Ville de Genève, Chambésy/GE, Switzerland.

Fruit morphology is highly diverse in Gesneriaceae, especially in the neotropical tribes Episcieae, Gloxinieae and Sinningieae. Fruits are ovoid or globose, forming either dehiscent capsules (dry or fleshy) or indehiscent "berries". Fleshy and colourful fruits are common in Episcieae, but rare in Gloxinieae and Sinningieae. Habitat appears to play an important role in favouring appropriate seed dispersal mechanisms. Anemochory is more common in open and dry environments combined with lithophytic habit. Hydrochory is often found in ground-dwelling herbs in rain forest. Zoochory (supposedly bird-dispersed seeds) is mainly observed in epiphytic subshrubs and found predominantly in cloud or mountain forests. Some intrageneric variation also occurs, as illustrated by the genus Sinningia. In the Neotropics, Gesneriaceae have produced dispersal strategies that can be regarded as more innovative than in the Paleotropics, paralleling what happened with floral features and pollination mechanisms.

10.8.1. On the origin of the fig: phylogenetics and biogeography of Moraceae

G. D. Weiblen;
University of Minnesota, Saint Paul, MN, United States.

The majority of species in the mulberry family (Moraceae) are figs (Ficus), marked by a specialized inflorescence (syconium) and an obligate mutualism with pollinating fig wasps. Because of the unique morphology of the syconium, it has been difficult to investigate the evolutionary position of the fig. Phylogenetic analysis of chloroplast and nuclear DNA sequences have identified the closest relatives of the figs and suggest that the ancestor of the fig was insect-pollinated with protective bracts encircling the flowers. Molecular dating with multiple fossil calibrations, and independent geological evidence suggest that fig pollination is at least 80-90 million years old. Molecular evidence together with Eurasian fossils suggests that the early diversification of Moraceae in the northern hemisphere and subsequent dispersal into the southern hemisphere is at least as plausible as a southern hemisphere origin, if not more so. That independent dating of pollinating fig wasps favored a southern origin for fig pollination highlights the need for multiple sources of evidence in biogeographical reconstructions.

10.8.2. A new dated comprehensive phylogeny for *Ficus*: insight into classification and co-evolution.

N. Rønsted, V. Savolainen;
Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Figs (genus *Ficus*, family Moraceae) constitute one of the largest genera of flowering plants with ca. 750 species of trees, shrubs and hemi-epiphytes primarily occurring in rainforests world-wide. Figs can only be pollinated by female Agaonid wasps that can only oviposit inside the fig cavity. The extreme species-specific mutualism between figs and their pollinating wasps has become a model system for studies of co-evolution. However, an accurate evaluation of patterns and processes of species diversification in a co-evolution system can only be performed if the phylogenies of both partners are known and can therefore be compared. This lecture presents the most comprehensive phylogenetic analysis of *Ficus* to date, based on nuclear encoded ITS and ETS sequences of about 150 species, showing both correlations and conflicts with traditional morphological classification. Independently inferred ages of closely associated fig and wasp lineages also provides the most compelling evidence to date for co-cladogensis in the fig-wasp mutualism during the last 60 millions years.

10.8.3. Inflorescence evolution and phylogeny of Artocarpeae, an early diverging Moraceae lineage

N. J. C. Zerega;
University of Minnesota, Plant Biology, St. Paul, MN, United States.

Artocarpeae is one of five tribes in the Moraceae (figs and mulberries) and is distributed throughout the tropics. The tribe includes the third largest genus in the family, Artocarpus (nearly 60 spp.), which comprises the pantropically cultivated breadfruit, A. altilis, and jackfruit, A. heterophyllus as well as several other species utilized for food or timber. The delimitation of the tribe and genera within it has been the subject of much uncertainty due to the difficulty in understanding the natural affinities of their complex inflorescences. Nuclear and plastid DNA sequences and morphological characters were used to reconstruct the phylogeny of Artocarpeae in order to test the monophyly of the current classification, trace the evolution of inflorescence characters, and identify the closest wild relatives of breadfruit and jackfruit. The results indicate that neither the tribe nor Artocarpus represent monophyletic lineages and provide a framework for guiding future classification and evolutionary studies of early diverging Moraceae lineages.

10.8.4. Phylogeny of *Castilleae* (Moraceae): Investigating the evolutionary history of the figs' closest relatives

W. L. Clement;
University of Minnesota, Twin Cities, St. Paul, MN, United States.

The tribe Castilleae (Moraceae) comprises 11 genera and 59 species distributed pantropically, including economically important species such as the Panama rubber tree (*Castilla elastica*). The sister lineage *Ficus* is well known for an obligate pollination mutualism with fig wasps. Despite the close relationship of Castilleae to these exemplars of coevolution, little is known about the evolutionary relationships or reproductive ecology within this group. DNA sequence data from the granule bound starch synthase gene and ITS as well as data from morphology were used in phylogenetic reconstruction. The phylogeny forms the foundation from which focused studies of character evolution, biogeography, and pollination biology are being conducted. This research represents the first phylogenetic investigation focused on species level relationships among Castilleae, and highlights the biology of an understudied plant group. The findings will contribute to understanding the origins of the fig-fig wasp mutualism, as well as the origins of plant diversity as 93% of Castilleae inhabit the Amazon basin, the most diverse tropical forest in the world.

10.8.5. Alternative utilization of food resource by a non-pollinating fig wasp and its implication on the fig - fig wasp mutualism

R. A. S. Pereira[1], S. P. Teixeira[2], F. Kjellberg[3];
[1]Depto de Biologia/FFCLRP-USP, Ribeirão Preto, Brazil, [2]Depto de Ciências Farmacêuticas/FCFRP-USP, Ribeirão Preto, Brazil, [3]Centre d'Ecologie Fonctionelle et Evolutive/CNRS, Montpellier, France.

We document here for the first time seed predation by kleptorasitic fig wasps, which is used as a low quality resource to produce small males. In figs sampled during April 2003, from a tree of *Ficus citrifolia* we observed males of *Idarnes* sp. (*carme* group) developing within structures that resembled fig seeds and that differed for the galls from which they usually emerge. A comparative anatomical examination showed that the bored structures were in fact bored seeds. Males that had developed feeding on seeds were smaller in size that ones that fed on galls, suggesting that the quality of the food resource is better in galls. Our data points out that alternative utilization of good seeds as food resource occurs more intensely in figs with fewer galls available for oviposition. Bored seeds were also observed in other high-infested *F. citrifolia* crops in Brazil, suggesting that this alternative resource utilization may occur frequently. Alternative seed predation represents a direct cost to plant's female function, which makes this cleptorasites more effective parasites of the fig - fig wasp mutualism.

10.9.1. Rosid reproductive structures - progress and prospects

J. Schönenberger;
Department of Botany, Stockholm University, Stockholm, Sweden.

With ca 70'000 species the rosids stand for more than a quarter of the total angiosperm species diversity. This taxonomic richness is reflected in a tremendous variety of floral organization and architecture. Rosids have in the recent past received extensive molecular phylogenetic study. As a result, monophyly and taxonomic composition of the group are well established. In addition, many subclades at the order level are now apparent. Deeper relationships, however, are still largely equivocal. As in many other parts of the plant tree of life, it will be impossible to reach an adequate understanding of the evolutionary history of the rosids without taking into account information from comparative morphological studies of extant and, in particular, also of fossil taxa. The fossil record of rosids is rich in well-preserved reproductive structures, and together with recent results from comparative studies of extant rosids, provides a wealth of structural data. Although much remains to be done at all levels, fresh attempts to synthesize and possibly reconcile results from molecular phylogenetics, comparative floral morphology, and palaeobotany, seem timely.

10.9.2. Fossil reproductive structures of Saxifragales and saxifrage evolution

E. J. Hermsen, K. C. Nixon, W. L. Crepet;
Cornell Univeristy, Ithaca, NY, United States.

While much attention has been paid to utilization of fossils in calibration of evolutionary rates on phylogenetic trees, less has been devoted to exploring another application of fossils in a phylogenetic context: that of giving insight into character evolution within plant lineages. In this study, extinct taxa in the order Saxifragles represented by well-preserved fossils will be incorporated into a phylogenetic tree of extant plants (calculated using morphological and molecular sequence data) to explore the evolution of reproductive characters in the group over geologic time. By incorporating fossils into analyses with extant taxa and examining the optimization of morphological characters on the resultant tree(s), it is possible to explore the order in which particular traits first appeared and to discover unique, derived characters (or character combinations) in extinct lineages of plants, phenomena that cannot necessarily be discovered through examination of extant lineages alone.

10.9.3. Reproductive structures of Leguminosae: phylogenetic and paleobotanical utility

P. S. Herendeen[1], G. P. Lewis[2], A. Bruneau[3];
[1]George Washington University, Washington DC, DC, United States, [2]Royal Botanic Gardens, Kew, United Kingdom, [3]Université de Montréal, Montreal, PQ, Canada.

The Leguminosae is the largest family in the rosid clade and its reproductive structures exhibit a great deal of morphological diversity. The fossil record of legumes is extensive and extends to the late Paleocene, with considerable taxonomic diversity appearing in the early to middle Eocene. Compression fossils of fruits and leaves are abundant and many have distinctive morphologies that are taxonomically diagnostic, but fossil flowers are relatively rare and often difficult to identify. Many other fossils represent dispersed organs that by themselves are not distinctive and therefore cannot be identified with precision. As a consequence, most legume clades that are known from the fossil record are documented based on fruits or leaves, but they are largely taxa that have distinctive morphologies. Ongoing phylogenetic studies of caesalpinioid legumes using molecular and morphological data will provide a robust phylogeny that, when fossils are incorporated, can be used to assess patterns and timing of morphological evolution in the diversification of this important family.

10.9.4. Evolutionary idiosyncrasies of floral features in rosids

P. K. Endress, M. L. Matthews;
University of Zurich, Zurich, Switzerland.

The new systematic circumscription of orders and higher groups of rosids based on molecular phylogenetic studies has revealed blatant lacunae in our knowledge on structural and biological characteristics of the new groups. New floral studies that go beyond traditionally considered features in larger clades of rosids may provide insight, not only into potential synapomorphies for these groups, but they are also beginning to give fresh insight into the evolutionary stability and lability of features. Such insight allows for the evolutionary behaviour and correlation of certain features at the level of the rosids or subclades of rosids. Although such studies are both time-consuming and difficult, beginning with the availability of liquid-fixed flowers at comparative stages of development, they are greatly needed for progress in evolutionary research. Better knowledge of the idiosyncrasies of flowers of extant plants will also be helpful for the systematic interpretation of fossil flowers.

10.9.5. Flowers and phylogenetic affinities of Normapolles plants - a complex of extinct fagalean lineages

E. M. Friis[1], J. Schönenberger[2], K. R. Pedersen[3];
[1]Department of Palaeobotany, Swedish Museum of Natural History, Stockholm, Sweden, [2]Department of Botany, Stockholm University, Stockholm, Sweden, [3]Department of Geology, University of Aarhus, Århus, Denmark.

The Normapolles complex, defined by its characteristic triporate pollen, constitutes an important and diverse element of many Late Cretaceous and Early Cainozoic floras of the Northern Hemisphere. Based on the dispersed pollen record alone it has been difficult to assess systematic affinities, but relationships with Fagales had been proposed. Over the past twenty years several, exquisitely preserved, Late Cretaceous inflorescences and flowers with Normapolles type pollen *in situ* have been described. On the basis of their general inflorescence structure, floral organisation, and pollen features they all have been suggested to be related to various members of Fagales, in particular to members of the clade comprising Betulaceae, Casuarinaceae, Juglandaceae, Myricaceae, Rhoipteleaceae, and Ticodendraceae. We present the results of a re-examination and synthesis of floral organisation and structure in Cretaceous Normapolles flowers and test the supposed paraphyly of the Normapolles complex by means of a phylogenetic analysis.

10.9.6. Floral structure and systematics in larger clades of rosids

M. L. Matthews, P. K. Endress;
Institute of Systematic Botany, Zürich, Switzerland.

Phylogenetic studies have greatly impacted upon the circumscription of taxa within the rosid clade, resulting in novel relationships at all systematic levels. In many cases, the floral structure of these taxa has never been compared, and in some families, even studies of their floral structure are lacking. Our aim has therefore been to concentrate on poorly studied and basal taxa within new orders, and within orders whose circumscription has significantly changed from traditional classifications. Specifically, to compile detailed analyses of floral structure for these taxa, and to make comparisons at both the intraordinal and interordinal levels, with the aim of deriving potential synapomorphies for these groups. We have focussed upon shared features that are less common among angiosperms. Lack of phylogenetic resolution however, at the base of rosids, does not (yet) allow for further interpretation of these features. Thus far, we have investigated the orders Crossosomatales, Cucurbitales, Oxalidales and Celastrales and will present overviews of these studies, including discussion of potential synapomorphies for each of these groups.

10.9.7. Flower evolution in Malvales with emphasis on the androecium

M. von Balthazar[1,2], **H. Janka**[3,4], C. Bayer[3], J. Schönenberger[5], W. S. Alverson[6], D. A. Baum[2];
[1]Department of Palaeobotany, Swedish Museum of Natural History, Stockholm, Sweden, [2]Department of Botany, University of Wisconsin, Madison, WI, United States, [3]Palmengarten der Stadt Frankfurt am Main, Frankfurt am Main, Germany, [4]Department of Botany and Molecular Evolution, Senckenberg Research Institute, Frankfurt am Main, Germany, [5]Department of Botany, Stockholm University, Stockholm, Sweden, [6]Environmental and Conservation Programs, The Field Museum, Chicago, IL, United States.

The order Malvales comprises Malvaceae s.l. (including former Tiliaceae, Sterculiaceae, and Bombacaceae) and ten smaller, less-known families (Bixaceae, Cistaceae, Cochlospermaceae, Diegodendraceae, Dipterocarpaceae, Muntingiaceae, Neuradaceae, Sarcolaenaceae, Sphaerosepalaceae, and

Thymelaeaceae). Molecular data support several subclades within the order, but deeper nodes remain largely unresolved. Neuradaceae, many Thymelaeaceae, some Dipterocarpaceae, some Malvaceae, and a few Sarcolaenaceae are characterized by a low number of stamens, which are arranged in one or two whorls. We show that the androecia of most other taxa of Malvales have numerous stamens, which often develop on a complex ring primordium in a centrifugal or more complicated pattern. Nonetheless, the androecia of these families have apparently a basically two-whorled ground plan. Furthermore, even the highly modified androecia of Malvaceae with androecial tubes and androecial lobes upon which 'half-anthers' are inserted seem to exhibit developmental and vascular patterns suggestive of a two-whorled organization.

10.10.1. Molecular systematic, floral developmental and anatomical revelations on generic relationships and evolutionary patterns in the Violaceae

M. Feng[1], H. E. Ballard, Jr.[2];
[1]Institute of Botany, Chinese Academy of Sciences, Beijing, China,
[2]Ohio University, Athens, OH, United States.

Recently completed molecular systematic investigations of the Violaceae using the chloroplast trnL-F spacer confirm prior rbcL results, rejecting subfamily Leonioideae and all traditional tribal groupings as non-monophyletic. The genus Hybanthus, defined by an enlarged saccate petal, is highly polyphyletic, comprising six divergent and biogeographically coherent lineages dispersed across the family. Floral developmental studies reveal distinctly zygomorphic corollas in mid-development of all studied genera, with "actinomorphy" achieved late in ontogeny; the family may have a zygomorphic, rather than actinomorphic, recent common ancestor. Developmental results clarify filament fusion and nectary morphology across genera. Xylem anatomy, palynology, chromosome numbers, calcium oxalate crystal morphology and distribution, androecial and other morphological traits, and biogeography support the numerous novel clades and generic placements from the chloroplast phylogenies. Suites of some of these traits provide the means to circumscribe and distinguish the six generic segregates currently lurking under Hybanthus.

10.10.2. Dismantling the polyphyletic genus *Hybanthus Jacq.* (Violaceae)

H. E. Ballard[1], J. de Paula-Souza[2], M. Feng[3];
[1]Ohio University, Athens, OH, United States, [2]Universidade de Sao Paulo, Sao Paulo, Brazil, [3]Chinese Academy of Sciences, Beijing, China.

The genus Hybanthus Jacq. differs from other Violaceae by its enlarged bottom petal and saccate base. Revisionary studies suggest over 100 species in the genus. Molecular phylogenetic analyses of the family using rbcL and trnL-F spacer sequences reveal Hybanthus as highly polyphyletic. Further investigation of the seven biogeographically coherent chloroplast clades has uncovered 12 morphological, anatomical and cytogenetic features circumscribing the clades, including corolla morphology, androecial morphology, fruit and seed morphology, calcium oxalate crystal morphology and distribution, and base chromosome number, with suggestions of further traits from embryos, pollen and vessel elements. Genera to segregate from Hybanthus sensu lato are (1) Hybanthus s. str. in Mesoamerica and the Caribbean [6 spp.]; (2) Cubelium Raf. in eastern North America [1 sp.]; (3 and 4) two unnamed groups in Mesoamerica [2 spp. each]; (5) Pombalia Vand. in the southwestern US and Latin America [55 spp.]; (6) Pigea DC. in South Africa, southern Australia and New Caledonia [15 spp.]; and (7) an unnamed group in Africa, Indochina and Southeast Asia [15-25 spp.].

10.10.3. Studies on the new endemic genus *Hybanthopsis* and other Brazilian hybanthoid violets

J. de Paula-Souza;
Universidade de São Paulo - ESALQ, Piracicaba - São Paulo, Brazil.

The tribe Violeae is represented in Brazil by ca. 40 spp., most of them belonging to *Hybanthus* (27 spp.), and the remaining is distributed among *Anchietea*, *Corynostylis*, *Noisettia*, *Schweiggeria* and *Viola*. Recently, the tribe was increased by another genus, with the description of *Hybanthopsis*, with a single species, *H. bahiensis* Paula-Souza, endemic to "caatingas" (xerophytic, deciduous vegetation) in Eastern Brazil. This is the fourth lianescent genus of the family, along with the Neotropical *Anchietea* and *Corynostylis*, and the South Pacific *Agatea* (also included at the Violeae). The phylogenetic relationships of the new genus are still unclear, but it is expected that it falls within the other 3 lianescent genera, which are grouped into a well-supported clade on preliminary studies on the phylogeny of the family. Although the flower structure of *Hybanthopsis* is most similar to *Hybanthus* or the lianescent *Agatea*, it is probably more closely allied to *Anchietea* due to its chartaceous capsule and semi-obsolete ridge on the seeds. The new genus is just one of the several novelties within the tribe Violeae on recent taxonomic studies with the family in Brazil.

10.10.4. Revision of African *Rinorea*: Diagnostic characters

G. Achoundong;
National Herbarium, Yaoundé, Cameroon.

Botanists working on African *Rinorea* have all experienced the difficulties of distinguishing species. The question was well highlighted by De Wildeman (1920), who published a revision of this group, building on the work of Engler (1904) and Brandt (1914). He stressed the need to discriminate *Rinorea* by using many stable, criteria, avoiding the use of variable characters. However, his resultant tentative keys remain unsatisfactory and their use has led to confusion in *Rinorea* identifications

To avoid these shortcomings, it is proposed here to base *Rinorea* delimitation on the correlation between primary and secondary characters as suggested by Leonard (1955). Primary characters are those located in flowers and particularly in the androecium; secondary characters are those shown by other structures. These correlations allow an improved delimitation of sections in the genus *Rinorea*. Within the sections, it then becomes easier to discriminate species. The aim of this paper is to suggest guidance on dividing African *Rinorea* into sections, and sections into species.

10.10.5. Lilliputian wonders in the Rosulate Violas (sect. Andinium)of Southern South America

J. M. Watson, A. R. Flores;
Fundación Claudio Gay, Los Andes, Chile.

Approximately 100 species of dwarf annual and perennial herbs comprise section *Andinium* of *Viola*, the so-called Andean rosulates. They range fairly continuously over 5400 km of longitude between the equator and Santa Cruz province, Argentina, and occur within five Andean nations. Although mainly alpine in vertical distribution and ecology, a few also descend to the Pacific coast. Of rather variable habit, their typical and most notable form consists of compressed or columnar rosettes a few cm high, these more like certain Crassulaceae or saxifragas than other known violets. Foliage is often arranged tightly in geometrical spirals. Flowers however are conservative and instantly betray their genus. Rosulates are frequent pioneers, associated with volcanic oreogeny and sites of little or no other cover. Many seem unable to tolerate direct competition. Other tendencies include mimetic coloration, spot or narrow endemism and small populations. *Andinium* contains a quarter of all *Viola* species, yet is hardly known. The taxonomy is undeveloped, having scarcely been studied for 75 years and never in its entirety. That situation is currently being addressed.

10.10.6. Allopolyploid evolution of the temperate Violas - results from chloroplast and nuclear gene markers

T. Marcussen[1], K. S. Jakobsen[1], B. Oxelman[2];
[1]Centre of Ecological and Evolutionary Synthesis (CEES), Oslo, Norway, [2]Department of Systematic Botany, Uppsala, Sweden.

Data from morphology, biogeography, chromosome numbers, crossing compatibilities and DNA sequence variation (ITS1&2) have been used to construct phylogenies of *Viola*. Together, they suggest that (*i*) the genus originated in South America, that (*ii*) its base chromosome number is $2n=12$ and that (*iii*) the blue-flowered temperate groups, having as base numbers $2n=20$ (section *Viola*) and $2n=24$ (section *Plagiostigma*), originated independently from within the basal, yellow-flowered section *Chamaemelanium* ($2n=12$). While all investigated *Viola* groups possess only a single ITS sequence type, isozyme studies have shown that most groups having $2n=20$ or higher numbers are in fact polyploid. The hybrid origins of these groups have so far not been fully resolved. We have examined polyploid groups of *Viola* using chloroplast DNA and low-copy nuclear gene markers. In contrast to ITS sequences, paralogues of low-copy nuclear genes are conserved in the polyploid groups. Chloroplasts are non-recombining and suitable to retrieve maternal lineages. Our preliminary results show that these markers are promising tools in disentangling the polyploid evolution within *Viola*.

10.10.7. Population features of hybridization in *Viola*: two case studies

J. Kirschner, J. Danihelka, A. Krahulcova, F. Krahulec;
Institute of Botany, Academy of Sciences, Pruhonice, Czech Republic.

Hybridization is a widespread phenomenon in *Viola*. Its extent and impacts in natural populations are documented: Allozyme analysis of five species of the sect. *Viola* and their hybrids along three transects show that hybrids are very common in natural populations, hybridization frequently operates across the ploidy levels, hybrids with one or both parents paleooctoploid are sterile. Most of the seed production of fertile hybrids comes from kleistogamous flowers, and chasmogamous flowers have much lower fertility, spatial distribution of hybrids along the transects reflects the ecological preferences of parents. Functionality of chasmogamous flowers in hybridization and the massive cleistogamy suggest a complex population structure in the sect. *Viola*. Introgression between a native, subendemic *V. lutea* subsp. *sudetica* (2n=50) and an introduced species, *V. tricolor* s. lat. (2n=26) was studied. Karyology shows a rapid spreading and persistence of the hybrid plants, formation of hybrid types having chromosome features outside the ranges of parents, and strong introgressive influence on the native parent about 25 years after the initial hybrid contact.

10.11.1. Land use history and forest plant metapopulations in dynamic landscapes

M. Vellend;
University of British Columbia, Vancouver, BC, Canada.

In fragmented landscapes, habitat patches are often destroyed and created through time, though most metapopulation models treat patch networks as static. Numerical simulations of classic Levins-type models can be used to demonstrate that for long-lived plants, such as forest herbs, historical land use can create disequilibria between landscape structure and patch occupancy that may endure for decades to centuries. We have also developed a generally-applicable, modified version of Hanski's Incidence Function Model (IFM) that incorporates landscape dynamics (i.e., habitat patch turnover), and we have parameterized the model with data on patch occupancy patterns for forest plants in central Lincolnshire, UK. Estimated colonization and extinction rates varied significantly among species with different life-history traits. Model simulations demonstrate a profound negative influence of habitat turnover rate on metapopulation dynamics and persistence, particularly for slow-colonizing species.

10.11.2. Genetic diversity and metapopulation dynamics in Mediterranean endemics

A. Mignot[1], I. Olivieri[2];
[1]Institut des Sciences de l'Evolution, University of Montpellier, France,
[2]Institut des Sciences de l'Evolution,, University of Montpellier, France.

Plant species often have a patchy and unstable distribution. When metapopulation dynamics is such that recolonization rate is larger than extinction rate, the species is actually healthy from a demographic point of view. Some species, conversely, appear as collections of highly stable local populations with little exchange among them, so that their viability is entirely dependent upon each population viability. When few populations constitute such species, they are highly threatened. I will describe the demographic and genetic work we are conducing on two endemic plant species living in rocky habitats of the Mediterranean basin *(Centaurea corymbosa* Pourret and *Brassica insularis* L.). Because they are characterized by highly stable local populations, they might not appear as highly threatened as other endemic species living in more human-disturbed environments. However these species are also characterized by small population sizes, so that demographic, genetic and environmental stochasticities might actually constitute major threats for their viability.

10.11.3. Effects of inter-population crosses between fragmented populations of the common *Lychnis flos-cuculi*

G. Vergnerie[1], S. Hoehn[1], M. Fischer[2];
[1]Institute for Environmental Sciences, Zurich, Switzerland, [2]Institut für Biochemie und Biologie, Potsdam, Germany.

To evaluate the consequence of adaptation to landscape heterogeneity and fragmentation, we use the common but declining *Lychnis flos-cuculi.*We know that our population show local adaption to environmental gradient and plants fitness components present an allee effects when comparing large and small populatlions. In spring 2003 we crossed 7 plants of each of 13 populations with a plant from: 1/ the same population, 2/ a small, 3/ a large, 4/ an ecologically similar and 5/ an ecologically dissimilar population. Crosses between populations yielded 26 % more seeds per fruit ($p<0.001$), which weighed 7 % less ($p<0.05$), indicating hybrid vigour for early fitness of the first generation of outcrossing. In the field, larger population produced higher flowering stems ($p<0.05$) but only when crossed with other large populations, indicating a detrimental effect of outbreeding for large populations. Currently we are growing some offspring in the greenhouse, other in the parental populations, and we produced F2 and backcrosses. Our results will allow to balance positive effects of heterosis and negative effects of disruption of adaptation in outbreeding crosses.

10.11.4. Predicting the fate of species in fragmented landscape based on their demography and dispersal ability

Z. Munzbergova[1,2], O. Tackenberg[3], T. Herben[1,2];
[1]Institute of Botany, Pruhonice, Czech Republic, [2]Department of Botany, Charles University, Prague, Czech Republic, [3]Institut für Botanik, Universität Regensburg, Germany.

Effect of habitat fragmentation on species survival is a major concern of species conservation. While there are a few model studies predicting the effect of landscape changes on survival of single species, the possibility to generalize these conclusions is still largely lacking. The aim of this study is thus to make general predictions on how species respond to future landscape change depending on their traits. Specifically, we want to examine how local population dynamics and dispersal affect prospect of species' survival at a landscape level. We used a spatially explicit metapopulation model and calibrated it with real data of a range of plant species. Data on local population dynamics were extracted from literature; data on wind dispersal distances were simulated using the model of Tackenberg (2003). To evaluate response of the species to landscape changes, we assessed survival of the species, their population size and habitat occupancy under different scenarios of habitat removal and frequency of local disturbance. The results show how species survival depends on local population dynamics as well as on its dispersal ability.

10.11.5. Metapopulation biology of a declining, poorly dispersed plant species in Brandenburg: a project towards efficient habitat networks in plant conservation

B. Seifert, M. Ristow, M. Fischer;
University of Potsdam, Institute of Biochemistry and Biology, Potsdam, Germany.

While systems of connected plant habitats have become legal requirements for plant conservation, guidelines for their design are scarce and their actual success is largely unknown. According to metapopulation theory species persist if local extinctions are balanced by (re)colonisations. While most studies in plant conservation biology concentrate on population viability and neglect colonisation, we study ecological and genetic determinants of both for the still common *Armeria elongata* in its patchily distributed habitats in the German federal state of Brandenburg. There, the viability of its populations is threatened by agricultural change, and the colonisation of new habitats is hampered by its poor seed dispersal. With spatially-explicit observations and experiments we address the dynamics of populations and meta-populations and their environmental and genetic drivers. We selected 24 extant populations for detailed demographic and genetic monitoring, and further monitor suitable, but currently unoccupied, sites. Our comprehensive approach aims to help adapting habitat networks to actual requirements of plant conservation.

10.11.6. Lattice models of plant populations with spatial local interaction between individuals

A. S. Komarov;
Institute of Physicochemical and Biological Problems in Soil Science of Russian Academy of Sciences, Pushchino, Moscow Region, Russian Federation.

Immobility of plants requires special mathematical methods for simulation of population dynamics. Simplification of the models can be done using lattice presentation of the population space. In this case cellular automata approach to simulation of plant populations or community dynamics can be developed and computer experiments can be carried out. Uniting this modeling approach with the concept of discrete description of plant ontogeny allows for developing of a set of discrete models for analyzing the spatial-temporal dynamics of plant populations and communities. Local interactions between species and individuals in terms of neighborhood can be introduced allowing for description of nonlinear population dynamics. Short-rhizome plants' population nonlinear dynamics at random extinction of individuals with different intensities, the role of asynchronous changes of age states, the rise of stable spatial structures from initial random pattern were studied. Events similar to phase transitions, conditions of population stability were found for different plant's life forms.

10.11.7. A comparison of life-history characters of arctic and alpine populations of the annual *Koenigia islandica*.

I. Wagner, A. M. Simons;
Carleton University, Ottawa, ON, Canada.

Major differences in environmental characteristics between arctic and alpine ecosystems exist, to which plants having populations in both arctic and alpine environments must adapt differently.

Population differentiation in life-history characters was tested for several populations of *Koenigia islandica*, an arctic-alpine annual with a wide, circumpolar distribution, by germinating and growing each population under simulated arctic and alpine conditions.

Several life-history characters are predicted to differ between arctic and alpine populations, including seed germination and reproductive strategies, as well as vegetative growth. For example, plants from northern populations grew better under simulated arctic conditions, reaching larger sizes and producing more flowers and seeds. Plants originating from low latitude environments seemed unable to benefit from the long photoperiods of arctic conditions, developing poorly and reaching smaller sizes. Also, seed stratification had different effects on the germinability of different populations.

10.12.1. Molecular, biochemical and phenotypic definition of the physiological impact of V-PPases on plants

P. A. Rea, B. J. Green;
Plant Science Institute, Department of Biology, University of Pennsylvania, Philadelphia, PA, United States.

Vacuolar pyrophosphate- (PPi-) energized proton pumps (V-PPases) were originally thought to be restricted to plants and comprise a category of structurally and functionally uniform membrane proteins. Recent studies, however, have established that these primary pumps are not only ancient, widespread and pertinent to the metabolism of many organisms including archaebacteria, proteobacteria and parasitic protists but also fall into two distinct subcategories, termed type I and type II. To define the impact these novel energy transducers have on the intact organism we have, using *Arabidopsis thaliana* as a model plant system, succeeded in isolating T-DNA insertion mutants for all of the key genes. Specifically, we now have three types of null mutant for the sole gene encoding the type I V-PPase and both of the genes encoding the type II V-PPases, and have assembled a broad range of probes for distinguishing type I and type II V-PPases at the molecular, protein and functional levels. The properties of these mutants, and what is known and what remains to be determined of the fundamental biochemical capabilities of V-PPases will be discussed.

10.12.2. The H+-PPase AVP1 Is required for organ development in *Arabidopsis*

J. Li[1], L. Lopez[1], H. Yang[1], G. Richter[2], J. Blakeslee[3], A. Bandyopadhyay[3], W. A. Peer[3], A. Murphy[3], S. Gilroy[2], **R. A. Gaxiola**[1];
[1]University of Connecticut, Storrs, CT, United States, [2]Pennsylvania State University, University Park, PA, United States, [3]Purdue University, West Lafayette, IN, United States.

Cells expend as much as 50% of their total intracellular energy reserves to maintain gradients of ions across their membranes. The electrochemical potential of these ion gradients represents stored energy. Plants and fungi are similar in that they use proton (H+) gradients as the "currency" with which to mediate transport of ions, whereas animal cells use Na+ gradients as the driving force. The H+-PPase AVP1 is classically thought of as maintaining the acidic nature of the plant vacuolar compartment. Here we report that AVP1 also plays a critical role in facilitating auxin transport and thereby coordinating development. AVP1 overexpression resulted in enhanced cell divisions at the onset of organ formation, hyperplasia, and increased auxin transport. In contrast, avp1-1 null mutants have severely disrupted root and shoot development and reduced auxin transport. AVP1 was localized to both the tonoplast and plasma membrane where it likely contributes to H+-mediated auxin influx. We conclude that AVP1 plays an important role in organ development through facilitating the auxin fluxes that regulate organogenesis.

10.12.3. The role of inorganic pyrophosphate as an alternative energy donor at low oxygen

P. Geigenberger;
Max Planck Institute Molecular Plant Physiology, Golm, Germany.

In contrast to animals, plants lack specialised circulation systems, and oxygen falls to low levels within many plant tissues. A specific role of PPi in conserving oxygen will be discussed. The cytosol of the plant cell contains significant levels of PPi, which are maintained at high levels in hypoxic tissues. PPi is utilised as an energy donor for sucrose mobilisation via sucrose synthase and UDPglucose pyrophosphorylase, for glycolysis via PPi-dependent PFK, and for tonoplast energisation via a PPi-dependent proton pump, each of these enzymes being induced by low oxygen. Each PPi dependent reaction actually duplicates an ATP consuming reaction, which in the case of invertase and the ATP-dependent proton pump are repressed under low oxygen. When sucrose synthase is bypassed by a route that utilises ATP instead of PPi, tissue oxygen tension and cellular energy state decrease. This provides evidence for an important role of PPi in recycling waste energy to fuel important central metabolic and cellular functions, thereby allowing both ATP and oxygen consumption to be decreased.

10.12.4. An ancient pyrophosphate-based stress bioenergetics was preserved during the evolution of the photosynthetic lineage

A. Serrano;
Instituto de Bioquímica Vegetal y Fotosíntesis, Seville, Spain.

Inorganic pyrophosphate (PPi) could arise through a variety of abiogenic processes in the primitive Earth. It is conceivable therefore that organisms in the earlier stages of biological evolution developed a PPi-based bioenergetics. Recent evidences indicate that proton-pumping pyrophosphatase (H^+-PPase), a key protein of that "primitive" energy metabolism, is present in a wide range of extant organisms of the three domains of life, although cyanobacteria, fungi and metazoa are remarkable exceptions. A prevalent feature of organisms having H^+-PPases is that they must chronically cope with a variety of environmental conditions -many of them resembling those of primitive Earth- that severely constrain the cell energy status (anoxia, extreme physico-chemical conditions, nutrient scarcity, etc.). We have found specific regulations at the genetic level of *R. rubrum* and algal H^+-PPases that support this proposal. An outstanding paradigm of this lifestyle is the photosynthetic lineage, from prokaryotes to plants, that includes the only multicellular organisms (metaphyta) in which H^+-PPases have been found so far *(supported by MEC BMC2001-563 grant)*.

10.12.5. The H+-pyrophosphatase is present in both prokaryotic and eukaryotic acidocalcisomes

R. Docampo, S. N. J. Moreno;
CTEGD, Athens, GA, United States.

The H+-pyrophosphatase has been shown to be a useful marker for acidocalcisomes. Acidocalcisomes are dense, acidic organelles with a high concentration of phosphorus present as pyrophosphate and polyphosphate complexed with calcium, and other cations. The acidocalcisome membrane contains a number of pumps

(Ca2+-ATPase, V-H+-ATPase, H+-PPase), exchangers (Na+/H+, Ca2+/H+), and channels (aquaporins), while its matrix contains enzymes related to pyrophosphate and polyphosphate metabolism (exopolyphosphatase, polyphosphate kinase, pyrophosphatase). Acidocalcisomes have been found in several pathogenic microorganisms as well as in the green alga Chlamydomonas reinhardtii, and the slime mould Dictyostelium discoideum. The identification of acidocalcisomes in bacteria and the finding that human platelet dense granules are homologous to acidocalcisomes, indicate that these organelles have been conserved from bacteria to humans. Acidocalcisomes function in the storage of cations and phosphorus, pyrophosphate and polyphosphate metabolism, calcium homeostasis, maintenance of intracellular pH homeostasis, and osmoregulation.

10.13.1. Engineering rubisco to improve yield: future potential or sisyphian task.

S. Gutteridge;
Stine Research Center, Newark, DE, United States.

Most projections paint a sobering picture of the ability of agriculture to keep delivering the yield increases necessary to support the future global population. By 2050, if there is only marginal improvement in field performance of major crops there could be a serious shortfall in production. Researchers are working intensively to find ways of sustaining the impressive increase in productivity of past years, but this might be impossible without turning over more land to agriculture; an unlikely scenario. Many of the strategies will necessarily involve engineering plants, but it takes many years to go from the lab to the field with a new stable variety that shows robust yield improvement. Furthermore, identifying which trait would provide a significant boost to yield is becoming a major challenge.

It is well recognized that a major constraint to plant productivity resides at the first step in C-fixation and alleviating this limitation could have a significant impact on yield. Although many of the necessary technological components to achieve this goal have been developed, putting them together will be a long-term undertaking.

10.13.2. Make or Break: Metabolism of the rubisco inhibitor, CA1P

J. Andralojc[1], R. A. C. Mitchell[1], P. J. Madgwick[1], A. J. Keys[1], S. Gutteridge[2], M. A. J. Parry[1];
[1]Rothamsted Research, Harpenden, United Kingdom, [2]DuPont Company, Wilmington, DE, United States.

We have recently established a route for the *de novo* biosynthesis of the naturally occurring Rubisco inhibitor, 2-carboxy-D-arabinitol 1-phosphate (CA1P), from recently assimilated carbon in the Calvin cycle. CA1P is present in many plant species at night and is broken down in the day by a specific phosphatase. We are currently attempting to identify and clone the genes involved in the biosynthesis and metabolism of CA1P, including those for the widely distributed but little studied branch chain sugar, D-hamamelose (2-hydroxymethyl-D-ribose) and its phosphate esters, which are intermediates in the biosynthesis of CA1P. In the course of this work, a gene thought to encode a CA1P-specific phosphatase has been cloned and Arabidopsis knock-out mutants obtained. This gene has been shown to direct the synthesis of a protein with CA1P phosphatase activity when incorporated into an *in vitro* wheat expression system. Oligonucleotide microarrays have also been used to examine hamamelose-induced differential gene expression in leaves of Arabidopsis.

10.13.3. Structural framework for catalysis and specificity in rubisco

I. Andersson;
Department of Molecular Biology, Swedish University of Agricultural Sciences, Uppsala, Sweden.

Photosynthetic efficiency is limited by the catalytic properties of the major photosynthetic CO_2-fixing enzyme, Rubisco (ribulose-1,5-bisphosphate carboxylase/oxygenase). Three-dimensional structures for Rubisco have been determined from several prokaryotic and eukaryotic sources. While these structures have provided a wealth of information and present an important framework for structure-function studies, no simple rationale for engineering a better enzyme has presented itself so far. However, results from genetic screening and site-directed mutagenesis show that amino acid substitutions in several distinct areas of the enzyme influence the catalytic properties of Rubisco. A survey of key structural features of both natural and engineered Rubisco variants will be presented along with results from recent studies on the molecular basis for the catalytic diversity of Rubisco.

10.13.4. Altering photosynthetic carbon fixation through rubisco engineering

S. M. Whitney;
Research School of Biological Sciences, Canberra, ACT, Australia.

Over the last decade, efforts to manipulate the photosynthetic CO_2-fixing enzyme, Rubisco, *in planta* by plastome-transformation technology have advanced considerably. Rubisco's catalytic properties have a profound impact on the efficiency of the photosynthetic process making it an obvious target for manipulation. The surgical precision of the homologous-recombination mechanism that enables plastome manipulation provides an excellent tool for testing our knowledge, and our predictions, about Rubisco biology. My groups ongoing plastome-transformation projects seek to address different aspects of Rubisco biology - its catalytic process, ways to control the expression of Rubisco transgenes, the folding and assembly of Rubisco subunits in the chloroplast, and the regulation of the introduced enzyme. This research is a prelude to the ultimate goal of deciphering ways to effectively transplant more efficient Rubiscos into plants and how to get the enzyme to assemble and function appropriately. An overview of newly developed strategies for engineering foreign Rubiscos into plastids using a single transformation step will be presented.

10.13.5. Faster rubisco is the key to superior nitrogen use efficiency in NADP-ME relative to NAD-ME C_4 grasses

O. Ghannoum[1], J. R. Evans[1], W. S. Chow[1], T. J. Andrews[1], J. P. Conroy[2], S. von Caemmerer[1];
[1]Research School of Biological Sciences, Australian National University, Canberra, Australia, [2]University of Western Sydney, Sydney, Australia.

In 27 C_4 grasses, photosynthetic and whole plant N use efficiency was greater in NADP-ME than NAD-ME species. This was due to lower N content in NADP-ME than NAD-ME leaves because neither assimilation rates nor plant dry mass differed significantly between the two C_4 subtypes. Relative to NAD-ME, NADP-ME leaves had greater *in vivo* (assimilation rate per ribulose-1,5-bisphosphate carboxylase/oxygenase (Rubisco) catalytic sites) and *in vitro* Rubisco turnover rate (k_{cat}) (3.8 *versus* 5.7 s^{-1} at 25 °C). In two NAD-ME and two NADP-ME grasses, 30% of leaf N was allocated to thylakoids. Soluble protein represented a smaller fraction of leaf N in NADP-ME (41%) than NAD-ME (53%) leaves, of which Rubisco accounted for one seventh. The majority (65%) of leaf N and chlorophyll was found in the mesophyll of NADP-ME and bundle sheath of NAD-ME leaves. The mesophyll-bundle sheath distribution of functional thylakoid complexes (photosystem I and II, and cytochrome *f*) varied among species, with a tendency to be mostly located in the mesophyll. In conclusion, superior N use efficiency of NADP-ME relative to NAD-ME grasses was achieved with less leaf N, and Rubisco having a faster k_{cat}.

10.13.6. Environmental and ecological aspects of CO_2 assimilation

M. A. J. Parry[1], A. J. Keys[1], P. J. Madgwick[1], R. Haslam[1], J. Galmes[2], H. Medrano[2], J. Flexas[2];
[1]Rothamsted Research, Herts, United Kingdom, [2]Universitat de les Illes Balears, Palma, Spain.

Rubisco is an inefficient enzyme with a low turnover number and a competing oxygenase activity that causes C3 plants to lose up to 50% of carbon fixed. Inefficiency is greatest at elevated temperature and when CO_2 is low (e.g. in drought when stomatal conductivity limits CO_2 availability at the site of Rubisco). We hypothesised that the selection pressure for high specificity factor (Ű) will be greatest under hot and arid conditions. Values of Ű for purified Rubisco from 24 species of C3 species found in diverse habitats with a wide range of environmental growth limitations were determined. Consistent with our hypothesis, Rubisco specificity factors tended to be higher in species from hotter and drier environments and in hemi-deciduous or evergreen species (Galmés et al. 2004). Molecular structures of Rubisco from such species may be exploited to improve crop performance. If introduced into tobacco, *Limonium gibertii* Rubisco would increase net photosynthesis by 29 %.

10.13.7. Underwater photosynthesis studies on a terrestrial species identify novel responses of gas exchange capacity and photosynthesis biochemistry to submergence

L. Mommer[1], T. L. Pons[2], J. H. Venema[3], E. J. W. Visser[1];
[1]Radboud University Nijmegen, Nijmegen, The Netherlands, [2]Utrecht University, Utrecht, The Netherlands, [3]University of Groningen, Groningen, The Netherlands.

Gas exchange is severely hampered when terrestrial plants are flooded. A straightforward way to reduce the shortages of oxygen and carbohydrates might be photosynthesis under water. Several terrestrial plants develop ‘aquatic’ leaves which show pronounced anatomical differences compared to the ‘aerial’ leaves. We investigated if this remarkable plasticity facilitates gas exchange capacity under water. The cuticle thickness of the flooding tolerant species *Rumex palustris* was reduced upon submergence, resulting in decreased diffusion resistance which greatly facilitated underwater photosynthesis. Furthermore, the photosynthetic machinery itself was affected by submergence. Rubisco contents were reduced upon acclimation to submergence, indicating a lower carboxylation capacity. Electron transport capacity was also reduced in these leaves, but not as strong as the change in Rubisco, indicating a substantial increase of the ratio between electron transport and carboxylation capacity upon submergence. This novel finding is striking since this ratio is believed to be very conservative.

10.14.1. Evolution in a community context: Multi-species selection on plant floral and defense traits

S. Y. Strauss;
University of California, Davis, CA, United States.

As members of multi-species communities, plants simultaneously integrate direct and indirect interactions with herbivores, pollinators and other species. Thus, traits expressed by plants may be influenced by a variety of selective agents. This perspective is in stark contrast to studies that focus on pairwise interactions, i.e., how floral traits are acted on solely by pollinators and how defensive traits reflect selection from herbivores. Here, I describe experimental studies in which the community context of selection on plant floral and defense traits is explored. For example, costs of plant defenses against herbivores may affect the size and/or numbers of flowers produced, the amount of floral rewards, or the palatability of these rewards. In such cases, a defended plant may become more pollinator limited, and pollinator preferences may constrain the response to selection from herbivores for increased defenses. Similar indirect interactions with non-pollinator species may constrain the evolution of floral traits

10.14.2. Linking above and belowground multitrophic interactions: root herbivory affects aboveground herbivore, parasitoid and hyperparasitoid performance via changes in plant quality

R. Soler[1], T. M. Bezemer[1,2], W. H. van der Putten[1,2], L. E. M. Vet[1,2], J. A. Harvey[1];
[1]NIOO, Heteren, The Netherlands, [2]Wageningen University and Research Centre, Wageningen, The Netherlands.

Plants and insects are part of a complex multitrophic environment, in which they closely interact. However, most of the studies have been focused mainly on bi-tritrophic aboveground subsystems. We studied whether root herbivory by *Delia radicum* can influence the development of the leaf feeder *Pieris brassicae*, its parasitoid *Cotesia glomerata* and its hyperparasitoid *Lysibia nana,* through changes in secondary plant compounds. In presence of root herbivory, the development time of the herbivore and the parasitoid significantly increased, and the adult size of the parasitoid and the hyperparasitoid were significantly reduced. Interestingly the effects were stronger at low root fly densities than at high levels of root herbivory. Higher glucosinolate (sinigrin) levels were recorded in plants exposed to belowground herbivory, suggesting that the reduced performance of the aboveground insects was via reduced plant quality. Our results show for the first time that root herbivory, via changes in plant quality, can reduce the performance of an aboveground three trophic level food chain.

10.14.3. *Arabidopsis*-a model for molecular approaches in plant volatile biology

D. Tholl[1], F. Chen[2], J. Petri[1], J. Gershenzon[1], E. Pichersky[2];
[1]Max Planck Institute for Chemical Ecology, Jena, Germany, [2]Department of Molecular, Cellular and Developmental Biology, University of Michigan, Ann, Arbor, MI, United States.

Volatile compounds are important mediators in plant environment interactions. We employ the genetic and genomic resources of *Arabidopsis thaliana* to study the molecular basis of biochemical and physiological processes as well as ecological functions of constitutive and inducible plant volatile emissions with particular focus on terpene volatiles. Arabidopsis flowers emit a complex mixture of monoterpene and sesquiterpene volatiles. In a reverse genetics approach, we have characterized all genes out of a large gene family of 32 terpene synthases (TPSs) that are responsible for the floral volatile emission. Analyses of gene expression and promoter activities revealed a highly restricted TPS activity in particular floral organs, the stigma and the intrafloral nectaries. Given the high vulnerability of these tissues to microbial infections, the active biosynthesis of terpenes at these sites suggests a primarily antimicrobial defense function for protection of reproductive organs. Studies with TPS knock out lines and different ecotypes under laboratory and field conditions will shed further light on the role of terpene volatiles in Arabidopsis flowers.

10.14.4. Phytochemical early warning systems: induced resistance to herbivores in ramet populations of clonal plants

S. Gòmez, J. F. Stuefer;
Experimental Plant Ecology, Nijmegen, The Netherlands.

Plants are constantly exposed to the threat of herbivore damage. Many species have developed inducible defence mechanisms to deter feeding animals after an initial attack has happened. Such inducible resistance is considered beneficial in environments with spatio-temporally variable herbivore pressures as the production of costly defence chemicals is avoided whenever they are not needed. In many plants the defence induction signal (or the defensive phytochemical) can be transported throughout the plant, thereby conferring resistance to damaged and undamaged plant parts. This phenomenon, termed induced systemic resistance may be of particular importance to physically connected ramets of clonal plants because it allows for the internal transmission of phytochemical warning signals over considerable distances, thereby giving ramets of clonal plant species potential advantages over non-clonal neighbours in the case of imminent herbivore attacks. Our experiments provide clear evidence for ISR in ramet populations of the clonal herb Trifolium repens, and they show that the systemic transmission of early warning signals is constrained by phloem flows.

10.14.5. Signals from the deep. Root induction alters shoot-induced direct and indirect defences in wild *Brassica oleracea*

N. M. van Dam[1], C. A. Raaijmakers[1], C. A. Hordijk[2], L. E. M. Vet[1,3];
[1]Netherlands Institute of Ecology (NIOO-KNAW), Heteren, The Netherlands, [2]Netherlands Institute of Ecology (NIOO-KNAW), Nieuwersluis, The Netherlands, [3]Laboratory of Entomology Wageningen University, Wageningen, The Netherlands.

Induced responses in plants are known to occur in both roots and shoots. In their natural environment, most plants will be attacked at both organs simultaneously. Because signaling hormones as well as induced defence products are transported systemically through the plant, root and shoot-induced responses may interact. Eventually, these interactions may constrain optimal defence induction. In wild *B. oleracea* we found that application of jasmonic acid (JA) to the roots yielded a significantly different glucosinolate profile in the shoots compared to shoot-application. Larvae of the specialist herbivore *Pieris rapae* performed significantly worse on root-induced plants. Similarly, plants pre-treated with JA at their roots before they were damaged and treated with *P. rapae* saliva, produced significantly different volatile profiles than plants pre-treated with JA to their shoots. Root induction thus affects both direct and indirect shoots defence levels. As a consequence, the presence of root feeders can have a significant effect on the aboveground multitrophic interactions associated with plants, and, eventually, plant fitness.

10.14.6. Variation in olfactory cues used by bees in flower selection

H. E. M. Dobson;
Whitman College, Walla Walla, WA, United States.

While it is known that flowers attract pollinators through the display of visual and olfactory stimuli, our findings suggest that the relative importance of these cues to bees selecting flowers varies with the particular bee-flower association. Using multiple-choice behavioral experiments (in cages and field) conducted on both solitary and bumble bees, and GC-MS analyses of floral scents, we investigated which floral stimuli are most decisive in a bee's discrimination among flowers. In different species of pollen-specialist bees, females locate host flowers using a specific interplay of cues, which include odors that originate primarily from the androecium, nectaries, gynoecium, and/or petals, depending on the flower fragrance chemistry. In bumble bees visiting *Rosa* species, petal cues are essential in attracting bees, whereas androecial stimuli, particularly pollen odor, determine whether a bee lands. Integrating behavioral and chemical studies is crucial to uncovering the dynamic sensory interactions between bees and floral traits.

10.14.7. Induction patterns in a Brassicaceae evoked by herbivory of a sequestering insect: correlating glucosinolate concentration and myrosinase activity

N. Martin, C. Müller;
Julius-von-Sachs Institute for Biosciences, Wuerzburg, Germany.

The binary defence system of Brassicaceae consists of preformed substrates and hydrolytic enzymes, namely glucosinolates and myrosinases. Upon tissue disruption these separately stored compounds interact to form various mostly toxic products.
We tested induction reactions of *Sinapis alba* following herbivory of larvae of the turnip sawfly *Athalia rosae*. Different developmental stages of larvae fed on young leaves of mature plants for 24 hours. Changes in primary and secondary metabolites were recorded in the damaged leaf as well as in the adjacent leaves and stems for the subsequent four days.
As these larvae sequester intact glucosinolates in their haemolymph, we determined plant glucosinolate concentrations as well as myrosinase activity.
Organ and time specific induction patterns upon herbivory were visible. These patterns differed according to the age of the feeding larvae and compound viewed. We assess whether leaves show stronger induction effects than stems and whether stems compared to leaves are defended via higher constitutive levels.

10.15.1. Biodiversity and ecological processes in tropical rain forests in the light of global land use change

R. Dirzo;
Universid Nacional Autónoma de México, Mexico, Mexico.

Habitat destruction and fragmentation constitute another major global environmental change and its current (and future) impact is likely to be of greatest significance in tropical ecosystems, where a large proportion of the Earth`s biodiversity is concentrated. Most of the available information regarding habitat deterioration is based on rates. These, although inconsistent among researchers, suggest that annual habitat loss is in the order of 10-20 million ha. However impressive these estimates do not consider that the remaining habitat consists of forest fragments, isolated and affected by edges, to varying degrees. In addition, deforestation and fragmentation may synergistically interact with other anthropogenic impacts (e.g. hunting or climatic change). In this symposium we review current information regarding the impacts of deforestation/fragmentation and their synergisms with other disruptions in terms of: I) first-order effects, as determined by changes in species composition and abundance; II) functional aspects, concerning alterations of the performance of individual species, and III) higher-order effects, in terms of disruptions of the ecological processes in which biodiversity participates, including cascading extinctions at local levels. Speakers in this symposium will illustrate examples that make it evident hat, even though local and global extinctions are a matter of concern from an evolutionary point of view, from a more functional perspective, we need to concern ourselves with the disruption of the functioning of individual components of biodiversity and with the extinction of ecological processes in tropical ecosystems.

10.15.2. Phenological study of the tree fern *Alsophila firma* (Baker) D.S.Conant in a Mexican montane forest

K. Mehltreter, J. G. García-Franco;
Instituto de Ecología, A.C., Xalapa, Mexico.

Fifteen of 19 Mexican tree fern species are protected by Mexican laws (NOM-059-ECOL-2001), but there does not exist sufficient ecological information to elaborate efficient conservation strategies. We present the first phenological data set of *Alsophila firma* (Baker) D.S.Conant. At the private montane forest reserve "Las Cañadas" (Huatusco, Veracruz, 19°10'35" N, 96°58'19" E, 1300 m a.s.l.), we observed a population of 31 individuals with a trunk of up to 2 m height. During one year, we measured monthly the length of the trunk and each leaf, and counted the number of living, fertile, new and dead leaves. From these data we calculated growth rates and leaf life span. *Alsophila firma* resulted to be a deciduous tree fern, shedding its pinnules from April to May at the beginning of the rainy season. Four to eight weeks later new leaves were produced synchronically. Leaves have a mean leaf life span of 10.0 ± 0.4 months. Individuals must be larger than 2 m to reproduce by spores, because only one individual became fertile. We estimate that at this site the oldest individuals of 9 m height will be at least 90 years old, because the mean annual trunk growth was 10.4 ± 1.4 cm.

10.15.3. Patterns of change in plant guilds during secondary succession in a tropical montane cloud forest area in Oaxaca, Mexico.

A. Blanco Macias, **R. F. del Castillo**;
Instituto Politecnico Nacional, Xoxocotlan, Oaxaca, Mexico.

Very little is known about the regeneration process of tropical montane cloud forest (TMCF) despite their ecological importance and the rapid disappearing of primary TMCF s on earth. We analysed the changes in composition and structure in five terrestrial plant guilds in three chronosequences each with 15, 45, 75, and >100 years after abandonment in Oaxaca, southern Mexico: We identified 209 species of plants distributed in 128 genera and 69 families. Each guild followed different patterns of change in density, species density (species / area), and richness across succession. Tree density was negatively correlated with shrubs, geophytes and low plants. As the age of the stand increased, the species richness, using rarefaction methods, and the species density of trees and lianas increased, but that of shrubs and low plants decreased. Except for trees and geophytes, the composition of abundant species in each guild was about the same. We conclude that the dynamics of each plant guild across succession should be considered in studies of vegetation dynamics and in programmes of forest management and conservation.

10.15.4. Cloud forest diversity of India

R. Srivastava, S. Biswas, R. P. S. Katwal;
Botany Division, Forest Research Institute (Indian Council of Forestry Research & Education), Dehradun, Uttaranchal, India.

Forest biodiversity and genetic resources largely depend upon the water regime. Bioclimatic regions differ from one another on the basis of precipitation, evapotranspiration and other inter-dependent aspects of biological diversity. Cloud forest ecosystem of Indian sub-continent have been least explored. Two main features of such cloud forest ecosystem strikingly appear as year round flow of fresh water through the streams and endemic tree species with unique architecture of crown. In India such ecosystems are distributed in Shillong plateau in north eastern part, Little Andaman and Nicobar Islands in southern most part, Wenlock downs forests in Nilgiri Hills in western Ghats. Research need and priorities emphasize on (i) inventorization and characterization of the biodiversity using recent trends (ii) development of database and networking (iii) support and assistance for conservation planning and participatory approach (iv) capacity building and imparting education , and (v) integration of traditional knowledge into scientific and appropriate technologies.

10.15.5. Method to create an index to analyze the structure of vegetation

M. Diazgranados;
Herbarium Pontificia Universidad Javeriana, Bogotá, Colombia.

A common problem in studies of structure is that there are many variables to analyze, and some times they suggest different interpretations. An index that represents the whole structure could be very helpful. I designed a method to create an Index of Structural Development (ISD), integrating horizontal and vertical structural aspects. Based in data of 34 variables sampled in 1084 trees of 14 diverse communities in an Tropical Humid Forest, after several filters and procedures (1st step: Barlett's and Scheffe's Tests, minimum squares; 2nd step: normality tests (K-S) and transformations (Box-Cox); 3rd step: Principal component analysis

(PCA) and Kaisers MSA) I chose five variables: total height (Ŭ), leaf mass height (ɓ), first branch height (ɔ), dbh (ŭ) and crown size (Ů), that were the most representative. I run another PCA to estimate the eigenvectors of each variable. These values were standardized to obtain final balanced values (FV) for each variable. Finally, I constructed the index with this structure: ISD = $FV_{Ŭ}Ŭ^{əŬ}$ + $FV_{ɓ}ɓ^{əɓ}$ + $FV_{ɔ}ɔ^{əɔ}$ + $FV_{ŭ}ŭ^{əŭ}$ + $FV_{Ů}Ů^{əŮ}$. The ISD showed a normal distribution and it was very useful in comparisons between tress or between communities.

10.15.6. Biomonitoring of disturbance in neotropical rainforests using bryophytes as indicators

U. Drehwald;
Zentrum für internationale Entwicklungs- und Umweltforschung, Giessen, Germany.

BRYOMONITOR is a computer program for monitoring disturbance and regeneration of neotropical rainforests using bryophytes as indicators. The program has been developed using field data from different areas in Ecuador, Peru, Bolivia and Argentina. It can be applied in wide parts of the Neotropics between sea level and 2000 m altitude. The program is based on the examination of changes in species composition of woody plants and bryophytes in rainforests having various degrees of disturbance. The program uses 34 indicator species, of which 17 are characteristic for primary forests and 17 species are typical for secondary forests. Ten tree stems must be examined from the ground to 2m in height for the application of the biomonitoring system. The computer program for Windows-PC calculates a naturalness index for the forest based on the presence of the indicator species. An index of 10-9 characterises primary forests. Typical logged forests show naturalness indices between 7 and 5 and secondary forests have indices between 2 and 4. An index of 1 is characteristic for isolated trees.
BRYOMONITOR can be used free of charge. It is available at http://www.drehwald.info.

10.16.1. Medicinal plants research and development for sustainable health

N. M. Ramaswamy;
NMR Foundation for Research and Development, Coimbatore, India.

Health is considered as prerequisite for achieving the supreme ends of life and preventive and curative aspects of diseases are considered as important components of the concept of positive health. The traditional Indian system of medicine predominantly use plant based raw materials in most of the preparations and formulations. Modern pharmacopoeia also contain at least ¼ drugs derived from plants and many other which are synthetic analogues built on prototype compounds isolated from plants. Medicinal plants being natural non-narcotic, having no side effect offer a range of safe, preventive and curative therapies which could be useful in achieving the goal of “Health for all” in a cost effective manner. China and India are two great producers of medicinal plants having more than 40% of global biodiversity. There is a growing demand for plant based medicines, health products, pharmaceuticals, food supplements, cosmetics etc. in the national and international markets. Several constraints exist due to inadequate awareness, inadequate investments in research and development, lack of quality and standardization norms etc. Recent developments in propagation and bioengineering of medicinal plants leading to value addition, conservation and genetic diversity, quality standardization, focused research and development on products lines, industry linkage etc. will be presented.

10.16.2. The usage of wild medicinal plants, berries, fruits and mushrooms in taiga area of Russia

E. A. Luginina;
Russian Research Institute of Game Management and Fur Farming, Kirov, Russian Federation.

The list of wild medicinal plants species, the average crop and the peculiarities of usage of the main species of wild berries, fruit plants and edible mushrooms in 2000-2003 are defined using the methods of questionnaire and natural investigations. It is determined that there are 227 species of medicinal plants, 27 species of fruits and berries, 250 species of edible mushrooms. In general, the stocks of medicinal plants in Kirov region have been being used for not more than 3,2% from possible stocking up volumes. Protected species: Centarea sumensis Kalen., Calypso bulbosa (L.) Oakes, Paeonia anomalia L., Pulsatilla patens (L.) Mill are often used as medicinal plants, especially in public medicine. The populations of this species are decreasing because of such influence. The increased usage of the resources of all studied species is noticed: berries and fruits - 5 times, edible mushrooms - 2 times more intensive compared to the level of 1980’s.

10.16.3. Ascertaining the genetic variability of *Andrographis paniculata* Nees in Tirunelveli hills in Tamilnadu in India

J. D. Britto;
St. Xavier's College, Palayamkottai, India.

Kalmegh (Andrographis paniculata Nees) belonging to the family Acanthaceae, is one of the most important herbs used in Indian traditional Ayurvedic and homeopathic system of medicine for treatment of liver disorders as a febrifuge, alternative, jaundice, worms, diarrhoea, dysentery and digestive complaints. It is also a blood purifier. The drug is mainly recognized for its diterpenoids - andrographolide and related compounds. Genetic improvement for quantitative traits in Kalmegh can be achieved through a clear understanding of the nature and amount of variability present in genotypes and the extent to which the desirable traits are heritable. In order to ascertain the genetic variability, plants were collected from different populations at various localities and Random Amplified Polymorphic DNA (RAPD) fingerprints were analyzed by Polymerase Chain Reaction (PCR) of genomic DNA using random primers. The RAPD fragments were scored for presence/absence to calculate Jaccard’s similarity index. Clustering based on similarity index was done following unweighted pair group with arithmetic mean method and a dendrogram was constructed and analyzed.

10.16.4. Ethnomedicinal plants and their indigenous uses to cure arthritis at Khunti, Ranchi district (Jharkhand), India.

M. Mahato, **R. Chandra**, J. Kumar;
Ethnobotanical and Medicinal Plants Laboratory, Ranchi University, Ranchi, Jharkhand,, India.

The term arthritis describes a range of readily diagnosable inflammatory conditions of the joints. The classification, diagnostic criteria and treatment approaches to these conditions have all been established to a greater or lesser extent in the international literature. However it is a common disease found frequently in all part of the world. The traditional knowledge of plant based remedies are said to be very useful to cure this disease. Authors carried out an ethno-botanical survey in the above-mentioned area for herbal medicine used in arthritis. The information is based on the exhaustive interview with local herbal practitioner and others who prescribe their own herbal preparation. During ethno-botanical survey, 70 plants belonging to 42 families have been reported from the study area used by the herbal practitioner of that area. Importance was given on their herbal formulation and mode of administration so that in future it’s scientific evaluation and pharmacological validation can be done.

10.16.5. A comparative study of the ethnomedicinal plants of Maharashtra in India and the Northern Provinces of Thailand

J. C. Kurian;
Mission College, Muak Lek, Saraburi, Thailand.

The presenter of this paper is the author of three books on medicinal plants and a Professor of Botany and Anthropology. He has carried out over 25 botanical and anthropological field expeditions among the tribal communities of Maharashtra in India and in the northern provinces of Chiangmai and Chiangrai in Thailand. In a powerpoint presentation this extensive work on the ethnomedicinal plants that are often administered by recognized magico-religious leaders or shamans brings to light interesting similarities and differences in the way midicinal plants are used by people in the two countries. The presentation covers the description and classification of the local diseases, the plants and the parts used, the medicinal use, the dosage and caution, if any. The Scope in the field of ethnomedicine in both countries is really great, especially for ethnobotanists, pharmacists and pharmaceutical companies.

10.16.6. Evaluation of antiperoxidative and anti-inflammatory property of a herbal formulation "Arthosafe" in adjuvant induced arthritic rats

B. Ramakrishnan[1,2];
[1]Dr.R.Baskar, Coimbatore, India, [2]Dr.G.R.Damodaran College of Science, Coimbatore, India.

Rhematoid arthritis is an autosomal disorder characterised by non-specific chronic inflammatory disease of the joints. The tissue damage might be due to the liberation of reactive oxygen species(ROS) from phagocytes invading the inflammatory tissues, which reacts with membrane lipids resulting in highly damaging reaction. The present study focus on the combination of four medicinal plants - Acalypha indica,Coriander sativum, Ricinus communis and Zingiber officinalis as an anti-inflammatory agent. 4 groups of 6 male rats were divided as Group I-normal control,Group II- injected 0.1 ml of Fruend Complete Adjuvant,Group III- administered herbal extract for 30 days, Group IV- adjuvant induced rats treated with extract for 30 days from day 21. As per observations, a significant increase in lipid peroxide with a simultaneous decrease in antioxidant levels were noticed in arthritic induced rats compared to controls.Supplementation with the herbal drug formulation restored the levels of lipid peroxides and antioxidants in treated rats. These observations suggests the efficacy of the herbal formulation as an antiperoxidative and anti-inflammatory agent.

10.16.7. Endemic and endangered medicinal plants of eastern ghats of India

N. Savithramma;
S.V.University, Tirupaty, India.

Eastern Ghats (EG) are one of the megacentres of endemism in India. The EG are the source of endemic plant gene pool. Tirupati-Cudapah-Nallamalai hills are the 11 th Hot spots of endemism of EG The geological factors of this forest area is cudapah formation and soil types with red and calcareous shales. The vegetation supports edaphic endemics like valuable *Pterocarpus santalinus* and *Santalum album* and narrow endemics like *Boswellia* type and *Calamus* type. Endemic Flagship species like *Actinodaphne madraspatana , Shorea tumbuggaia* Keystone endemic species of *Memecylon* and other highly important medicinal endemic species like *Pimpinella tirupatiensis* ,*Lucas lavandulaefolia*, Boswellia ovalifoliolata , *Decaschistia cudapahensis* , *D. crotonifolia* , *D.rufa*, *Cassia mountana , Aglaia elaegnoides . Indigofera barberi*, *Rhynchosia beddomei* , *Cycas beddomei* . Southern parts of the hills are harbouring local endemics lilke *Andrographis nallamalayana* , *Eriolaena lushingtonii* , *E. hookeriana*, *Crotalaria madhurensis, Nilagirianthus circarensis*.The gene pool nitches will be discussed.

11.1.1. Chimeric studies on the organization of the shoot apical meristem

R. W. Korn;
Bellarmine University, Louisville, KY, United States.

Eversporting chimeras provide an excellent opportunity for the analysis of the shoot apical meristem (SAM). Data from seven species of Cupressaceae indicate green-yellow chimeras on wild type green shoots produce stable yellow shoots 82-92% of the time. This information best supports the idea that a single apical cell in a yellow tunica undergoes a replacement periclinal division (Dermen’s concept) to give one daughter cell in the corpus. The chimeric result of this divison is then explained as an asymmetric deployment of the yellow clone produced from the original yellow sister corpus cell. Similar results were found for three spiraea varieties, indicating that some, if not all, dicots also have an apical cell in SAM. Computer model studies on growth rates in various regions of SAM give an apical and stable dome only when the growth rate is highest at the apex and decreases with distance from this site. Also, the green-yellow chimeric shoot regions range from two to15 nodes in length and the data follows a gamma distribution, suggesting the growth just below SAM where leaves form is far more active than above at the stem apex.

11.1.2. Stem cell niches in plants

A. Sarkar, E. Tucker, **T. Laux**;
University of Freiburg, Freiburg, Germany.

The stem cell populations of shoot and root meristems are reliably maintained although cells continuously leave the meristem and are replaced by new ones. We previously showed that the stem cells in shoot meristem are controlled by signals from an underlying organizing center, expressing the WUSCHEL gene (Cell 95, 805-815), and that the size of the stem cell population is dynamically regulated by a feedback loop between stem cells and organizing center (Cell 100, 635-644). This signaling circuitry appears to have the potential to act as a self-regulatory system that is integrated into a larger regulatory network to control organ formation from the shoot apex (Development 129, 3195-206; ibid. 130, 3163-3173). In the root meristem, stem cells maintenance requires short range signaling from the quiescent center (Scheres group, Nature 390, 287-289). Here we discuss commonalities and differences between the stem cell niches in both apical meristems.

11.1.3. Involvement of the *Arabidopsis* ET family in cell differentiation

R. Ivanov[1], J. Tiedemann[1], A. Czihal[1], A. Tewes[1], H. Mock[1], M. Ellerstrom[2], H. Baumlein[1];
[1]IPK, Gatersleben, Germany, [2]Botanical Institute, Gothenburg, Sweden.

EFFECTORS OF TRANSCRIPTION (ET) are plant specific proteins characterized by 2-4 C-terminal DNA and zinc binding repeats with a highly conserved cystein pattern. Over-expression in tobacco results in phenotypic changes including dwarfism, reduced xylem lignification, ectopic anthocyanin synthesis and poor germination rate. Transient expression studies on gibberellin (GA)-regulated gene promoters and feedback induction of GA synthesis genes in ectopic over-expression lines suggest that ET factors function as modulators of GA-responses.

Here we report an initial characterisation of the three- member gene family found in the *Arabidopsis* genome. Mutant analysis indicates that ET factors are involved in the control of cell differentiation interacting with KNOX-like (KNAT) genes as well as controlling the expression of the GA-induced cell cycle regulator GASA4. The action of ET is topologically restricted by a mechanism preventing them from entering the nucleus in non-differentiating cells.

11.1.4. Towards a model for organ initiation patterns at the shoot apical meristem

J. A. Traas[1], P. Barbier de reuille[1], I. Courseau[1], H. Morin[1], C. Godin[2];
[1]INRA, Versailles, France, [2]INRIA, Montpellier, France.

During the last decade an impressive body of knowledge concerning shoot meristem function has been generated. The complexity of these data is such, that an integrated view of meristem function is not possible. Therefore, adapted mathematical and informatics approaches are now required to integrate the knowledge. Here we will present the first results obtained on the mathematical modelling of auxin fluxes in the meristem. Auxin is actively transported from cell to cell. Polar localised membrane proteins of the PIN1 family facilitate this transport and recent hypotheses suggest that auxin maxima created by these proteins are at the basis of organ initiation. To further test this concept, we have analysed the patterns of PIN1 distribution at the shoot apex using specially designed modelling tools, The results not only confirm that this distribution is compatible with existing hypotheses, but, in addition, they reveal novel properties of the PIN1 network. In particular they suggest an important role for the central zone at the meristem summit in the re-distribution of auxin. Experimental data to test the implications of the computer simulations will be presented.

11.1.5. Leaf dissection: Growth analysis and genetics

E. P. Groot, S. Gleissberg;
Johannes Gutenberg-Universität, Mainz, Germany.

Leaves can be simple and entire, or they can be dissected. Leaf dissection is the process of elaborating the margin of leaves into segments such as teeth, lobes and leaflets. The portion of the leaf margin competent for fractionation into segments is the marginal blastozone. One approach to understanding the interplay of gene networks and leaf dissection is to analyze mutants for differences in growth, development and gene expression patterns. Growth analysis of mutants in dissection depth reveal alterations in: timing of initiation, initial size, and relative growth rates. Mutants altering complexity of dissection appear to act through controlling the duration of competence of the marginal blastozone. There is neither a universal developmental mechanism or gene for altering dissection depth, nor a common gene network for the complexity of dissection. This indicates multiple and possibly redundant genetic pathways that specify dissection in angiosperm leaves.

11.2.1. genetic and proteomic analysis of gravity signal transduction in *Arabidopsis* roots

P. H. Masson[1], L. Young[1], N. Murthy UM[1], G. Sabat[1], B. Harrison[1], J. Stanga[1], C. Neal[1], L. Vaughn[1], B. Moffatt[2];
[1]University of Wisconsin-Madison, Madison, WI, United States,
[2]University of Waterloo, Waterloo, ON, Canada.

Arabidopsis roots respond to gravistimulation by developing a curvature that is modulated by a lateral gradient of auxin. This gradient originates in the columella statocytes through lateral repositioning of the PIN3 auxin efflux facilitator. We used genetics to identify proteins that contribute to gravity signal transduction. ARG1 and ARL2 are needed for lateral auxin transport across the cap. ARG1 is associated with the vesicular trafficking pathway, suggesting it regulates PIN3 function or trafficking. Genetic modifiers of *arg1-2* were obtained and shown to enhance the gravitropic defect of *arg1-2*. The corresponding proteins function in interpretation of the gravity-vector signal. Furthermore, a proteomic approach allowed identification of root-tip proteins that are differentially represented in response to gravistimulation. Subsequent reverse genetic studies demonstrate a role for adenosine kinase and the AdoMet pathway in gravity signal transduction (This work was supported by grants from NASA and NSF).

11.2.2. Signal transduction pathway for gravitaxis in the flagellate Euglena

D. P. Häder;
Institut für Botanik und Pharmazeutische Biologie, Erlangen, Germany.

A recent experiment on a sounding rocket comparing immobilized *Euglena gracilis* cells with mobile cells demonstrated that a passive buoy effect can account for no mare than 20 % of the orientation of the cells in a gravity field. The cells show either positive or negative gravitaxis depending on other external or internal factors. The negative gravitaxis of older cells is inverted into a positive one by stress factors such as increasing salinity or exposing the cells to excessive visible or UV radiation mediated by reactive oxygen species (ROS). The primary reception for the gravity vector seems to involve mechanosensitive ion channels which specifically gate calcium ions inwardly. The influx of Ca^{2+} activates calmodulin which has been shown to be involved in the sensory transduction chain of graviorientation. In addition, adenylyl cyclase is involved; it produces cAMP which has also been shown to be the key messenger in phototaxis in the same organism mediating flagellar reorientation and thus course correction of the swimming path.

11.2.3. How to activate a plant gravireceptor

M. Braun, **C. Limbach**, J. Hauslage;
Institute of Plant Molecular Physiology and Biotechnology, Bonn, Germany.

Plant gravity sensing involves controversially discussed mechanisms by which higher plants translate the physical signal from amyloplast (statolith) sedimentation into a physiological signal. Gravisensing cells of characean green algae, rhizoids and protonemata, were established as model systems for studying specific aspects of gravitropism including the early gravisensing mechanisms. Experiments performed on ground and in microgravity have demonstrated that actin and myosin are key players in the process of gravity sensing. Actomyosin forces keep statoliths in a position of balance, in which they compensate the effect of gravity and they provide a guiding system that directs sedimenting statoliths to specific graviperception sites on the plasma membrane, where gravireceptors are activated that initiate the graviresponse. Gravisensitivity, therefore, is basically determined by molecular interactions between statoliths and actomyosin. Parabolic flight experiments promise to disclose the mechanisms of gravireceptor activation in higher and lower plants.

11.2.4. Gravity-regulated oxygen uptake in root apices

S. Mancuso[1], S. Mugnai[1], E. Azzarello[1], A. Schick[2], F. Baluska[2], D. Volkmann[2];
[1]Department of Horticulture, University of Firenze, Italy, [2]Institut für Zelluläre und Molekulare Botanik, University of Bonn, Germany.

Using two O_2-selective microelectrodes, operated non-invasively in self-referencing mode to simultaneously measure oxygen fluxes in different regions of the root apex, we observed gravity-regulated asymmetric oxygen influxes changes in the transition zone. The kinetics of these changes have been studied on ground and under changing gravitational conditions during parabolic flights. On ground, approximately 20 s after changing the position of the roots from the vertical to the horizontal, oxygen influx increase selectively on the physically upper root flank of the transition zone and remained stable on the lower flank. The oxygen asymmetry appeared 18 ± 2 s (mean ± SD) after repositioning. Taking into account the tilting procedure (around 15 s), the first signal can be hypothesized to appear few seconds after stimulation. During parabolic flights we detected an enhancement of the oxygen influx already after 3.5 ± 0.3 s of attaining the microgravity conditions. This rapid change in the oxygen flux into root apices is by far the fastest ever reported plant response to gravity. The significance of these results on the nature of the graviperception will be discussed

11.2.5. The PIN auxin efflux facilitator network controls growth and patterning in roots and shoots of *Arabidopsis*

K. Palme[1], I. A. Paponov[2], F. Ditengou[2], O. Tietz[2], X. Li[2], W. D. Teale[2], A. Dovzhenko[2], I. Blilou[1];
[1]Department of Molecular Genetics, Utrecht University, Utrecht, The Netherlands, [2]Institut für Biologie II , Universität Freiburg, Freiburg, Germany.

The plant hormone auxin has long been known to play a crucial role in plant growth and development, but how it affects so many different processes has been a mystery. Recent evidence from genetic and molecular studies has begun to reveal a possible mechanism for auxin action. We will present an overview on auxin's role in roots and shoots. Local accumulation of the plant growth regulator auxin mediates pattern formation in Arabidopsis roots and influences outgrowth and development of lateral root- and shoot-derived primordia. It was unclear however how auxin can simultaneously regulate patterning and organ outgrowth and how its distribution is stabilized in a primordium-specific manner. We show that the PIN auxin efflux facilitator genes collectively control auxin distribution to regulate cell division and cell expansion in the primary root and shoot. It is widely believed that the PIN proteins are crucial for proper cellular co-ordination. This family of auxin efflux facilitators occurs in monocotyledonous and dicotyledonous plants. We will summarize their evolutionary history, expression profiles, and, where appropriate, relating them to protein function. The joint action of these genes has an important role in pattern formation by focusing the auxin maximum and restricting the expression domain of other genes.

11.2.6. Gravity stimulation induces fast and transient transcriptional regulation in roots.

J. M. Kimbrough[1], R. Salinas-Mondragon[1], C. Brown[2], H. Winter-Sederoff[1];
[1]NC State University, Raleigh, NC, United States, [2]Kenan Institute for Engineering, Technology & Science, Raleigh, NC, United States.

Plant roots sense changes in the vector of gravity which ultimately leads to a differential growth response. To understand the regulation of gene expression involved in gravitropism, we carried out a time-course analysis of whole genome transcript changes throughout the first hour of gravitropic and mechanical stimulation in the *Arabidopsis* root apex using microarray technology. Our results indicate both the relative abundance and timing of events are important for establishment of gene expression cascades for either stimulus. Significant changes in transcriptional regulation occurred throughout the first hour of gravity and mechanical stimulation in diverse gene families coding for transcription factors, cell wall modifying enzymes, transporters, protein kinases and phosphatases, hormone metabolism and cell cycle proteins. Functional characterization of a cluster of fast and transiently regulated gravity specific genes will give new insights into signal transduction elements and pathways involved in root gravitropism and their integration with other stress responses.

11.2.7. SGR5 encoding a zinc finger protein involved in gravitropism of *Arabidopsis* stem

M. Tasaka;
NAIST, Ikoma, Japan.

Plant can change the growth orientation after sensing the gravity orientation. To elucidate molecular mechanisms of the gravitropism, we have characterized abnormal shoot gravitropic mutants (sgr) of Arabidopsis. We have shown that 1) endoderm cells in the inflorescence stems are graviperception sites, 2) amyloplasts sedimentation in these cells is important for gravity perception and 3) amyloplasts movements are controlled by the vacuolar membrane dynamics. The sgr5-1 showed reduced gravitropism only in inflorescence stems, in which amyloplasts sedimented normally. The SGR5 encodes a novel zinc finger protein with coiled-coil motif. The functional SGR5-GFP protein located in the nucleus, suggesting SGR5 may function as a transcription factor. The GUS driven by SGR5 promoter is expressed in several tissue layers including endoderm cells. When SGR5 was specifically expressed in the endoderm of sgr5-1, transgenic plant showed normal gravitropism. These data indicated that SGR5 might be involved in the gravity perception, signal formation and/or signal transduction process in the endoderm cells after amyloplasts sedimentation.

11.3.1. Bilabiate flowers: the ultimate response to bees?

C. Westerkamp[1], R. Classen-Bockhoff[2];
[1]Departamento de Biologia, Universidade Federal do Ceará, Fortaleza, Brazil, [2]Institut für Spezielle Botanik und Botanischer Garten, Mainz, Germany.

Bees are by far the most important pollinators as they have to nourish offspring, especially with pollen. Therefore, they must visit many more flowers than do all other pollinators. As bees try to maximize pollen harvest, however, they often leave nothing for pollination. To reserve pollen for its original purpose, flowers should offer nectar or other non-pollen attractants, hide pollen from early perception and place it out of immediate reach of the (fore)legs generally used in pollen uptake. Hiding pollen below bees as in keel blossoms requires mechanically complex flowers, as all legs have to be kept busy. Locating pollen on top of the visitor is much more advantageous: Inside a dorsiventral flower, a closely fitting upper lip impedes access, and in flight, when grooming and reloading usually occur, the beating wings make pollen unavailable. Bilabiate flowers are obviously an optimal adaptation to (and against!) bees, they evolved in many angiosperm groups, especially the Lamiales. Originating from this obvious key innovation, alleys were opened up to more sophisticated flowers and new pollinators, as will be shown in the presentation.

11.3.2. Evolution in the genus *Salvia*; species radiations, floral innovations, and biogeography

J. B. Walker, K. J. Sytsma;
University of Wisconsin-Madison, Madison, WI, United States.

The genus *Salvia* has traditionally included any member of the tribe Mentheae (Lamiaceae) with only two stamens, and with each stamen expressing an elongate connective. Our data suggests an independent origin of the elongate connective on at least two different occasions: once in the New World, and at least once in the Old World. We investigate the elongation of the connective tissue in members of tribe Mentheae from a phylogenetic standpoint, characterize staminal morphology in each radiation, and address the implication of the non-monophyly of *Salvia* on the manner in which the lever-mechanism of pollination has originated in *Salvia*. Associated with each major radiation of *Salvia*, we can document the following progression: abortion of two of the four stamens, swelling of the connective tissue, slight elongation of the connective tissue separating the thecae, further elongation of the connective tissue resulting in two much separated thecae, but no lever mechanism, and finally, abortion of the posterior theca and employment of a lever mechanism. Significant species radiations have only occurred in those lineages employing a lever mechanism of pollination.

11.3.3. Structure of inflorescences in the genus *Salvia* L. (Lamiaceae)

E. V. Baikova;
Central Siberian Botanical Garden, Siberian Branch of the Russian Academy of Sciences, Novosibirsk, Russian Federation.

The structural analysis of flower arrangement in Salvia important for taxonomy, phylogenetics and floral biology has been performed. About 600 species were studied, 44 of them were cultivated in Central Siberian Botanical Garden in Novosibirsk, Russia. Two basic variants of floriferous axial systems which are synflorescence and intercalary florescence were established. Structure of synflorescences in various Salvia species was determined by the branching order of axes and by the number of floral units. The floral unit in studied species was always compound and indeterminate, it was thyrsus, sometimes reduced to botryoid one. Floral leaves were usually present but occasionally were deciduous. Intercalary florescences of two types were revealed only in the subgenus Calosphace. The first one was floriferous zone homologous to thyrsus, with the reduced cymes as lateral subunits. The second type was intercalary double raceme. The main trends of evolutionary transformations of inflorescence are the following: reduction of metamers of axes, reduction of a number of elements, polymerization of subunits and formation of brightly coloured enlarged bracts.

11.3.4. Floral diversity and pollen transfer in bird pollinated *Salvia* species

P. Wester, R. Claßen-Bockhoff;
Institut für Spezielle Botanik, Johannes Gutenberg-Universität, Mainz, Germany.

Among the more than 900 Salvia species about 250 are bird pollinated. With few exceptions, they occur in the New World. They belong to five different sections and show a high floral diversity. The staminal lever which ensures precise pollen transfer in most bee pollinated species by its easily going reversible movement is strongly influenced by the transition from bee to bird pollination. In many ornithophilous species the staminal lever is functional, but in some it is restricted or completely reduced. Diverse modifications of the lever and their consequences for the pollen transfer by birds are illustrated. They range from narrow corollas which leave no space for any lever movement to immobile levers due to a stiff or even lacking joint and completely reduced lower connective arms. It is assumed that the driving force behind the diverse modes of reduction is the necessity to enlarge the distance between nectar and pollen, thereby ensuring pollen deposition on the birds' feathered head. This is achieved by corolla elongation and/or exposition of the pollen-sacs. As soon as pollen is freely accessible the lever movement loses its significance for pollination.

11.3.5. Pollination in the Australian endemic genera *Hemigenia* R.Br. and *Microcorys* R.Br. (Lamiaceae): the role of staminodes and mobile anthers.

G. R. Guerin;
University of Adelaide, Adelaide, Australia.

The fertile stamens of *Hemigenia* R.Br. and *Microcorys* R.Br. have enlarged anther connective tissue. The upper end of the anther bears a fertile theca, and the lower end may be bearded or bear a reduced theca. The entire anther is mobile on the filament. Insects visiting the flowers push the lower end of the anther to access nectar and in doing so lever the upper end onto their head or back. The bearding on the lower ends of the anthers catches adjacent anthers so that they lever in unison towards the pollinator. The flowers are protandrous. The mature style touches the pollinator in the same place as the fertile thecae. The mobile anthers combined with corolla shape provide precise pollen deposition and therefore effective mechanical isolation. In some species, the abaxial stamens are sterile, and the anthers are reduced to club-like lobes. These staminodes protrude from the lower corolla lip and guide the insect into the throat. Observations of pollination in the wild have demonstrated isolation by exclusion of inappropriate size pollinators, and pollination by insect castes defined by size and feeding mode.

11.3.6. Floral design and pollination syndromes in southern African species of *Plectranthus* (Lamiaceae)

C. J. Potgieter, T. J. Edwards;
University of KwaZulu-Natal, Pietermaritzburg, South Africa.

Amongst the ca. fifty species of *Plectranthus* that occur in southern Africa, three main pollination syndromes have been described. A pollination syndrome involving the long-proboscid nemestrinid fly, *Stenobasipteron wiedemanni* (with proboscides up to 30 mm long), operates in species with long corolla tubes that occur in forest habitat along the eastern seaboard of the region. Another group of species with sigmoid-shaped corolla tubes is pollinated by medium-proboscid nemestrinid flies and long-proboscid bees (with proboscides up to 10 mm long) that are able to access nectar with flexible proboscides. The remaining shorter-tubed species are pollinated by a group of generalist bees and flies, amongst which acrocerid flies (*Psilodera* spp.) are of particular interest due to their intermediate position in relation to corolla tube length. Corolla shape and size, as well as habitat preference, largely determine which suite of pollinators are utilised by species of *Plectranthus*. This paper outlines adaptations in floral design in response to pollinator type.

11.3.7. Floral characteristics, pollen viability, and stigma receptivity in two gynodioecious protandrous species (*Teucrium capitatum* and *Origanum syriacum*), (Lamiaceae).

A. Dafni[1], T. Rodríguez-Riaño[2];
[1]Laboratory of Pollination Ecology, Institute of Evolution, Haifa University, Haifa, Austria, [2]Departamento de Biologia y Producccion Vegetal, Unidad de Botanica, Facultad de Ciencias, Universidad de Extremadura, Badajoz, Spain.

Testing the relationship between stigma receptivity and pollen viability in *Teucrium capitatum* L. and *Origanum syriacum* L. we found three plant types in each species: plants bearing hermaphrodite flowers or male fertile flowers (MF), plants bearing female or male sterile flowers (MS), and intermediate plants bearing flowers with different degrees of pollen abortion (INT). Plant types differed in flower size, with the MS flowers being shorter than the other two types. There was no difference in style length between plants types in *T. capitatum* did not differ in style length. Stigma receptivity increase over the lifetime of the flower followed different models of curves (logarithmic in MS and INT flowers with a slight tendency to a linear model in INT, and exponential and cubic in MF flowers from *Teucrium* and *Origanum* respectively). Pollen viability steadily declined with flower age and their relationship clearly showed a female phase totally conditioned by a male phase. Each species followed different strategies to avoid pollen-stigma interference but followed the same strategies to avoid “pollen clogging”.

11.4.1. Dating the origins of plants endemic to the Corso-Sardinian microplate: A window on the biogeography of the western Mediterranean basin

E. Conti;
Institute of Systematic Botany, Zurich, Switzerland.

Corsica and Sardinia, the largest islands of the W Mediterranean, have been identified as two of the areas with the highest species richness in the Mediterranean basin, hence they play a key role for understanding Mediterranean biodiversity. Furthermore, the well-known geologic history of the Corso-Sardinian microplate, marked by the Late Oligocene split from northeastern Spain and southern France, and proposed land bridges with Tuscany during the Miocene and northwestern Italy during the Pleistocene, provides the necessary framework to investigate the relative contribution of land connections and over-water dispersal to the assembly of the endemic flora. The origin of a selected group of Corso-Sardinian endemics is being investigated through a combination of phylogenetic analysis, molecular dating, and ancestral area reconstruction. After a review of the geologic history of the Corso-Sardinian microplate, preliminary results will be presented on the origin of *Ruta corsica* (Rutaceae), eight endemics in the Boraginaceae, and three endemics in the Araceae.

11.4.2. Plant hybridization in the western Mediterranean basin: disturbing forces for species cohesiveness or key inputs for plant speciation?

J. A. Rosselló;
Jardí Botànic, University of Valencia, Valencia, Spain.

The Western Mediterranean basin is one of the rich speciose sites within the whole Mediterranean hotspot and includes many endemic taxa showing a restricted distribution. For a long time it has been assumed that most of this plant diversity has been shaped by geographical and ecological patterns. Geographical variability in several Mediterranean species has been usually treated as noise when dealing with taxonomic treatments, since the peripheral populations of several allopatric species may sometimes be linked by a mosaic of morphologically intermediate, but geographically still discontinuous, non-interbreeding and long-isolated populations. However, increasing evidence shows that interspecific gene flow (without genome duplication through polyploidy) has been of great importance in driving cryptic speciation in several groups. In this talk, we will show that speciation by geographic isolation and a further superimposed pattern of complex gene flow among narrowly endemic taxa and widespread species has been involved in the diversification of this Mediterranean flora. This work has supported by funds of the project REN2001-3506-CO1-01.

11.4.3. Models for reticulate evolution in Mediterranean lineages: Does Armeria break molds?

G. Nieto Feliner;
Real Jardín Botánico, CSIC, Madrid, Spain.

Reticulate evolution in *Armeria* has been documented using several sources of evidence including nuclear ribosomal DNA and non-coding chloroplast DNA sequence data, among others. Some patterns of molecular variation discovered by our team in this genus and the inferred responsible mechanisms were eventually considered extraordinary. These include a species-independent geographical structure for ITS variation, the mechanisms proposed to account for such structure (extensive hybridization and biased concerted evolution of these regions) and the phylogenetic signal found in the same ITS data set. Other features also detected in *Armeria* were considered unusual, such as the sharing of chloroplast haplotypes by different species in the same massifs, the species-independent geographical structure for chloroplast sequence data, the highly variable intraspecific RAPD profiles, or the inferred compilospecies model of evolution. Recently published and ongoing studies particularly in the Mediterranean on other plant groups have questioned the rarity of such patterns associated to reticulation.

11.4.4. Phylogenetic patterns and polyploid evolution within the Mediterranean genus *Centaurium* (Gentianaceae - Chironieae)

G. Mansion[1], L. Zeltner[1], F. Bretagnolle[2];
[1]University of Neuchatel, Neuchatel, Switzerland, [2]UMR (Biology and Management of Weeds), Dijon, France.

The genus *Centaurium* (Gentianaceae) comprises ca. 27 annual species and subspecies primarily distributed in the Mediterranean basin. Phylogenetic relationships, inferred from sequences of both nrDNA (internal transcribed spacer, ITS) and cpDNA (*trnL* intron and *trnL-F* spacer) regions, confirm the monophyly of *Centaurium* and reveal the importance of polyploidy within the genus. In each ITS clade, diploid to hexaploid species of *Centaurium* occur. Furthermore, polyploidization is often associated with hybridization events, as suggested by the importance of additive polymorphic sites detected in the ITS region. Hence, reticulation appears to be the main cause of phylogenetic incongruence _ and resulting systematic controversies _ detected in the genus. Based on molecular and cytological evidences, the origin of some polyploid systems is discussed. Allopolyploidy associated or not with introgression, appears to be the main evolutionary trend in *Centaurium*, and only a few autopolyploid taxa have been detected so far.

11.4.5. Evolution of Mediterranean Malveae: molecular phylogenetics, ploidy level and genome size

J. Fuertes Aguilar, P. Escobar García;
Real Jardín Botánico, CSIC, Madrid, Spain.

Mediterranean Malveae include species of *Malva*, *Lavatera*, *Malope*, and *Althaea*. All of them except one (*L. trimestris*) belong to a lineage of polyploids where *L. phoenicea* and the genus *Malope* are placed in basal positions. Within this natural group, molecular phylogenetic analyses based on nrDNA (ITS) and cpDNA sequences (*trn*L-F + *psb*A-*trn*H) reveal the presence of several natural lineages incongruent with classical taxonomy e.g. the Malvoid group, the Lavateroid group, the *M. moschata* group, and annual altheas. The Malvoid group, supported by cpDNA and nuclear evidence include two lineages: one Macaronesian-W Mediterranean and another mostly Temperate-Mediterranean which extends to *Lavatera* from E Africa, Australia and California. In this group ploidy level ranges from 6x-12x, but genome size only correlates with ploidy among annual herbs.The Lavateroid group has morphologically diversified in W Mediterranean preserving a low nucleotide divergence in cpDNA sequences, ploidy level (6x) and genome size. The uncertain placement of *L. trimestris* (2x), and *M. hispanica* (4x), incongruent between chloroplast and nuclear phylogenies, is discussed.

11.4.6. Evolutionary history of the Aegean *Nigella arvensis* alliance (Ranunculaceae)

H. P. Comes[1], C. Bittkau[2];
[1]Paris-Lodron-Universität, Salzburg, Austria, [2]Johannes Gutenberg-Universität, Mainz, Germany.

Phylogenetic, phylogeographic and population genetic analyses were used to elucidate the evolutionary history of the Aegean *Nigella arvensis* alliance based on ITS sequence and cpDNA haplotype variation. The study revealed three major cpDNA lineages in the Western, Central, and Eastern Aegean that likely evolved *in situ* from a pan-Aegean ancestral stock as a result of fragmentation events, triggered by post-Messinian sea flooding, Pleistocene eustatic changes and corresponding climate fluctuations. Founder events played an insignificant role in the group's history. Rather, the alliance is identified as a poor seed disperser prone to genetic drift. In particular, observed levels of cpDNA differentiation *between* Kikladian island populations (*N. degenii*) largely reflect Holocene island fragmentation and genetic drift in the near absence of seed flow since their time of common ancestry. The phylogeographic history inferred for the alliance conforms remarkably well to previous hypotheses about the dominant evolutionary processes driving plant evolution in the Aegean: past fragmentation and genetic drift coupled with restricted gene flow.

11.4.7. Phylogenetic biogeography of Crassulaceae: comparing patterns of lineages endemic to Macaronesia and southern Africa

M. E. Mort[1,2];
[1]Dept. of Ecology & Evolutionary Biology, Lawrence, KS, United States, [2]Natural History Museum & Biodiversity Research Center, Lawrence, KS, United States.

Crassulaceae are a medium-sized family of leaf-succulent herbs and shrubs. The family is geographically widespread, but discrete centers of diversity occur in southern Africa, Macaronesia, Mexico/South America, and Asia. Phylogenetic analyses of the family based on cpDNA RFLPs and *matK* sequences are congruent and recover six major clades. Lower-level phylogenetic studies employing broad taxonomic sampling and extensive molecular data have been conducted on two of these lineages: the Macaronesian clade and the southern African genus *Crassula*. It is possible to use these phylogenies to compare biogeographic patterns and dispersal events among the species comprising these insular and continental lineages. Among species in the Macaronesian clade dispersal between islands into similar ecological zones is common, with radiation on a single island occurring only rarely. Thus, many of the clades comprise species that are geographically widespread, yet morphologically similar. This same pattern occurs among species of *Crassula*; however, several clades within *Crassula* contain morphologically diverse species that are geographically cohesive.

11.5.1. Basidiomycetous phylogeny seen through the electron microscope

R. Bauer, F. Oberwinkler;
Universität Tübingen, Lehrstuhl Spezielle Botanik und Mykologie, 72076 Tübingen, Germany.

Because of some inconsistencies in molecular phylogenetic hypotheses, ultrastructural characteristics continue to play an important role in interpreting the evolution of basidiomycetes. In this talk, significant ultrastructural characteristics of these fungi, such as septal pore apparatus, spindle pole bodies, symplechosomes, colacosomes as well as myco- and phytoparasitic cellular interactions etc. will be discussed with a focus on their role as phylogenetic markers. Interestingly, the basal basidiomycetous groups are especially rich in features at the ultrastructural level. Furthermore, septal architecture and mode of cellular host-parasite interactions varied in the ustilaginomycetous history, whereas septal pore caps developed in some variations in the hymenomycetous evolution. From the ultrastructural point of view the obvious questions to address are the following: are the Urediniomycetes and the Atractiellales monophyletic? Is *Cryptomycocolax abnorme* the most basal basidiomycete? Was mycoparasitism the fundamental motor in the early basidiomycete evolution?

11.5.2. Quantification and characterization of substrate mycelium by microscopy

R. Agerer, S. Raidl;
Biodiversity Research: Mycology, München, Germany.

The biomass of fungal mycelium within the soil is of particular interest, when ectomycorrhizal fungi have to be considered as an important sink of tree carbohydrates. Between 15 and 30% of the net photosynthesis products are estimated as the investment into the symbionts for adequate tree growth. Some biochemical markers have already been applied (ergosterol and phospholipid fatty acids) combined with a subtractive design to calculate the living mycelium of ectomycorrhizae. We try to estimate the ectomycorrhizal mycelium by microscopy, combining image analysis with a calibration with TaqMan Real Time PCR of the extramatrical mycelium of synthesized ectomycorrhizae. We show that ectomycorrhizae of different exploration types can differ greatly in their mycelial biomass, their organization, and their exploiting range. Given that the mycelium biomass of Tylospora asterophora is set to 100 %, Piloderma croceum produces 200 %, and Rhizopogon roseolus about 1600%.

11.5.3. Efficient visualization and analysis of fluorescently labelled subcellular structures of living yeast cells

H. Wolinski[1], B. Heise[2], E. P. Klement[2], A. Sonnleitner[3], S. D. Kohlwein[1];
[1]SFB Biomembrane Research Center, IMB-Biochemistry, Graz, Austria, [2]Department of Knowledge-Based Mathematical Systems, Linz, Austria, [3]Center for Biomedical Nanotechnology, Upper Austrian Research GmbH, Linz, Austria.

Two novel procedures and sample applications for efficient visualization and statistical analysis of fluorescently (multi)labelled subcellular structures in living yeast cells are presented. First, we show a threshold-based technique for semi-automatic registration of GFP-labelled, three-dimensional yeast structures. For this purpose, we take advantage of features of a modular software system (amira®), as well as of a novel highly efficient image reconstruction algorithm for counting yeast cells in differential interference contrast (DIC) images. Second, we introduce a custom-made software add-on for amira® visualization platforms, called '4D Assistant', which facilitates and accelerates the extraction of useful information from complex multi-channel 4D data sets. The tool was applied for simultaneous visualization of the migration of endoplasmic reticulum and mitochondria during cellular growth and division. Both techniques are not only highly useful for yeast specific applications but also applicable to other biological systems.

11.5.4. Three-dimensional visualization of fungal nuclei in binucleate ascospores

P. A. Blanz[1], H. Wolinski[2];
[1]Institute of Plant Sciences, Karl Franzens University, Graz, Austria, [2]Institute of Molecular Biosciences, Karl Franzens University, Graz, Austria.

Confocal laser scanning microscopy (CLSM) and 3D-visualization are techniques of choice for detection and three-dimensional visualization of complex fungal nuclear structures. In *Xanthoria parietina* asci, we studied the development of the eight ascospores which undergo an additional mitosis in order to become binucleate. Our study of the fungal nuclei comprises three steps: 1) We developed a method for specific and simultaneous staining of fungal nuclei in lichens with high contrast. The method includes NaOH-treatment of fixed sectioned samples and subsequent nuclear staining using SYTOX Green™. 2) We analysed these pretreated sections by use of a confocal laser scanning microsope. Both, high contrast of stained nuclei and fluorescence of cytoplasm provided advantageous preconditions for extraction of volume data using different 3D-visualization techniques. 3) Applying a state-of-the-art image processing software to the data from the stacks of pictures of the z-axis, we got good insight into the nuclear behaviour of the binucleate ascospores.

11.5.5. Microscopy and molecular biology join forces to unravel the mysteries of haustorial function

R. T. Voegele, K. Mendgen;
Phytopathologie, Konstanz, Germany.

Obligate biotrophic fungi such as the rust - and the powdery mildew fungi are important plant pathogens. The analysis of the underlying host-parasite interactions is faced with a variety of obstacles. For example, obligate biotrophic fungi cannot be genetically modified or grown without their respective host plants. This excludes them from the application of a variety of modern techniques successfully used on other pathogens. We are trying to elucidate the roles of one of the hallmarks of obligate biotrophic interactions, the so called haustoria. These are specially differentiated hyphae formed inside an infected plant cell. The close contact between the haustorium and the host cell is an ideal prerequisite for the exchange not only of nutrients, but also of information. Our laboratory has established a combination of molecular and cytological tools to elucidate the processes involved in establishing and maintaining the obligate biotrophic state using the interactions of rust fungi with a variety of host plants as a model system.

11.5.6. In vivo observation of nuclear envelope removal during "open mitosis" in the basidiomycete plant-pathogen *Ustilago maydis*

U. Theisen, G. Steinberg;
MPI for terrestrial Microbiology, Marburg, Germany.

In animals and higher plants the nuclear envelope disassembles in mitosis to allow the interaction of chromosomes with the mitotic division machinery. Although lower eukaryotes are commonly thought to undergo mitosis within a closed envelope, ultrastructural data indicate that many basidiomycete fungi undergo an "open mitosis", including the pathogenic fungi *Cryptococcus neoformans* and *Ustilago maydis*. Here we describe the mechanism of nuclear-envelope breakdown in *U. maydis* using life cell imaging. In interphase the nucleus is located in the mother cell. Prior to mitosis, the spindle-pole body nucleates microtubules that reach into the daughter cell. Dynein at microtubule tips appears to exert force on the spindle-pole body, which leads to the formation of a long nuclear extension that reaches into the bud. Chromosomes migrate through this extension and, together with the spindle-pole bodies leave the old envelope, which remains in the mother cell until late telophase. Breakage and removal of the envelope required nuclear migration into the bud, as misplaced nuclei underwent a "closed" mitosis. Our data indicate that dynein-mediated pre-mitotic nuclear migration participates in nuclear envelope removal in *U. maydis*.

11.5.7. TEM-based studies for the occurrence and characterization of a mycovirus in sunflower downy mildew *Plasmopara halstedii*

M. Heller-Dohmen[1], A. J. P. Pfitzner[2], A. Heller[1], O. Spring[1];
[1]Institute for Botany (210), Stuttgart, Germany, [2]Institute for Virology (240), Stuttgart, Germany.

TEM studies using a negative staining technique revealed the presence of a virus in 23 of 26 isolates of *P. halstedii* deriving from 5 European and 3 American countries. Ultrathin sections showed the virus either dispersed throughout the cytoplasm or in membrane-bound vesicles in all stages of its host's life cycle. The virus occurred in 8 different pathotypes of *P. halstedii*, but was absent in sunflower and in 8 other species of Oomycota. The virus measured 37 nm in diameter. Its isometric capside consisted of a polypeptide of 36 kD. Two major types of single-stranded RNA were detected comprising of 3.3×10^3 and 1.6×10^3 nucleotides, respectively. No significant differences neither in morphology nor in biochemical composition between the viruses of different *P. halstedii* isolates were found. The virus found in this study did not differ from the *P. halstedii*-Virus, first found in an isolate by Gulya et al. (1990) and described by Mayhew et al. (1992).

11.6.1. Phylogeny and evolutionary patterns in Nymphaeales: integrating genes, genomes and morphology

T. Borsch[1], K. W. Hilu[2], C. Löhne[1], J. Wiersema[3];
[1]Nees-Institut für Biodiversität der Pflanzen, Universität Bonn, Bonn, Germany, [2]Department of Biology, Virginia Polytechnic Institute and State University, Blacksburg, VA, United States, [3]United States Department of Agriculture, Beltsville, MD, United States.

The eight extant genera of Nymphaeales comprise species-poor (*Brasenia*, *Ondinea*) and species-rich (*Nymphaea, Nuphar*) genera and major lineages distributed on different continents. To evaluate monophyly and phylogenetic position of Nymphaeales genera, a dataset comprising multiple non-coding and fast-evolving regions from all three genomes was generated for a dense sampling (30 species). Three major lineages are resolved: *Nuphar*, Cabombaceae and core Nymphaeaceae (remaining genera). This dataset complements an enormous amount of phenotypic data, which is available through works of over a century. Based on molecular trees, the evolution of important characters such as floral architecture, reproductive systems, pollen morphology, and ploidy levels is reconstructed. Phenotypic data are evaluated for their support of insufficiently supported nodes of molecular trees based on combined data. The phenotypic data are placed in a phylogenetic context in an effort to bridge the gap to the fossil record.

11.6.2. Nymphaeales - phytogeography and spatial diversification

C. Löhne[1], J. Wiersema[2], V. Wilde[3], W. Barthlott[1], T. Borsch[1];
[1]Nees-Institut für Biodiversität der Pflanzen, Universität Bonn, Bonn, Germany, [2]United States Department of Agriculture, Beltsville, MD, United States, [3]Paläobotanik, Senckenberg Forschungsinstitut, Frankfurt am Main, Germany.

Nymphaeales, consisting of 70 species in 8 extant genera (*Barclaya*, *Brasenia*, *Cabomba*, *Euryale*, *Nuphar*, *Nymphaea*, *Ondinea*, *Victoria*), constitute the "first" clade of extant angiosperms with global distribution. Within the family biogeographic patterns differ strongly, ranging from local endemics (e.g., *Ondinea*) to cosmopolitans (e.g., *Brasenia*). Moreover, continental disjunctions of closely related taxa like *Victoria* (South America) and *Euryale* (East Asia) raise questions on the biogeographic history of the family. In this study we analyze extant patterns of biodiversity in Nymphaeales using a GIS database including all species. A multi-gene phylogeny with a dense taxon sampling designed to cover the geographically distinct lineages (including all subgenera of *Nymphaea*) serves to uncover historical processes and causes for recent distributional patterns. Ancestral areas are reconstructed by dispersal-vicariance analysis (DIVA). The findings are compared with the fossil record of Nymphaeales to evaluate whether recent distributions are rather relictual or are the outcome of recent radiations.

11.6.3. Pollination biology of night-flowering Nymphaea (Nymphaeaceae) species

G. Hirthe[1], J. Knudsen[2], B. Piechulla[3], S. Porembski[1], J. Wiersema[4];
[1]Institute for Biodiversity Research, University of Rostock, Rostock, Germany, [2]Gotland University, Visby, Sweden, [3]Dept. of Biological Sciences, Biochemistry, University of Rostock, Rostock, Germany, [4]USDA/ARS, Systematic Botany and Mycology Laboratory, Beltsville Agricultural Research Center, Beltsville, MD, United States.

The large and specialized flowers of some Nymphaeaceae are exceptional among basal angiosperms. The genus *Nymphaea* is classified in five subgenera of which three are day-blooming and pollinated by bees and syrphid flies. Neotropical subgenus *Hydrocallis* is night-flowering with large dynastine beetles as pollinators. The specialized pollination mode is similar to the related genus *Victoria*. Although nocturnal like *Hydrocallis*, the flowers of the palaeotropical subgenus *Lotos* remain open until noon. *Nymphaea lotus* of the subgenus *Lotos* is pollinated by a dynastine beetle species as well as generalistic bees. It is likely that slower flower closure enables alternative pollinators to visit and pollinate flowers during the early day. The close relationship between *Hydrocallis* and *Lotos* regarding morphology and beetle pollination provide evidence that specialized beetle pollination was the original pollination mode of *N. lotus* and the spatial and temporal absence of the beetles are responsible for the observed generalized pollination. Future work will focus on floral traits selecting pollinators such as flower opening and scent emission.

11.6.4. Divergence times and historical biogeography of Nymphaeales

M. Yoo[1], C. D. Bell[2], P. S. Soltis[3,4], D. E. Soltis[1,4];
[1]Department of Botany, Gainesville, FL, United States, [2]Department of Biology, New Orleans, LA, United States, [3]Florida Museum of Natural History, Gainesville, FL, United States, [4]The Genetics Institute, Gainesville, FL, United States.

Nymphaeales (Nymphaeaceae and Cabombaceae) comprise eight genera and approximately 70 species, with a worldwide distribution in tropical to temperate regions. Previous analyses of molecular and morphological data have provided a well-resolved and strongly supported generic-level phylogeny for the order. From published nuclear 18S rDNA, and plastid *rbcL* and *matK* DNA sequences, we estimated the divergence times of genera in Nymphaeales. We applied four different methods, a strict molecular clock, nonparametric rate smoothing, penalized likelihood, and a Bayesian method, to estimate divergence times. Our results indicate that extant Nymphaeales diversified into major clades during the Eocene (44.6±7.9 mya); extant genera of Nymphaeaceae date to 41.1±7.7 mya, and extant Cabombaceae diversified during the Miocene (19.9±5.6 mya). Whereas the stem lineage of Nymphaeales is old based on fossil evidence (125-115 mya), our results indicate that extant Nymphaeales diversified relatively recently. We infer that the ancestor of Nymphaeales occupied the American and Eurasian continents during the Eocene; this inference is supported by the fossil record.

11.6.5. Lower Cretaceous evidence for the Cabombaceae water lily lineage and use to leaf architectural characters to identify major clades

D. W. Taylor;
Indiana University Southeast, New Albany, IN, United States.

Molecular phylogenies suggest that there are three clades in the Nymphaeales. The *Brasenia*-like fossils from the Albian of Jordan have orbicular, simple, entire margined, peltate, alternatel leaves with long petioles attached to slender shoots. Venation is palmate with four (five) primary veins of which one has pinnate secondaries and the others branch dichotomously. Primaries and secondaries curve to form brochidodromous loops. The tertiaries are variable and intergrade with the quaternaries in a reticulate to random reticulate manner, although some leaves, like the stems and petioles, have little detail. The affinity to the Nymphaeales is based on the peltate attachment, leaf shape, leaf architectural characters, and the apparent aquatic nature of the leaves and stems covered with mucilage while to Cabombaceae clade is based on the shape of the leaf and the aquatic shoots, as opposed to rhizomes. Fossils show at least two clades existed by the Albian 110mya. An examination of leaf architecture characters reveals consistent characters to identify the order and show trends in the clades and may allow understanding of the detailed relationships of the fossils.

11.6.6. Environmental control of sepalness and petalness in waterlilies

K. Warner[1], P. J. Rudall[2], M. W. Frohlich[1];
[1]Natural History Museum, London, United Kingdom, [2]Royal Botanical Garden, Kew, United Kingdom.

The conventional concept of an "undifferentiated perianth" obscures the fact that individual perianth organs may be differentiated into sepaloid (sepal like) and petaloid (petal like) regions. We have observed such differentiation in genera from several families including the basal angiosperms Nuphar and Nymphaea (Nymphaeaceae). In Nuphar the perianth organs traditionally called sepals exhibit both yellow petaloid and green sepaloid patches that show anatomical distinctions in addition to color differences. In Nymphaea the perianth organs near the boundary between "sepals" and "petals" are often subdivided into sepaloid and petaloid regions, rather than being intermediate in morphology over their entire surfaces. Our data suggest that the environment of a perianth organ helps specify these regions. The traditional concept of "sepal" and "petal" includes a hidden assumption that we believe is false: that sepalness and petalness must refer to whole perianth organs. We suggest a novel theory of perianth evolution, in which differentiation of the perianth into sepals and petals was predated by the evolution of sepalness and petalness.

11.6.7. Over 12,000 new *Nuphar* and *Amborella* gene sequences shed light on ancestral angiosperm transcriptome

J. H. Leebens-Mack[1], L. Cui[1], D. E. Soltis[2], P. S. Soltis[2], J. E. Carlson[1], W. G. Farmerie[2], P. Wall[1], L. Zahn[1], M. Buzgo[2], S. Kim[2];
[1]The Pensylvaina State University, University Park, PA, United States, [2]University of Florida, Gainsville, FL, United States.

Multigene reconstructions of the seed plant phylogeny place *Amborella* and Nymphaeales as successive sister lineages to all other extant angiosperms or *Amborella* plus Nymphaeales as the basal clade. Genomic investigations of these lineages will, therefore, aid inference of gene content and genome structure in the most recent common ancestor of all extant angiosperms. The Floral Genome Project has generated over 17,000 expressed sequence tags (ESTs) for genes expressed in early flower development in *Amborella trichopoda* and *Nuphar advena,* representing over 6000 genes for each species. A concentration of duplicate genes identified in the *Nuphar* data suggests that it is an ancient polyploid. Phylogenetic analyses of gene families including sequences from *Amborella*, *Nuphar* and other angiosperms are elucidating the minimal set of floral development genes in the most recent common ancestor of all extant angiosperms and identifying potentially novel floral regulators. The new *Amborella* and *Nuphar* sequences provide critical references for estimating the timing of gene and genome duplications relative to the earliest branching events in angiosperm history.

11.7.1. Gentians were not always blue - the why, when, and where of gentian evolution

L. Struwe;
Rutgers University, New Brunswick, NJ, United States.

The gentian family has been the focus of intense phylogenetic research on tribal, generic and species level for over 10 years and we now have a new understanding of its complex historical patterns. Currently over 30 scientist are part of this on-going effort (see Gentian Research Network, http://www.rci.rutgers.edu/~struwe/gentnet/). This widespread family of 90+ genera and 1600 species contains a wide morphological, ecological, and distributional diversity. Recent analyses focusing on monophyletic groups of all levels and all geographic areas (Latin America, Indian Ocean Basin, etc.) utilizing GIS, molecular clocks, and molecular-based evolutionary hypothesis have lead to a deeper understanding of the evolution of this diversity. This overview provides a couple of peeks into the history of the originally-not-so-blue gentians and their tropical ancient lineages. For example, detailed species level studies in South America show environmentally-induced speciation in tropical forests and mountains. Recent results in all six tribes are reviewed with their associated insights in morphological, karyological, and biogeographic evolution.

11.7.2. Common weeds to rare habitat specialists: Speciation and distribution patterns of *Chelonanthus* within South America

K. B. Lepis, A. Gorczyca, L. Struwe;
Rutgers University, New Brunswick, NJ, United States.

The neotropical genus *Chelonanthus* Gilg (Helieae) has been determined to be paraphyletic based on cladistic analyses of 5S-NTS and ITS sequences, and is composed of two lineages. One consists of *C. purpurascens*, with purple corollas and pollen shed as polyads. The second is all other species with green, yellow, to white corollas and pollen shed as tetrads. Molecular and detailed morphological characters are being analyzed to determine the relationships within and between the taxa. These species exhibit a continuum of habitat strategies, and another aim of the study is to investigate the evolution of habitat strategies within the light-colored corolla species. Within *Chelonanthus* examples of wide-ranging weeds, wide-spread habitat specialists and narrow endemics exist. Phylogenetic relationships and biogeography are analyzed to determine if habitat specialists are derived from habitat generalists and to elucidate the geographic origin in a historical perspective.

11.7.3. Tracing back the modes of speciation in *Halenia* (Gentianaceae) using a combined phylogenetic and GIS approach

B. von Hagen, E. Welk;
Institut fuer Geobotanik, Halle, Germany.

A molecular phylogenetic analysis of *Halenia* reveals clear cut large scale biogeographical relationships and the analysis of diversification rates shows that migration to new regions was followed by an immediate increase of speciation rates relative to sister taxa from regions which have been colonized earlier. To test whether speciation rates in *Halenia* are generally triggered by new possibilities of spatial isolation or by ecologically driven divergence we applied GIS (global information system) data on digitized distribution data of all species. The detailed distributions have become available as part of a complete taxonomical revision of the genus. We have developed macroecological niche models for each clade and used these to predict the distribution of sister clades. In some cases the predictions of the ecological niche model is excellent in others rather poor. The first result may point to allopatric speciation and the latter to ecological niche differentiation. Quantitatively the first process seems to have been more important in *Halenia* than the second.

11.7.4. Phylogenetic relationships within the genus *Sebaea* s.l. based on molecular and morphological data: evidence of polyphyly and its consequences on the evolutionary history of the tribe Exaceae.

J. Kissling, G. Mansion, P. Küpfer;
Laboratoire de botanique évolutive, CH-2007 Neuchâtel, Switzerland.

To reconstruct the evolutionary history of the genus *Sebaea* s.l. (ca. 85 species), molecular analyses were performed using 76 cpDNA (*trn*LF) and 56 nrDNA (ITS) sequences. In addition morphological characters were included to a combined data matrix to detect possible non-molecular synapomorphies. Both molecular data sets highly support the monophyly of the tribe Exaceae, and further reveal the polyphyly of the main genus *Sebaea*. A first well-supported and basal clade comprises *Sebaea* s.s., a genus of mainly South African distribution. The remaining species form a more derived clade that consists of a primarily African genus - treated here as *Exochaenium* - that is closely related to *Exacum*, *Tachiadenus*, *Ornichia* and *Gentianothamnus*. Further, preliminary morphological data support a distinction between *Sebaea* and *Exochaenium*, whose mainly differ by floral characters. Finally, biogeographical patterns can be inferred for the tribe Exaceae, with a South African origin (including the Cape region) for *Sebaea*, followed by several migrations to Central Africa (*Exochaenium*), Madagascar (*Exacum*, *Tachiadenus*, *Ornichia*, *Gentianothamnus*), and Asia (*Exacum*).

11.7.5. *Prepusa* and *Senaea* (Helieae-Gentianaceae): endangered and endemic genera from Brazil with six-merous flowers

M. F. Calió[1], J. R. Pirani[1], W. Peters[2], L. Struwe[2];
[1]Instituto de Biociências, São Paulo, Brazil, [2]Cook College, New Brunswick, NJ, United States.

Prepusa Mart. and Senaea Taub. (Gentianaceae) have never been revised since their original description in the 19th century. Based on analysis of herbarium collections from several herbaria, five species of Prepusa and two species of Senaea were recognized. A close relationship between the two genera is supported by sharing 6-merous flowers, a unique pollen tetrad type, and a membranaceous calyx. The 6-merous flower is a unique morphologic feature within the neotropical tribe Helieae, otherwise nearly exclusively 4- or 5-merous. Prepusa species present a large and showy calyx, longer than or almost as long as the corolla, whereas the Senaea species have a calyx much smaller than the corolla. These two gentian genera are rare montane herbs or shrubs endemic to restricted areas of four Brazilian states (Bahia, Espírito Santo, Minas Gerais and Rio de Janeiro). A taxonomic revision of these two genera is presented including field keys to species, morphological descriptions and illustrations, current status, and maps on their geographic distribution to aid in the conservation of these endangered and evolutionary unique species.

11.7.6. Phylogenetic relationships within the New World endemic *Zeltnera* (Gentianaceae-Chironiinae) inferred from molecular and karyological data

G. Mansion, L. Zeltner;
University of Neuchatel, Neuchatel, Switzerland.

The New World endemic genus *Zeltnera* consists of 25 species mainly distributed in the western part of the United States and Mexico. Chromosome counts performed on 149 populations (24 species) reveal extensive congruence between chromosomal groups and the assemblages obtained from analyses of nuclear ribosomal DNA (ITS) and chloroplast DNA (*trn*L intron and *trn*L-F intergenic spacer) sequences. Karyological and molecular data sets support three main biogeographic groups for *Zeltnera*. A first and mainly unresolved cluster ($n = 17$ and $n = 20$) occurs in California, whereas two other clades are centered in the Texas region ($n = 20$ and $n = 21$) and Mexico ($n = 21$ and $n = 22$), respectively. Under the assumption of a molecular clock, and using both dispersal and vicariance explanations for the current distribution of the respective species, we can hypothesize a North American origin for the genus, with considerable diversification in the early Pliocene (ca. 5 mya). Geological events, such as desert formation and mountain orogenies, have created insuperable barriers that today separate the three major and likely vicariant groups.

11.7.7. Systematics of Macrocarpaea (Gentianaceae) including an infrageneric classification based on seed morphology, palynology, floral morphology and molecular characters

J. R. Grant;
Université de Neuchâtel, Neuchâtel, Switzerland.

Macrocarpaea has numerous seed and pollen types that have been systematically useful in in establishing an infrageneric classification together with a phylogeny based on ITS and 5s-NTS sequences. The genus of 106 species has an origin in the Atlantic coastal forest of Brazil, yet has undergone large-scale speciation within the Andean Cordillera. Four sections are recognized within Macrocarpaea: Sect. Tabacifoliae comprises 4 species that occur in Southeastern Brazil and characterized by Flattened-type seeds. Sect. Macrocarpaea comprises 42 species largely of the Northern Andes (Colombia and Venezuela), southern Mesoamerica (Costa Rica and Panama), Pantepui of the Guayana Shield, and the Greater Antilles of the Caribbean (Cuba, Hispaniola, and Jamaica) characterized by Rimmed-type seeds. Sect. Magnolifoliae comprises 18 species of the Central Andes (Ecuador, Peru, and Bolivia) characterized by Corymbosa-type Pollen and Winged-type seeds. Sect. Choriophylla comprises 37 taxa largely of the Central Andes (W Colombia, Ecuador, Peru, Bolivia), especially the Huancabamba region of Ecuador and Peru characterized by Perimetrically winged-type seeds.

11.8.1. Understanding the systematics, ecology and evolution of Podostemaceae: What is the future?

C. Philbrick;
Western Connecticut State University, Danbury, CT, United States.

This talk will summarize recent advances and highlight key areas that remain poorly known in the understanding of Podostemaceae. Taxonomic insight has improved dramatically in some geographic regions but remains inadequate in others where taxonomic circumscriptions remain suspect. The incidence of monotypic genera at ca. 40% illustrates the present artificial genus concept. Exciting insights have come from the application of phylogenetic principles to probe questions of evolutionary relationships, biogeographic patterns, and character evolution, yet these have been applied to a minority of the family. Understanding of ecology remains poor. Factors that influence local species distributions remain unknown and the role that plants play in the ecology of tropical rivers is little clarified. Essentially nothing is known about how genetic variation is partitioned within and between populations. Such insight would be valuable for addressing taxonomic, ecological and conservation issues. Conservation concerns remain to be clarified. Reported high species endemism, combined with intense human impacts on their habitats, are a sobering combination.

11.8.2. Molecular phylogeny and biogeography of Podostemaceae

M. Kato, Y. Kita;
Department of Biological Sciences, University of Tokyo, Tokyo, Japan.

The matK-deduced phylogeny of Podostemaceae shows that the family is divided into three subfamilies. Podostemoideae has several clades comprising the largest number of species. The basalmost is an American clade, and the rest of the subfamily is divided into an Afro-American clade and an Asian clade. Tristichoideae is a small, basically Asian subfamily with an exception of Afro-American Tristicha, the ancestor of which likely migrated from Asia. Weddellinoideae is a monogeneric American subfamily being sister to Podostemoideae. The phylogenetic pattern may reflect the biogeographical history of major groups. It is likely that Podostemaceae underwent an early geographic split to Asia (as Tristichoideae) and America (as Weddellinoideae + Podostemoideae), and then parts of Podostemoideae expanded to Africa or migrated to Asia. The geographic changes accompanied remarkable modifications in embryonic developmental pattern and the resulting body plan. Dalzellia and Indotristicha (Tristichoideae) and Cladopus and Hydrobryum (Podostemoideae) exhibit saltational evolution.

11.8.3. Systematics, phylogeny, and conservation of podostemads in the New World.

A. Novelo;
Instituto de Biología, México, D.F., Mexico.

The taxonomy of Podostemaceae in the Americas started in 1775 with the description of *Mourera fluviatilis* from French Guyana. Subsequently nearly 160 species (in 19 genera) have been described. Though Peter van Royen (1950s) published the most comprehensive taxonomic treatment of New World Podostemaceae, much of the taxonomy remains tentative. The circumscription of many New World genera is troublesome. The genus *Podostemum* will be used to illustrate the use of phylogenetic analyses to redefine generic boundaries. The results of phylogenetic analyses will also demonstrate difficulties involved in the circumscriptions of such genera as *Apinagia*, *Marathrum* and *Oserya*. The emphasis on hydroelectric power (dam building) in South America, combined with reported high levels of species endemism, leads to conservation concerns in the family. Yet such concerns can be difficult to clarify because of taxonomic uncertainty. The genus *Castelnavia* will be used exemplify this problem. Finally, the importance of field collecting will be shown by discussing taxonomic diversity of Podostemaceae in Mexico and southern Brazil (especially *Podostemum*).

11.8.4. Systematics, phylogeny and conservation of Podostemaceae in Africa

G. K. Ameka;
Department of Botany, University of Ghana, Legon, Accra, Ghana, Accra, Ghana.

The first accounts of the Podostemaceae from Africa appeared in the literature in 1849 and 1852 by Tulasne. Since then about 80 publications on African (including Madagascar) Podostemaceae are available. Africa has 16 genera and c. 79 species, making it the second center of biodiversity, apart from tropical America. Eight out of the 16 genera are monotypic and occur in Africa and Madagascar; five of them have monotypic genera restricted to Africa; two of them are monotypic genera endemic to Madagascar; and one species is widespread in Africa and Madagascar. Seven other genera consist of 2 - 7 species. The genus *Ledermanniella* is exceptionally large, containing c. 45 spp. It contains more than half of all Podostemaceae taxa from Africa. Most Podostemaceae genera and species in Africa occur in the mountains of Cameroon and Gabon. Several African taxa are not intensively studied. The Ghanaian Podostemaceae, with c. 4 endemic species and a widespread one, however, are well known due to intensive field work and additional lab studies.

11.8.5. Embryological and reproductive structures of Podostemaceae

I. F. Jäger-Zürn;
-, Königstein, Germany.

Flowering is at the intersection of submerged to aerial life at subsiding water level when the plants become exposed. It means a change from aquatic to xerophytic life on sun heated rocks. This condition necessitates sure and rapid fertilisation (2-3 d) and resources present for a period of gradual limitation of supply at seed ripening (2-3 w). The strategy of Podostemaceae to accomplish these needs is manifold.: Fertile pollen and fertilisable embryo sacs developed at submerged life; pollination autogamous or cleistogamous, rarely allogamous; acceleration of the embryo sac development (restriction to the micropylar quartet of the embryo sac, reduced *Allium* type); no double fertilisation, hence no endosperm; but already existing tissue as a nutrient of the embryo (“nucellar plasmodium”); suspensor haustorium; the outer cells of the testa mucilaginous upon wetted; high seed set, but largely propagated by clonal growth. The particularities are discussed, new own results on microsporogenesis and new palynological data presented.

11.8.6. Organ identity of the plant body in some Indian Podostemoideae (Podostemaceae)

A. Sehgal;
Dept of Botany, Miranda House, Univ Delhi, Delhi, India.

The Podostemaceae is a unique family of aquatic angiosperms. The Indian Podostemoideae are characterized by a dorsiventrally thalloid plant body. The nature of the plant body has long been a subject of dispute. Determining the origin, structure and function of an organ can give an insight into its identity. We have traced the ontogenetic details from seed germination to seedling establishment and studied the structure and development of the plant body in a few Indian podostemads to interpret the thallus and its components. The cytohistological zonation of the thallus tips in these taxa is similar to the tunica- corpus of the shoot apical meristems of typical angiosperms.The secondary vegetative shoots that arise endogenously prior to the initiation of lateral thallus branches, are stemless and show limited growth. The lateral thallus branches arise exogenously and are proximal to secondary vegetative shoots. They repeat the same growth pattern as that of the main dorsiventral stem. The lateral thallus branch can be interpreted as a structure with fuzzy boundaries.

11.8.7. Comparative and developmental morphology of roots and shoots in African Podostemaceae.

R. Rutishauser;
Institute of Systematic Botany, Zurich, Switzerland.

Podostemaceae show morphological novelties not known from other flowering plants, e.g. crustaceous or ribbon-like green roots (many taxa), terminal double-sheathed leaves (e.g. *L. bowlingii*, Ghana), endogenous formation of flowers along stems due to dedifferentiation of cortex tissue (e.g. *Ledermanniella letouzeyi*, Cameroon), epiphyllous flowers (e.g. *L. prasina*, Cameroon). Several unique morphological characters of African Podostemaceae are listed in the homepage www.systbot.unizh.ch/podostemaceae/. Some architectural peculiarities of African Podostemaceae (e.g. double-sheathed leaves) are also known from American and Asian taxa. Botanists disagree about how to best interpret the vegetative body of Podostemaceae. It may be described as partially homologous with the classical root-shoot model that applies to most other angiosperms. Structural terms such as 'root', 'shoot', 'stem' and 'leaf' in Podostemaceae do not necessarily imply a total homology with these categories in typical angiosperms.

11.9.1. The Proteaceae: divergences, dates and classification

N. P. Barker[1], P. H. Weston[2], F. Rutschmann[3];
[1]Rhodes University, Grahamstown, South Africa, [2]Royal Botanic Gardens, Sydney, Sydney, Australia, [3]Institute for Systematic Botany, Zurich, Switzerland.

Following the analyses of several DNA sequence data sets, the classification of the Proteaceae requires re-alignment. We present a new classification at subfamily, tribal and subtribal rank. Five subfamilies, 12 tribes (two of which are new) and 11 subtribes (three of which are new) are recognized. However, numerous taxa are considered *incertae cedis*, and await further examination. Using a subset of taxa representing major lineages of the family, the molecular data (*atp*B, *rbc*L and the *atp*B-*rbc*L spacer regions) were subjected to various molecular dating analyses using several fossil calibration points. Our results for some clades are consistent with the widely held hypothesis that the Proteaceae are a "Gondwanic group", with trans-oceanic disjunctions caused by continental drift. However, some clades with intercontinental distributions are estimated to be much younger than the ocean basins that they span. These anomalies are striking enough to challenge biogeographic orthodoxy.

11.9.2. The fossil record of fruits of the Proteaceae

M. E. Dettmann[1], H. T. Clifford[2];
[1]University of Queensland, St Lucia, Australia, [2]Queensland Museum, South Brisbane, Australia.

The record of fossil fruits of the Proteaceae is reviewed based on comparative studies involving morphological and anatomical characters with fruits of extant members of the family. Fossil fruits/infructescences that unambiguously belong to the family are confirmed for the Tertiary of Australia and South America. Fossil fruits reported from the Tertiary of New Zealand and Antarctica may also belong to the family, but require further investigation.

The majority of fruit taxa are consistent with fruits of subfamily Grevilleoideae, a notable exception being the large distinctive fruits, recovered from mid-Tertiary sediments in southeastern Australia, of *Xylocaryon lockii* which conform with those of *Eidothea,* currently nested within the subfamily Proteoideae based on chloroplast DNA sequence data. The record of subfamily Grevilleoideae includes *Orites* follicles from the Paleocene of Patagonia, "cones" of *Banksia* from the Paleogene and Neogene of Australia, and indehiscent to tardily dehiscent fruits from latest Eocene-Miocene sediments of eastern Australia allied to those of several taxa within tribes Macadamieae and Grevilleeae.

11.9.3. A phylogenetic approach to the fossil record of Proteaceae (Proteales): insights from the Banksieae

H. Sauquet[1,2], **D. J. Cantrill**[1,2];
[1]Department of Palaeobotany, Stockholm, Sweden, [2]Swedish Museum of Natural History, Stockholm, Sweden.

Proteaceae (1700 spp) have a particularly rich fossil history throughout southern Gondwana. Extending back to the mid-Cretaceous they thus represent an ideal model to test biogeographic hypotheses in the Southern Hemisphere. However, the appropriate use of fossil data in Proteaceae has so far suffered both from methodological problems and insufficient knowledge of morphological diversity within the extant family. Here we use tribe Banksieae (180 spp) to illustrate the need for a more rigorous approach to fossil Proteaceae. Based on special features of this group, various palynomorphs and macrofossils from the Cenozoic of Australia and New Zealand have been assigned to Banksieae without ambiguity. In particular, diporate pollen grains are almost exclusive to the four genera in the tribe. We report new substantial palynological data on extant Banksieae, and discuss the assignment of diporate palynomorphs and serrate leaves and their reliability as calibration points in molecular dating analyses.

11.9.4. Morphology, genes, and fossils to infer evolution in Platanaceae

T. Denk[1], G. W. Grimm[2], M. V. Tekleva[3];
[1]Swedish Museum of Natural History, Stockholm, Sweden, [2]Eberhard-Karls University, Tuebingen, Germany, [3]Palaeontological Institute, Russian Academy of Sciences, Moscow, Russian Federation.

The family Platanaceae consists of a single genus today that comprises only 7 species. The fossil record shows that the family extends back to the mid Cretaceous, and, based on findings of reproductive structures and leaf fossils, suggests a much higher diversity of the family for the Cretaceous and early Cenozoic. A combined morphological-molecular study shows a) three distinct genetic lineages within *Platanus*: The East Asian *P. kerrii*, an eastern N American/Central American clade, and a Pacific N American-European clade, b) that all three lineages appear to be present in the fossil record already in the Cretaceous, c) that a number of morphological characters are stable from the Cretaceous to present (pollen), d) that leaf epidermal features in modern *Platanus* are more complex than previously assumed but basically do follow a general pattern found in basal angiosperms and basal eudicots, which limits its value to discriminate fossil “Platanaceae” against other families, e) that leaf architecture provides a valuable tool to discriminate *Platanus* against other taxa, and, finally, that no indication for a close Proteaceae-Platanaceae relationship exists.

11.9.5. Cuticular features of fossil Platanaceae and their taxonomical importance

L. B. Golovneva;
Komarov Botanical Institute, St.-Petersburg, Russian Federation.

Platanoid foliage and reproductive structures are known from middle Albian. The taxonomical and morphological diversity of extinct Platanaceae in the Cretaceous and Palaeogene was significantly higher than diversity of extant family. All representatives of the family Platanaceae possess very similar and rather specific cuticular structure. The investigation of intact cuticle of fossil leaves allows the recognition of platanaceous affinity of many morphotypes, because their systematic position is not always obvious from morphology. Recently about 15 genera of fossil platanoids have been distinguished on the basis of leaf morphology and cuticular structure. The diversity of epidermal characters of the Cretaceous platanoids was also higher than is known for modern species of *Platanus*. Some extinct genera are characterized by a diagnostic complex of specialized cuticular features. The investigation of cuticle structure also provides a means to distinguish species with similar morphology, because morphological variability of the majority of taxa is very high.

11.9.6. Fossil reproductive structures: re-evaluation of Cretaceous diversity in Platanaceae

N. Maslova, M. Tekleva;
Paleontological Institute Russian Academy of Sciences, Moscow, Russian Federation.

Extant members of the families Platanaceae and Hamamelidaceae are easily differentiated by their reproductive morphology. The recent *Platanus* is characterized by naked flowers having an apocarpous gynoecium with a varying number of elements. In contrast, extant Hamamelidaceae are characterized by a syncarpous semiinferior ovary of two carpels. In the fossil record platanoids and hamamelids (in particular altingioids) are often similar in the macromorphology of their reproductive organs making their distinction difficult. For example, the extinct platanoids had a constant number of carpels per flower and a well-developed perianth. Among the hamamelids extinct types with monocarpellate flowers are known. Although extant altingioids have naked flowers, our study has revealed well-developed perianths in early hamamelids as well. These findings suggest the previously believed high Cretaceous diversity of Platanaceae needs re-evaluation. This work is supported by the Russian Foundation for Basic Research, project 03-05-64794.

11.10.1. Grapevine imprinted by natural and human factors

R. Bessis;
Institut Universitaire de la Vigne et du Vin, Dijon, France.

I Genetic inheritance of grapevines involved with vegetative multiplication.
- Factors enhancing diversity.
- Typicity and its constraints including the limits of varietal creation and considering the effects of viruses.

Conclusion regarding the variable nature of vegetative multiplication focusing on variability outside of sexual breeding.

II Phenotypic character of grapevines depending on natural factors.
- Environmental factors such as soil, water stress, solar orientation, climate....
- Biological factors. Examples concerning natural defences will be detailed. Elicitation with resveratrol response will be dicussed looking at the process from the genus to the leaves, to the berries and the wine. External effects of resveratrol existence on fungi and human consumers will be shown. Looking at these new factors as material for continued evolution.

Conclusion : the preexisting notion of “terroir” and its relationship with the grapevine characteristics detailed in this discussion.

11.10.2. Shoot architecture in the Vitaceae

J. M. Gerrath;
University of Northern Iowa, Cedar Falls, IA, United States.

Most Vitaceae possess a distinctive shoot architectural pattern, characterized by leaf-opposed tendrils. Shoots are modular, consisting of three-node repeating cycles. Five architectural models have been described, based on the pattern of tendril and axillary bud occurrence at each node. The relationship between mature growth form, shoot architecture, and shoot ontogeny will be compared in three species of *Cyphostemma* (*C. juttae*, a herbaceous succulent with terminal inflorescences, lacking tendrils, *C. mappia*, a woody shrub with terminal inflorescences, lacking tendrils, and *C. simulans*, a liane, with leaf-opposed tendrils and axillary inflorescences). These results will be discussed in the context of the relationship between mature architecture and shoot ontogeny. Evidence for the most likely evolutionary pathway, from Pattern 1 with spiral phyllotaxy and no tendrils, to Pattern 5 with distichous phyllotaxy and continuous tendrils and axillary buds, will be presented. The question of whether this unique shoot pattern should be considered to be monopodial, sympodial, or a combination will be discussed.

11.10.3. Molecular analysis of flowering transition in grapevine (*Vitis vinifera* L.)

J. M. Martinez-Zapater[1], M. Calonje[2], P. Cubas[1], M. Carmona[2];
[1]Centro Nacional de Biotecnologia, CSIC, Madrid, Spain,
[2]Departamento de Biotecnologia, ETSIA, UPM, Madrid, Spain.

Flowering in grapevine (*Vitis vinifera* L.) seems to be promoted by the summer rise in temperature and light intensity. As a result, lateral meristems produced at shoot apical meristems in summer latent buds proliferate and differentiate to produce a cluster of inflorescence meristems in place of tendril primordia. After winter dormancy, inflorescence meristems will give rise to clusters of flower meristems and flowers. To understand the molecular mechanisms underlying this process, we have characterized *VFL*, *VAP1* and *VFUL*, putative *Vitis* orthologs of *LFY, AP1* and *FUL* genes, responsible for flower meristem identity in Arabidopsis. *VFL* expression is detected in all analyzed meristems and primordia. However, consistent with a role in flower initiation, *VFL* transcripts accumulate in proliferating lateral meristems giving rise to inflorescence meristems. *VFUL* and *VAP1* are also highly expressed in lateral meristems and inflorescences and flower meristems. Interestingly, they also accumulate throughout tendril development. This expression pattern provides molecular support to the origin of tendrils as modified reproductive organs adapted to climb.

11.10.4. Floral development in the Vitaceae

U. Posluszny;
University of Guelph, Guelph, ON, Canada.

The common perception in the Vitaceae is that variation in reproductive structures is small and therefore of little use systematically below the generic level. This perception, unfortunately, is based on a small database of floral studies in the Vitaceae, especially very few floral ontogenetic studies. In the past twenty years we have examined the floral development of 12 species in 6 genera and have noted a significant amount of variation and a clear evolutionary trend. Floral characteristics shared in the Vitaceae include; inflorescence branching as compound dichasia, bisexual flowers, precocious initiation of a calyx ring, unfused non-showy petals which overarch the petal-opposed stamens and bicarpellate gynoecia (four ovules) with septa forming from the inner ovular walls. In derived members of the Vitaceae (i.e. *Vitis*) certain floral structures such as the calyx ring and the nectary disk have been modified. The questions concerning an evolutionary trend in the flowers of the Vitaceae will be further explored by examining three members of the genus *Cyphostemma*, *C. juttae*, *C. mappia* and *C. simulans*.

11.10.5. On the diversity and evolutionary diversification of Vitaceae in Asia.

A. Soejima[1], J. Wen[2];
[1]Osaka Prefecture University, Sakai, Japan, [2]Field Museum of Natural History, Chicago, IL, United States.

Asia is one of the major centers of diversity for the grape family Vitaceae. Twelve of the 14 genera in the family are distributed in tropical and temperate Asia including three endemic genera: Acareosperma, Nothocissus and Pterisanthes. Several large genera such as Ampelocissus, Tetrastigma and Vitis have their highest diversity in Asia. A few genera have conspicuously disjunctive distribution between Asia and the New World. Our chloroplast sequence data (trnL-trnF, atpB-rbcL and rps16 intron) suggest that the Asian species of Cayratia and Tetrastigma and the largely African Cyphostemma form a clade, with Cayratia possibly being paraphyletic. Nothocissus and Pterisanthes, two small Asian endemic genera, are nested in the clade of Ampelocissus. The position of Yua is not well resolved. The North American species of Parthenocissus are highly distinct from the Asian relatives. The results suggest that: (1) multiple migration between Asia and the New World; (2) ancient origins of the intercontinental disjunctions between the two continents in Vitaceae; and (3) the evolutionary radiation at both species and generic levels in eastern and southeastern Asia.

11.10.6. Vitaceae systematics in South America

J. A. Lombardi;
Instituto de Biociências, Rio Claro, Brazil.

To date, in South America, the Vitaceae is represented by 65 species in 2 genera, *Cissus*, with 64, and *Vitis*, with one.

A recent study on the Neotropical *Cissus* accounted for 75 species, 62 of which in South America, but, these last two years, I have described two more.

My study reveals that, for species delimitation hair types and fruits and seeds morphology are more important than density of hairs, and leaf shape.

The traditional species groups are first delimited through leaf shape, a tricky characteristic for species determination because of the great variation of leaf shape and composition in the same species as well as in a one individual, since composite leaves have probably evolved many times in *Cissus*. Thirteen are recognized, excluding seven uncertain species.

These groups are provisional, and other characteristics such as anatomical and histochemical ones (latex has been observed in the *C. trigona* group) and molecular approaches should be performed to analyze a lot of useful data, contributing to a more solid subgeneric division of *Cissus*, not only in South America but worldwide, with the collaboration of all taxonomists interested in this fascinating family.

11.10.7. Is the genus *Cissus* (Vitaceae) monophyletic? A molecular study of the Australian radiation

M. Rossetto[1], B. Jackes[2];
[1]National Herbarium of NSW, Sydney, Australia, [2]Tropical Plant Sciences, James Cook University, Townsville, Australia.

The *trnL* (UAA) intron and the ITS1 region were sequenced to investigate relationships among the five genera of Vitaceae present in Australia. Mostly congruent results were obtained between separate and combined data sets, with all major clades being shared among trees. All bootstrap consensus trees obtained from single sequences or combined analysis strongly suggest that *Cissus* is polyphyletic, corroborating the morphological inconsistencies reported previously. *Cissus opaca* and *Clematicissus angustissima* consistently group in a clade sister to *C. tweediana* and *Rhoicissus tridentata*. A further four taxa (*C. antarctica*, *C. hypoglauca*, *C. oblonga*, and *C. sterculiifolia*) also grouped within a clade clearly disjunct from the main *Cissus* group. Our results suggest that these five species currently classified as *Cissus* should be segregated from the genus. Of further interest is the close relationship between *Cayratia* / *Tetrastigma* and the lack of support for *Nothocissus* as a separate genus. Overall, the results presented provide new insights into the relationships within a number of Vitaceae genera and suggest directions for future studies.

11.11.1. Comparative population viability and life history of Florida scrub species and implications for fire management and conservation

E. S. Menges;
Archbold Biological Station, Lake Placid, FL, United States.

I integrate information from long-term studies, chronosequences, and experiments into life history and population viability analyses (PVA) of Florida scrub plants, to suggest evolutionarily relevant fire regimes (ERFR). Resprouting shrubs dominate more frequently burned scrub (scrubby flatwoods, hickory scrub) and will probably be resilient to a range of fire return intervals (FRI). For seeders, time to first reproduction, inter-fire demography of adults, and seed banks may constrain FRI. Florida rosemary scrub is dominated by a seeder (*Ceratiola ericoides*), which can be eliminated by frequent fires (< 10 years) or by fire suppression (> 80 years). Because we cannot yet closely specify ERFR based on life history information, PVAs provide more precise recommendations. For two species that grow in oak-hickory scrub, PVA suggests short (6-12 year) FRI. PVAs on two rosemary scrub herbs (*Hypericum cumulicola* and *Eryngium cuneifolium*) suggest frequent fires would promote their persistence. I argue that a moderate amount of pyrodiversity can promote biodiversity while not harming individual species' viability.

11.11.2. Demography of *Oritrophium peruvianum* and impacts of harvesting on its populations in the Venezuelan Andes

T. Ulian[1], M. C. Trevisan[2], R. A. Cheke[1];
[1]Natural Resources Institute, Chatham Maritime, Kent, United Kingdom, [2]Universidad de Los Andes, Merida, Venezuela.

The population dynamics of the medicinal plant *Oritrophium peruvianum* were analyzed using a five stage time-invariant linear matrix model. The growth rates of two populations monitored in the Venezuelan Andes were greater than one (1.32 and 1.13). Growth rates were more sensitive to changes in the survival of individuals than in reproduction. The most significant transition was the survival of small adults whilst large adults contributed little to their growth rates. Different harvesting regimes were simulated by removing different proportions of individuals from selected stage classes. A uniform harvesting of the adult stages each year up to 20-40% could be applied without threatening the population survivals. The harvesting of small adults would affect the growth rates of the populations most, whilst the complete removal of large adults would have the least impact. The optimal sustainable harvesting was calculated by maximising the total yield among different sustainable harvesting policies. The most sustainable practical policy would allow harvesting of all large adults and different proportions of the small and middle-sized plants each year.

11.11.3. Population stage structure as a quick-and-dirty population viability indicator: how dirty is it ?

G. Oostermeijer;
Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands.

In the 1980's Rabotnov published a series of papers on 'coenopopulation structures' of plants. I adopted his way of looking at populations as a method to obtain a relatively good idea of the demographic viability of populations of threatened plants within one censusing season. The basic idea is to examine the stage structure of many (sub)populations and relate them to various aspects of habitat quality, such as vegetation composition and structure and soil variables, and different types of habitat management. For our study species, *Gentiana pneumonanthe, Salvia pratensis, Veronica austriaca* and *Liparis loeselii*, the method has proven very valuable for decisions concerning optimal habitat management, although its limitations also became apparent. In my paper, I will bring together our studies with those published on other species, to investigate whether this quick-and-dirty method of assessing population viability really works and to report on its pros and cons for the practical conservation management of endangered plant species.

11.11.4. Demography of the declining grassland plant *Trifolium montanum* in central Germany: the influence of site productivity

D. Matthies[1], M. Schleuning[2];
[1]Dept. of Biology, Marburg, Germany, [2]Dept. of Biology, Marburg, Germany.

We studied the demography of the long-lived, declining plant *T. montanum* and the structure of its populations in central Germany. Intensive demographic monitoring in nine populations revealed that with increasing nutrient availability at a site the finite growth rate of populations (ə) decreased. The decrease in ə was the result of reduced growth and increased mortality of non-reproductive plants. In a clipping experiment ə increased significantly from 0.91 in unmanaged to 1.13 in managed plots, indicating that the detrimental effects of high nutrient availability were due to increased light competition. The removal of 25% of the vegetation was enough to release light competition and to considerably reduce the mortality of non-reproductive plants. Nutrient availability also influenced the structure of populations. The density of immature plants strongly decreased with increasing productivity in 20 populations of *T. montanum*, indicating reduced recruitment at high productivity sites. Our results suggest that nutrient enrichment is the major cause of the decline of *T. montanum* and that many of the remnant populations are strongly threatened.

11.11.5. On the relationship between longevity and population dynamics: the demographic component of life history evolution in plants

M. B. García[1], **F. X. Picó**[2], J. Ehrlén[3];
[1]Instituto Pirenaico de Ecología CSIC, Zaragoza, Spain, [2]Center for Ecological Research and Forestry Applications (CREAF), Barcelona, Spain, [3]University of Stockholm, Stockholm, Sweden.

Theory predicted the evolution of life histories towards short or long lived life spans through life history trade-offs. The goal of this paper is to reveal that life span and demographic behavior are intricately related, emphasizing the demographic component of life history evolution. To this end, we investigated the relationship between longevity and population growth rate, a surrogate of global fitness. Our study included 24 demographic datasets of herbs using population matrix models. For each dataset of study, we computed longevity, mean and temporal variance in population growth rate, and demographic importance of life history traits (based on elasticity and variance contribution analyses). Results clearly indicate that long-lived plants exhibit more stable and less variable population behavior than short-lived plants. The relative importance of fecundity decreased with increasing longevity whereas that of survivorship showed the opposite pattern. We conclude that longevities are a good predictor of population dynamical trends in plants. Results are presented and discussed on the basis of the evolution of plant life histories.

11.11.6. Competitive effect is a linear function of neighbour biomass in *Kochia scoparia*

J. Weiner[1], D. Ramseier[2];
[1]Royal Veterinary and Agricultural University, Frederiksberg, Denmark, [2]ETH, Zürich, Switzerland.

To investigate the effects of neighbour size on competitive effect, we grew target Kochia scoparia individuals surrounded six equidistant, even-aged, conspecific neighbours. We varied neighbour size by sowing neighbours at different times, and we varied the sowing time for the target plants to generate variation in both neighbour and subject size. We analyzed the growth of focal plants over two time intervals as a function of their own size and the size of their neighbours at the beginning of the interval.

When competition was intense, the relative growth rate of target plants was primarily determined by the size of their neighbours. There was a negative linear relationship between the relative growth rate of target plants over and the biomass of their neighbours at the beginning of the interval. The size of the target plant itself did not make a significant additional contribution to predicating its growth rate.

There was no evidence of size-asymmetric competition. Neighbours larger than the target plant had more of an effect than smaller neighbours, but the per unit effect of neighbour biomass was the same for neighbours larger and those smaller than the target plant.

11.11.7. Effects of multiple herbivores on the population dynamics of a perennial herb

R. Leimu[1], K. Lehtilä[2];
[1]University of Turku, Turku, Finland, [2]Södertörn University College, Huddinge, Sweden.

We present a modelling approach to be used in estimating simultaneously the long-term fitness effects of multiple herbivores on perennial plants. We examined the effects of two specialist herbivores, a pre-dispersal seed predator and a leaf-feeding moth, on the population dynamics and long-term fitness of their shared host plant. We compared the relative roles of seed predation and leaf herbivory in determining plant population dynamics. Demographic data were collected during three years and this data was combined with the effects of natural levels of herbivory. Both seed predation and leaf herbivory reduced population growth of their host plant, but only very high damage levels changed the growth trend of the vigorously growing populations from positive to negative. Seed predation was more important in determining plant population growth than leaf herbivory. Moreover, the impact of leaf herbivory was insignificant in a situation where seed predation intensity was very high.

11.12.1. Leaf canopy as a dynamic system: ecophysiology and optimality in leaf turnover

K. Hikosaka, S. Oikawa, N. Osada, T. Hirose;
Tohoku University, Sendai, Japan.

Leaf canopy is a dynamic system, where leaves are produced and fall with time. We developed a model of leaf turnover in a canopy (Hikosaka 2003 Am Nat). In the model, the rate of leaf production is a function of the canopy photosynthetic rate and leaf loss results from the leaf area that exceeds the optimal leaf area index. The model predicted environmental response of leaf area index and canopy photosynthesis. We further developed a model in which an indivudual has two canopies (e.g. two branches on a tree). When the two canopies are exposed to different light environment from each other, development of the two canopies depended on the degree of physiological integration between the canopies (i.e. reallocation of photosynthates and nitrogen). Using monospecific stands of an annual, we analysed leaf turnover and its environmental dependence. Both light environment in the canopy and nitrogen availability were shown to affect leaf production and shedding (Oikawa et al. 2005 Oecol).

11.12.2. Nitrogen-use efficiency in canopy and understory species in a beech forest

Y. Yasumura, K. Hikosaka, T. Hirose;
Tohoku University, Sendai, Japan.

We studied nitrogen (N) use in coexisting species in a mature beech forest. Leaf-level nitrogen use efficiency (NUE_L), defined as the amount of leaf produced per unit N taken up into leaves, was similar between canopy (*Fagus crenata*) and understory (*Lindera umbellata* and *Magnolia salicifolia*) species. NUE_L was analyzed further as the product of the leaf-level N productivity (NP_L; growth rate per unit leaf N) and the mean residence time of leaf N (MRT_L). Plants with higher NP_L can produce biomass more rapidly, while those with longer MRT_L can use the same N for a longer period. NP_L was significantly higher in the canopy species owing to higher irradiance. MRT_L, on the other hand, was significantly shorter in the canopy species mainly because wind removed a larger portion of green leaf before leaf N could be salvaged during autumnal senescence. We conclude that the canopy and understory species had similar NUE_L but through different mechanisms. This study also highlighted the importance of environmental incidents (e.g. wind) in determining plant performances in natural stands.

11.12.3. Foliage traits that determine the efficiency of light capture in mountain birch

P. J. Kaitaniemi;
Hyytiälä Forestry Field Station, University of Helsinki, Korkeakoski, Finland.

Structure, size and number of leaves per shoot can be variable within plant species. These traits participate in light capture together with the spatial arrangement of shoots. The amount of variation in leaf traits and 3D plant architecture in a mountain birch (*Betula pubescens* ssp. *czerepanovii*) population was measured and utilized in computer simulations to identify leaf traits that determine the efficiency of light capture and photosynthesis. Photosynthetic nitrogen use efficiency (PNUE) was estimated as the potential rate of photosynthesis (P_{max}) per nitrogen lost at leaf senescence. Shoot-specific PNUE followed an U-shape curve with respect to leaf weight per area ratio (LWA) that estimated nitrogen allocation. Small leaf area per shoot and low LWA was an efficient combination, and also observed in real trees. Small leaves and high LWA was another efficient combination, but not observed. High LWA was associated with large leaves of old stems where the nitrogen cost of leaf production increased without an adequate return in P_{max}. This resulted in decrease of PNUE despite higher P_{max}. Especially young mountain birch trees are sparing in their use of nitrogen.

11.12.4. Modeling light capture and carbon gain in tropical shrub seedlings: correlations with growth in different light environments

F. Valladares;
Centro de Ciencias Medioambientales CSIC, Madrid, Spain.

Realistic 3-D reconstruction of plant crowns has led to accurate predictions of light capture and carbon gain, but explorations of how these predictions relate to plant performance remain scant. Seedlings of 15 *Psychotria* species that co-occur in a lowland tropical forest in Panama were grown in low, intermediate and high light. 3-5 plants per treatment and species were measured 4-8 times throughout their development during their first 1- 1.5 year. Crown architecture was reconstructed with the computer model Yplant, leaf photosynthesis was measured following standard protocols and above ground relative growth rate (aRGR) was calculated from sequential biomass estimates. Light absorption efficiency was inversely related to self-shading and directly related to whole plant daily carbon gain (DCG). DCG as estimated by Yplant was a good predictor of aRGR in the intermediate and low light environments, but not in the high light environment where stress effects overrode any significant relationship. Gap and understory species overlapped in most measures though there was a tendency for gap plants to segregate out to higher carbon gains and aRGR.

11.12.5. Leaf and shoot biomechanics and light interception efficiency in temperate trees

Ü. Niinemets;
Department of Plant Physiology, University of Tartu, Tartu, Estonia.

Intercepted irradiance per unit dry mass (light harvesting efficiency) widely differs among the leaves and shoots of varying architecture. This partly reflects the inherent trade offs between the high investment of photosynthetic resources per unit leaf or shoot surface area, and enhanced exposure of chlorophyll within the laves and leaves within the shoots. While the first strategy improves the whole leaf and shoot photosynthetic potentials at high light, the second alleviates light limitations in low irradiance. Apart from the adaptational variation in light harvesting efficiency with the total amount of light, biomechanical characteristics of foliage significantly alter the light harvesting efficiency of the foliage. In particular, leaves of varying size and shape require different fractional biomass investments in self-support to avoid self-shading and keeping leaves in positions maximizing irradiance capture. Apart from penumbra, variations in leaf size and shape are thought to affect plant light harvesting only to a minor extent. Due to different biomechanical costs, these species-specific features strongly alter light capture efficiency.

11.12.6. Biomass allocation and light capture in a very successional tropical forest stand

N. P. R. Anten, G. Selaya, J. J. C. Netten, R. J. Oomen, M. Matthies;
Department of Plant Ecology, Utrecht, The Netherlands.

We analyzed a 1 y/o secondary forest stand that contained a number of short- and long-lived pioneer species. It was hypothesized that at this stage, where plants from the two groups did not differ much in size, short-lived pioneers use their biomass more efficiently to grow tall and capture light giving them a competitive advantage. With a canopy model we evaluated interspecific differences in stem characteristics, leaf display and biomass allocation in terms whole plant light capture. Short-lived pioneers were indeed somewhat taller for a given amount of mass than long-lived pioneers. This was because they invested relatively more mass in their stem, and because they had lighter wood. Short-lived pioneers had lower leaf mass- and leaf area ratios. They captured more light in absolute terms and per unit leaf area or leaf mass. However they did not capture more light per unit total mass, which contradicted our hypothesis. Physiological characteristics enabling a high light-use efficiency might be more important in giving short-lived pioneers a competitive advantage than morphological traits that allow for a high light capture per unit mass.

11.12.7. Towards a mechanistic explanation of a steady state in growing trees

F. J. Sterck[1], F. Schieving[2];
[1]Forest Ecology and Management Group, Wageningen, The Netherlands, [2]Plant Sciences, Utrecht, The Netherlands.

When a tree ceases to grow in height, it continues to grow in stem diameter and may reproduce for decennia or even centuries. These observations suggest that adult trees have a constant amount of living biomass, and ‘simply’ replace leaves, flowers and fruits in the crown, and sapwood in the stem. What mechanisms contribute to the switch from vegetative expansion to reproductive steady state? And why do different tree species reach such a steady state at different heights and in different light environments? Using a new functional-structural plant growth model, we first show how the effects of tree size and shading (by surrounding forest and tree-crown) on the carbon economy and meristem responses result in a growing 3D-structure such as a tree. In reply to our questions, we show how inter-specific differences in meristem responses and leaf and sapwood turnover rates contribute to a steady state in tree species that grow to different adult sizes, and come to a steady state in different forest light environments.

11.13.1. Solar UV-B radiation, plants and terrestrial ecosystems

M. M. Caldwell[1,2];
[1]National Science Foundation, Washington, DC, United States, [2]Utah State University, Logan, UT, United States.

Stratospheric ozone reduction has been the impetus for understanding how solar UV-B (280-320 nm) radiation affects plants from gene regulation to ecosystem-level ramifications. Depending on the environmental history of the plant and wavelength composition, solar UV-B can be damaging. But, usually repair and mitigation are effective in curtailing appreciable inhibition. Solar UV-B can also regulate many plant processes such as altered growth allocation and secondary chemistry. These, in turn, can be manifested at different tropic levels such as altered herbivory, decomposition of plant litter, and plant competition. Changes in soil microbial activity, peatland microfaunal and fungal biodiversity have also been attributed to UV-B effects mediated through the higher plants. Direct UV-B effects on fungal communities exposed to sunlight on litter and leaf surfaces also have been reported. Finally, some plant and ecosystem effects appear to be the result of abiotic UV-B photochemical effects on litter and the lower atmosphere. In order for all of these effects to be relevant to ozone layer reduction, the UV responses must have specific spectral properties.

11.13.2. UV-B induced responses of plants at the molecular level: What we know and what we need to know

B. R. Jordan;
Agriculture & Life Sciences Division, PO Box 84, Lincoln University, Canterbury, New Zealand.

Molecular events underlying plant responses to UV-B radiation are beginning to be understood. UV-B clearly impacts at the level of the transcriptome. This modification of gene activity is not merely a consequence of DNA damage/repair, but is modulated through specific signal transduction pathways. This signal transduction mechanism is now the focus of substantial research: looking for the UV-B photoreceptor(s), identifying signal transduction components and investigating the interaction with the plant genome. Understanding these complex networks will provide valuable insights to a variety of UV-B responses including plant defence mechanisms, species variation and interaction with other environmental stress factors. With the application of modern tools of molecular biology such as DNA-chip technology, new insights are being gained. In this brief presentation, I will review our understanding of UV-B responses at the molecular level and identify areas for future exploration.

11.13.3. Plant morphological responses to UV-B: mechanisms and ecological consequences

P. W. Barnes[1], J. R. Shinkle[2], S. D. Flint[3], R. J. Ryel[3];
[1]Loyola University New Orleans, New Orleans, LA, United States, [2]Trinity University, San Antonio, TX, United States, [3]Utah State University, Logan, UT, United States.

Exposure to ultraviolet-B radiation (UV-B; 280-320 nm) at ambient or enhanced levels can result in a wide variety of morphological alterations in higher plants, but the mechanisms and ecological significance of these changes remain poorly understood. Results from laboratory studies indicate that certain morphological responses to UV-B (stem elongation) involve multiple sensory systems. In dim-red light grown and white-light grown seedlings of cucumber, short-term exposure to full-spectrum UV-B (280-320 nm) and long wavelength UV-B (300-320 nm) both induced inhibition in hypocotyl elongation but treatments differed in the timing and duration of the responses, dose responses, reciprocity adherence, and association with DNA damage/repair. Results from multi-species canopy simulations indicate that subtle changes in shoot morphology can lead to large shifts in interspecific light capture, and more so for mixtures of broad-leaved than narrow-leaved species. Alterations in the ratios of UV-B:UV-A:PAR occur within canopies and these spectral changes have the potential to modify the effects of UV-B on shoot morphology and competitive interactions.

11.13.4. Sensitivity of pasture plants to UV-B radiation and interaction with drought

R. W. Hofmann[1], B. D. Campbell[1], D. W. Fountain[2];
[1]AgResearch, Palmerston North, New Zealand, [2]Massey University, Palmerston North, New Zealand.

During summer, high levels of ultraviolet-B (UV-B) radiation frequently coincide with periods of drought in New Zealand. White clover (*Trifolium repens* L.) is the key legume component of pasture ecosystems in New Zealand, where it usually grows in association with perennial ryegrass (*Lolium perenne* L.). We sought to evaluate responses to UV-B radiation and drought in white clover plants grown separately or together with ryegrass in a sward. Our results revealed significant interactions between the two stress forms, suggesting ameliorating effects of the UV-B × drought combination for white clover growth. Results in white clover leaves showed marked increases of flavonoid levels, particularly quercetin glycosides, in response to UV-B and drought. Furthermore, our findings link accumulation of quercetin glycosides to UV-B protection. We are currently using comprehensive metabolite analysis (metabolomics) to identify other key plant compounds that can be used for the development of stress-resistant forage cultivars.

11.13.5. Ambient UV radiation levels negatively affect the endemic Antarctic moss, *Grimmia antarctici*.

S. A. Robinson[1], J. D. Turnbull[1], C. E. Lovelock[2];
[1]Institute for Conservation Biology, University of Wollongong, Wollongong, NSW, Australia, [2]Centre for Marine Studies, University of Queensland, St Lucia, QLD 4072, Australia.

Over recent decades, Antarctic plants have been exposed to the largest relative increase in UV-B exposure as a result of ozone depletion. Open-sided plexiglass screens were used to reduce UV levels by 77% over turves of the endemic Antarctic bryophyte, *Grimmia antarctici,* and the effect on pigment concentrations, surface reflectance and physiological and morphological parameters was investigated over 14 months. *G. antarctici* was affected negatively by ambient levels of UV radiation. Chlorophyll content was significantly lower in plants grown under near ambient UV, whilst the relative proportions of photoprotective carotenoids, especially ß-carotene and zeaxanthin, increased. No evidence for accumulation of UV-B absorbing pigments in response to UV radiation was observed. Although photosynthetic rates were not affected, there was evidence of UV effects on morphology. Given that other Antarctic bryophytes possess UV-B absorbing pigments that should offer better protection under ambient UV-B radiation, these findings suggest that *G. antarctici* may be disadvantaged under a climate with continuing high levels of springtime UV-B radiation.

11.13.6. Effects of supplemental UV-B radiation on photochemical activity, photosynthetic pigments and UV-B-absorbing compounds in two oak species

I. Mészáros[1], R. Láposi[1], S. Veres[1], É. Sárvári[2], E. Bai[1], A. Gáspár[1], V. Oláh[1], G. Lakatos[1];
[1]Debrecen University, Debrecen, Hungary, [2]Eötvös Lóránd University, Budapest, Hungary.

The aim of this work was to compare the photosynthetic responses of two tree species (*Quercus petraea*, *Quercus robur*) and to determine the leaf level protection under enhanced UV-radiation in outdoor experiments. Three-year seedlings of both species were exposed to enhanced UV-B radiation (40 % of the ambient level) from bud-break until leaf senescence. Under enhanced UV-B, increases of specific leaf mass (SLM) and reduction of leaf chlorophyll content were observed but the total carotenoid content remained high. Both oak species responded with an increase of the VAZ pool to enhanced UVB. High values of potential photochemical efficiency (Fv/Fm) were maintained in both species during the vegetation season. On clear days, loss of Fv/Fm was observed from morning till midday which was larger under enhanced UV-B for both species, suggesting that UV-B exposure enhanced the sensitivity of seedlings to photoinhibition. Enhanced UV-B increased the amount of UV-B absorbing compounds in leaves of *Q. robur*, but it only slightly affected these levels in leaves of *Q. petraea*.

11.13.7. Impacts of ambient solar UV (280-400 nm) radiation on three tropical legumes

M. Jayakumar[1], P. Amudha[2], G. Kulandaivelu[2];
[1]VHNSN College, Virudhunagar, India, [2]Madurai Kamaraj University, Madurai, India.

Tropical regions currently receive the highest level of global solar ultraviolet (UV) radiation, especially UV-B (280-320 nm). The high level of solar UV-B radiation reaching the earth's surface is an important environmental concern. The average daily dose of UV-B radiation in Madurai, South India (10^{o} N) is 10 KJ m^{-2}. This is approximately 50% more than the average daily UV-B radiation in many European countries. A field study was conducted using selective filters. Either the UV-B (< 320 nm) or UV-B & A (<400 nm) portions of the solar spectrum was removed and the effects were followed in *Cyamopsis tetragonoloba, Vigna mungo* and *Vigna radiata*. When compared to ambient radiation, exclusion of solar UV-B increased seedling height, leaf area, fresh weight and dry weight, and the crop yield by 50% in *Cyamopsis tetragonoloba*. The extent of this increase was slightly less under UV-B & A exclusion. In *Vigna mungo* a significant reduction was seen in solar UV excluded plants, while *Vigna radiata* was found to be unaffected.

11.14.1. Biosynthesis of indole and benzoxazinones in Zea mays

A. Gierl;
Lehrstuhl für Genetik, Technische Universität München, Freising, Germany.

Plant secondary metabolites constitute a large field of chemical biodiversity that is important for the survival strategies of plants. A secondary metabolic pathway can be defined by the branchpoint from primary metabolism and the downstream reactions that lead to end product formation. Evolution has generated specific enzymes that catalyse these reactions. The formation of indole branches off from tryptophan biosynthesis and is catalysed by enzymes resembling tryptophan synthase alpha subunits. In maize, indole can either function as volatile signal for communication with insects or be converted into benzoxazinoids by at least eight specific enzymes. Benzoxozinoids function as general plant defence chemicals. Gene duplication was essential for the evolution of the genes encoding these pathways. The examples show that gene duplication does not necessarily result in redundancy, rather it is a prerequisite for the generation of biodiversity.

11.14.2. Gene structures and functional diversification of enzymes of secondary metabolism in *Lotus japonicus*

S. Ayabe[1], N. Shimada[1], S. Sawai[1], T. Aoki[1], S. Sato[2], Y. Nakamura[2], T. Kaneko[2], S. Tabata[2];
[1]Nihon University, Fujisawa, Kanagawa, Japan, [2]Kazusa DNA Research Institute, Kisarazu, Chiba, Japan.

Leguminous plants have a diverse array of secondary metabolites with eco-physiological functions. To gain insights into their molecular evolution, we analyzed the gene structures in a model legume, *Lotus japonicus*, and catalytic activities of enzymes of legume-specific and general (iso)flavonoid pathway and oxidosqualene cyclases (OSCs) constructing triterpenoid skeletons. A total of four and five genes of chalcone polyketide reductase in the 5-deoxy(iso)flavonoid biosynthesis and dihydroflavonol reductase (DFR) involved in anthocyanin/condensed tannin pathway, respectively, constituted tandem clusters. Functional diversity of DFR isozymes was correlated to an amino acid variation in a region reported to control the substrate preferences. Three chalcone isomerases (CHIs) producing 5-deoxyflavonoids and one general CHI were also present as a tandem gene cluster. Eight OSCs compose two sets of gene clusters, and exon length polymorphism was found to be responsible for the product variations. Local gene duplication and specific mutation of the genes were thus indicated to be critical in the diversification of secondary metabolism.

11.14.3. Pinoresinol-lariciresinol reductases with different stereoselectivity

C. von Heimendahl, M. Treml, **E. Fuss**;
Institut für Entwicklungs- und Molekularbiologie der Pflanzen, Düsseldorf, Germany.

Pinoresinol-lariciresinol reductases (PLRs) which are involved in lignan biosynthesis form together with phenylcoumaran benzylic ether reductases (PCBERs) and isoflavone reductases (IFRs) an evolutionary strongly related group of reductases [Gang et al. (1999) JBC 274, 7516-7527]. Whereas PLRs and IFRs work enantiospecifically PCBERs do not. We could isolate DNA sequences encoding PLRs from lignan accumulating suspension cultures from *Linum album* and *L. usitatissimum*. The proteins which were heterologously expressed in *E. coli* show opposite enantiospecificity with respect to the substrate pinoresinol and the product secoisolariciresinol. Mutants of the PLR from *L. album* which are generated by site-directed mutagenesis and expressed in *E. coli* are under investigation to figure out the molecular reasons for the opposite enantiospecificity. Furthermore, we could isolate two sequences encoding PLRs beside six further sequences probably encoding PCBERs from *Arabidopsis thaliana*. Data about the activity of the heterologously expressed proteins will be presented.

11.14.4. Divergent evolution in the flavonoid dioxygenase family

S. Martens, Y. Gebhardt, S. Witte, U. Matern;
Institut für Pharmazeutische Biologie, Marburg/Lahn, Germany.

Plants classified to the Apiaceen family are known to accumulate various flavonoids belonging to distinct subclasses. Four 2-oxoglutarate dependent dioxygenases, flavone synthase I, flavanone 3ß-hydroxylase, flavonol synthase and anthocyanidin synthase, are involved in the biosynthesis of these secondary metabolites. We have cloned genes encoding putative dioxygenases from several plants of Apiaceen family. The unique occurrence of flavone synthase I in this family and the high sequence similarity towards flavanone 3ß-hydroxylase is of special interest in evolutionary context. Functional identification of cDNAs from Ammi majus, Anethum graveolens, Apium graveolens, Pimpinella anisum, Conium maculatum and Daucus carota coding for either flavone synthase I or flavanone 3ß-hydroxylase, followed by molecular and phylogenetic analysis of the obtained sequence data, were performed to extend our knowledge of Apiaceae 2-oxoglutarate-dependent dioxygenases. After analysis of the data we postulate that FNS I results from a gene duplication of FHT and functional diversification during evolution.

11.14.5. Molecular cloning and expression of progesterone 5ɓ-reductase from *Digitalis lanata* Erh.

V. Herl, G. Fischer, F. Müller-Uri, W. Kreis;
LS Pharmazeutische Biologie, Erlangen, Germany.

Digitalis lanata Ehrh. is an important medicinal plant. Cardiac glycosides isolated thereof are used in the treatment of cardiac insufficiency in man. *Digitalis* glycosides are mainly synthesized and accumulated in the rosette leaves. Although their biosynthesis has been studied extensively, molecular biology approaches have only be tried for few cardenolide biosynthesis specific enzymes and their corresponding genes. We have isolated a cDNA clone from *Digitalis lanata* leaves that encodes a progesterone 5ɓ-reductase (5ɓ-POR). 5ɓ-POR catalyses the conversion of progesterone to 5ɓ-pregnane-3,20-dione, a putative precursor of all 5ɓ-configured cardenolides. Over-expression of the protein was achieved in *E. coli* using the pQE expression vector system. The purified recombinant protein showed 5ɓ-POR activity. Meanwhile, 5ɓ-POR cDNA clones have been isolated from 9 *Digitalis* species, and it was demonstrated that this gene is highly conserved within the genus. 5ɓ-POR cDNAs were also isolated from 4 *Isoplexis* species, and our data support the opinion that *Isoplexis* and *Digitalis* should be combined into one genus. Evolutionary aspects will be discussed.

11.14.6. A possible evolutionary link between camalexin from *Arabidopsis* and a topoisomerase-inhibitor from Streptomyces

R. Schuhegger, A. Grabrucker, E. Glawischnig;
Lehrstuhl für Genetik, Freising, Germany.

The evolution of secondary metabolites of similar chemical structure in distantly related organisms is poorly understood. 3-Thiazol-2'-yl-indole (camalexin) is the major phytoalexin of Arabidopsis. Camalexin biosynthesis involves the cytochrome P450 genes CYP79B2 and CYP71B15, which are temporally and spatially induced after pathogen challenge. A biologically active derivative of camalexin (BE 10988) is synthesized by a Streptomyces strain. We investigate whether the biosynthesis of this derivative shares common intermediates of camalexin biosynthesis and also involves cytochrome P450s, which are mechanistically comparable to the corresponding plant enzymes. In Streptomyces, cystein conjugation is most likely catalyzed by a non-ribosomal peptide synthase, which is a target to isolate BE 10988 biosynthetic genes. As cystein is universally present, conjugation of secondary metabolites with cystein could involve enzymatic domains conserved between plants and bacteria.

11.14.7. Microevolution of toxin synthesis in cyanobacteria

R. Kurmayer[1], G. Christiansen[2], J. Fastner[3], T. Börner[4];
[1]Austrian Academy of Sciences, Institute for Limnology, Mondsee, Austria, [2]University of Hawaii at Manoa, Honolulu, HI, United States, [3]Federal Environmental Agency, Berlin, Germany, [4]Humboldt University, Institute for Biology, Berlin, Germany.

Cyanobacteria do occur frequently in surface water and contain a high diversity of bioactive compounds. Typically isolates of the same species differ in composition of bioactive peptides but cannot be discriminated in the microscope nor by traditional taxonomic markers (i.e. 16S rDNA). Those peptides are formed by modular multienzymes which belong to the largest enzymes inside the cell. The ecological mechanisms affecting existing pathways of secondary metabolite synthesis are not understood. We have identified DNA rearrangements and mutations within gene regions (mcy) involved in the synthesis of the toxic peptide microcystin (MC) which are either linked to specific structural variants differing in bioactivity or complete inactivation of the total mcy gene cluster (55 kb). Inactive mcy genotypes have been found in relatively high numbers in lakes. Insertions found within the inactive mcy gene cluster contained conserved domains assigned to transposable elements. New structural variants specific to populations have been found. It is speculated that transposable elements can explain the abundance of mcy mutants and DNA rearrangements in our lakes.

11.15.1. The effects of tree species diversity on nutrient cycling and ecosystem productivity

J. Bauhus[1], P. K. Khanna[1], D. I. Forrester[2];
[1]Institute of Silviculture, Freiburg University, Freiburg, Germany,
[2]School of Forest and Ecosystem Science, University of Melbourne, Melbourne, Australia.

Tree species have different growth efficiencies and capacities to acquire and recycle nutrients resulting in specific productivities and effects on the nutrient cycle. Mixing species may simply create a patchwork pattern of these specific effects, or it can result in synergistic or antagonistic effects between species. This review focuses on the latter: mechanisms responsible for changes in forest productivity that result from the interactions of tree species in mixed stands. In particular, we will focus on competition, facilitation and competitive reduction, and the species attributes and processes that produce these interactions. The effects of species mixtures on nutrient acquisition, cycling and losses will be reviewed, and the relative importance of diversity on the one side and specific species attributes on the other side examined. In addition, experimental approaches and methods that can be employed to investigate the effects of increasing tree diversity will be discussed.

11.15.2. Spatial heterogeneity of abiotic parameters in Kakamega Forest: a process that preserves tree diversity

H. Todt[1,2], M. Oesker[1,2], D. Uster[2], R. Gliniars[1], W. Musila[1], H. Dalitz[1];
[1]University of Hohenheim, Stuttgart, Germany, [2]University of Bielefeld, Bielefeld, Germany.

Canopy structure defines abiotic parameters such as light, water, and nutrient distribution in the understorey. These parameters characterize the niches for the seedling survival and establishment. If a highly divers forest specifies more different niches than a less divers forest, more species should be able to establish the highly divers forest and thus the diversity preserves itself. Amount and variability of throughfall and its chemical properties were measured since September 2001 on a grid based design in 9 plots with 9 rain collectors each. Tree species composition was evaluated. Hemispherical images were taken to describe the canopy structure with parameters such as canopy openness, LAI, and radiation. Spatial heterogeneity of rainfall exists on and between all plots with different values of heterogeneity in the plots triplets and different amounts of throughfall precipitation. The variance of the precipitation of the plots is compared with the total variance of precipitation and with vegetation structure characteristics such as light values and tree diversity.

11.15.3. Woody invasive species increase nutrient cycling in the granitic Seychelles

C. Kueffer, G. Klingler, K. Zirfass, E. Schumacher, S. Güsewell, P. J. Edwards;
Geobotanical Institute, Zürich, Switzerland.

Invasive plant species tend to have larger specific leaf area (SLA) and higher nutrient concentrations compared to native species. These properties may lead to faster litter decomposition and increased soil nutrient availability. To test for such impacts, we compared leaf litter properties and decomposition rates of 6 native and 6 invasive woody species in forests of the granitic Seychelles. Litter bags were incubated in the field and in the greenhouse. Nutrient availability in soil was determined under stands of two invasive (one N-fixing) and one native species. Tree seedlings were grown in pots with these soils to assess soil fertility and nutrient limitation. As hypothesised, litter of invasive species had higher SLA and nutrient content than native litter and decomposed faster. We found indication of elevated viz. reduced (N-fixing species) available P in soils under invasive species. The phytometer experiment suggested that seedling growth in these soils is P-limited, and that P-limitation is alleviated under one invasive species. This may cause a positive feedback since invasive woody species in the Seychelles thrive best on nutrient-rich soils.

11.15.4. Different pollination efficiency and outcrossing by birds and bees in *Metrosideros excelsa* (Myrtaceae)

G. H. J. Schmidt-Adam[1], B. G. Murray[2], A. Young[3];
[1]Massey University, Auckland, New Zealand, [2]University of Auckland, Auckland, New Zealand, [3]CSIRO Plant Industry, Canberra, Australia.

Loss or modification of native pollinator guilds can have profound effects on plant reproductive output. Exclusion experiments were used to assess the effect of birds and bees on seed production and outcrossing in *Metrosideros excelsa,* a New Zealand tree species that has lost several indigenous bird pollinators on the mainland. Native birds are more important pollinators of *M.excelsa* than native bees. On Little Barrier Island, an island off the mainland with an original contingent of indigenous birds and bees, the number of fertile seeds per capsule was 48% higher after open pollination than in treatments with bee visitation only and 34% higher than treatments allowing autonomous self-pollination only. Estimated outcrossing rates were higher (t_m = 0.71) for open pollination in the upper canopy than for the treatment with bee access only (t_m = 0.40). In a modified mainland population with predominantly introduced birds and bees, seed production for all treatments was higher than on Little Barrier Island, indicating that introduced flower visitors and autonomous self-pollination are now important for seed production in *M. excelsa* on the New Zealand mainland.

11.15.5. Effects of tree stand diversity on insect herbivory: results from several long-term experiments in boreal and temeperate forests

J. Koricheva[1], H. Vehvilainen[2], J. Riihimaki[2];
[1]Royal Holloway, University of London, Egham, United Kingdom,
[2]Section of Ecology, University of Turku, Turku, Finland.

We examined the effects of tree stand diversity on insect herbivory in several long-term experiments in Finland, Sweden and England where tree species diversity of stands has been manipulated. In the Finnish experiments, insect herbivory on silver birch was higher in birch monocultures than in birch mixtures with Scots pine, but only at the beginning of the season and only in mixtures which contained 75% of pine. No effects of stand diversity were found on insect herbivory on silver birch growing in monocultures or in mixtures with Scots pine and Norway spruce in the Swedish experiment. In the second rotation of the Gisburn forest diversity experiment (NW England), insect herbivory on sessile oak and black alder was lowest in monocultures and particularly high in oak-alder mixtures. We conclude that the effects of forest stand species diversity on insect herbivores vary from positive to negative depending on the type of herbivores present, the identity of tree species constituting a mixture, time of the season and geographic locality. In other words, forest diversification does not provide a universal remedy for insect pest problems.

11.15.6. A global network of biodiversity experiments in forests

M. Scherer-Lorenzen;
Swiss Federal Institute of Technology Zurich (ETH), Zurich, Switzerland.

During the last five years, several attempts have been made to establish large-scale and long-term experiments designed to examine the effects of enhancing tree diversity in plantation forests on ecosystem functioning and to identify underlying mechanisms. These projects are based in Germany, Finland, Panama and Borneo. Each of these experiments comprises an experimental diversity gradient of large plots planted with different numbers and types of tree species. The presentation will give overviews of the experimental designs and of the first results, focusing on the BIOTREE (BIOdiversity and ecosystem processes in experimental TREE stands) experiment in Germany. In that project, 81 plots covering more than 80ha were afforested with trees of varying species richness and functional diversity on three different sites. In total, 250.000 saplings have been planted. Several ecosystem processes will be monitored regularly, with an emphasis on tree growth, carbon sequestration, and nutrient cycling.

11.16.1. Application of Bioindication and Biomonitoring as Innovative Biotechniques for Pollution Control Measurements

B. Markert, S. Wuenschmann, S. Fraenzle;
International Graduate School, Zittau, Germany.

Bioindicators reflect organisms (or parts of organisms or communities of organisms) that contain information on quality of the environment. When data and information obtained by bioindication are moved up to the level of knowledge the subjectivity of interpretation increases with the complexity and dynamics of a system ("staircase of knowing"). From there a comparison of instrumental measurements with the use of bioindicators/biomonitors with respect to harmonisation and quality control will be drawn. Precision, accuracy, calibration and harmonisation in between national standards and international routines seem to be the leading goals in quality studies of international working groups dealing with biomonitoring throughout the world. The newly developed Multi-Markered-Bioindicator-Concept (MMBC) will fill the gap in between human health aspects or environmental protection purposes. Markert, BA., Breure, AM. and Zechmeister, HG (eds.) (2003) Bioindicators & Biomonitors. Principles, Concepts and Applications. Elsevier, Amsterdam, pp. 998.

11.16.2. Monitoring the effects of air pollution and nitrogen deposition by the diversity of epiphytic lichens and correlation with the incidence of respiratory cancer mortality in central Italy

S. Loppi;
University of Siena, Siena, Italy.

In field monitoring studies, it is very difficult to separate the effects of many intercorrelated variables, and the interpretation of lichen biomonitoring surveys in terms of air pollution is open to some controversy. It is well known that lichens are sensitive to air pollution, however, other ecological variables such as climate and substratum also induce variations in the frequencies of lichen species. As a consequence, it is not always easy to discriminate between the effects of pollution and those of other environmental changes. Now that SO_2 is no longer the dominant air pollutant, the total lichen diversity seems to have lost its predictive value for air pollution, and when using the diversity of epiphytic lichens for monitoring environmental pollution, the interpretation of the results could consist of several maps, each of which based on different groups of species, and each of which interpreted in a different way. Several examples from central Italy will be given to show all these situations, including correlations of lichen diversity counts using reduced datasets of selected species with the incidence of respiratory cancer mortality.

11.16.3. Stress effects of NH+4 deposition in *Thymus pulegioides* L. using a biomarker pattern of amino acids as indicator

A. Jalba[1,2], H. Weber Ravn[2], H. Lokke[2];
[1]Universite Libre de Bruxelles, Bruxelles, Belgium, [2]National Environmental Research Institute, Silkeborg, Denmark.

A 24 days experiment on *Thymus pulegioides* L. species was performed, simulating NH^+_4 deposition and soil eutrophication. The aqueous solution of urea was used as NH^+_4 source, in serial concentrations of 6,5 g/L, 13 g/L, and 26 g/L, added at once in the soil. Thin Layer Chromatography and High Performant Planar Chromatography methods were used in order to assess the sensitivity and stability of phytochemical changes (biomarker pattern) following the exposure. The content of glutamine, serine, alanine, valine and isoleucine showed positive correlation with the urea concentrations applied. The correlation time span from exposure/ amino acid content showed different behaviors depending on each amino acid. The biomarker pattern was correlated to the morphological and ecophysiological changes exhibited by plants. A stimulation of plant growth was observed at the highest exposure concentration, but the biomarker pattern appeared very strong even for the lowest exposure concentration, when no visual signs were detectable. The possible use of biomarker pattern method as an “early warning system” related to the NH^+_4, NH_3 or other forms of N deposition is discussed.

11.16.4. Botany and public health - worth of plant species richness to human health

A. K. F. Malsch, C. Hornberg;
University of Bielefeld, Bielefeld, Germany.

Environmental (public) health matters ranges from environmental medicine (comprises human toxicology and environmental epidemiology) to holistic approaches in human ecology. All research areas increasingly support preventive strategies and health promotion, since globalisation uncovers the dependency of human health from ecosystem health and in particular from plant species richness. Plants provide many important ecosystem-services: 1) utility services (indicators, food, clothes, pharmaceutics, oxygen e.g.), 2) protection services (flood and erosion control, buffer function e.g.) and 3) recreation services (active or passive relaxation in “green” nature). Sustainable ecosystem management is pre-condition for human health protection and promotion. This holds true especially in urban areas where natural recreation areas are most important from ecological and public health perspective. There are manifold interdisciplinary research interfaces between ecology and public health waiting to be tackled.

11.16.5. Marine macroalgae as indicators of metal contamination in seawater: active and passive biomonitoring, metal uptake and chlorophyll fluorescence approaches

D. B. Stengel, L. Morrison, H. Baumann;
Dept. of Botany, Martin Ryan Institute and Environmental Change Institute, National University of Ireland, Galway, Ireland.

Traditionally representatives of the Phaeophyta, Chlorophyta and Rhodophyta have been used as biomonitors for marine metal contamination, even though metal concentration factors differed greatly between different species. In addition, it is now accepted that metal accumulation is influenced by species-specific and seasonal growth patterns, biochemical composition (e.g. phenol and polysaccharide contents and composition), as well as ambient environmental conditions affecting metal bioavailability. To evaluate the potential of marine macroalgae as both sensitive and reliable biosensors for metal contamination in seawater, different species were applied as passive biomonitors (analysis of metals in algae from different locations, different thallus parts and different species within sites) and active biomonitors using transplantation techniques. Metal uptake properties of different macroalgae were compared under different temperature and salinity regimes. In vivo chlorophyll fluorescence (PAM-2000, Walz, Germany) was used to quantify metal toxicity of different species during and after exposure to metals at different concentrations.

11.16.6. Phytotoxicity tests to be used in ecological risk assessment of heavy metal polluted soils

P. Cesaro, **A. Volante**, N. Massa, E. Bona, G. Lingua, G. Berta;
Università del Piemonte Orientale "A. Avogadro", Alessandria, Italy.

Plants respond to metal toxicity by eliciting a number of bio-marker endpoints that can be detected at various levels of organization, ranging from gross morphology to organ, cellular and molecular levels. We analysed the effects of the soil of two industrial sites situated in the provinces of Alessandria and Savona (Italy) on *Pisum sativum* plants. In addition to the conventional germination tests and root growth analyses, we calculated the percentages of dividing mitotic cells (mitotic index), of the mitotic phases in the root apices, and of the mitotic anomalies. DNA loss and damage were evaluated by flow cytometry and comet assay, respectively. Lower mitotic indices, an increase of the percentages of prophases and mitotic anomalies (as sticky or broken chromosomes, and bridges in anaphases) were found. DNA loss was also detected in treated plants and comet tests were strongly positive, suggesting DNA damages. All together, our results showed a high level of toxic substances in the soil and suggest the use of the described biotests (highly sensitive) in evaluating soil pollution.

11.16.7. Metadata and classification and regression trees on accumulation of metals in mosses

W. Schröder, R. Pesch;
Institute for Environmental Science, Vechta, Germany.

The UNECE Metals in Mosses Surveys provide exposure data for ecotoxicological risk assessments by measuring the accumulation of metals. Measurement data and metadata from the German Surveys 1990, 1995 and 2000 are analysed with regard to the following hypotheses: 1. The metal accumulation in mosses is correlated with the distance of the sampling sites to emission sources. 2. The metal loads are correlated with the distance between the sampling points and trees because of canopy drip effects. 3. Topographical features like inclination, exposition and altitude cause spatial variability of the accumulation. 4. Moss species accumulate metals specifically. 5. The accumulation varies with ecoregions. The metadata describe the measurement sites with respect to some of those surrounding environmental conditions that could be relevant for the spatial variances of the metal accumulation in mosses. The statistical design to investigate these hypotheses includes GIS-techniques, contingency tables and correlation analysis, geostatistics as well as Classification and Regression Trees (CART). CART is used for a multivariate typology of the metal accumulation.

11.17.1. Invasive alien plant species and biodiversity changes: a local perspective.

B. E. Tokarska-Guzik, **B. M. Wegrzynek**, A. Urbisz, T. Nowak, A. Urbisz;
University of Silesia, Katowice, Poland.

The aim of the study is to describe the impact of invasive plant species on the native flora and vegetation with respect to particular phytogeographical region of Poland. The researched area was the Silesian Upland (southern Poland) which is considered significantly species rich and diverse. At the same time it is still perceived both in Poland and Europe as an ecological disaster area with a strongly distorted and modified natural environment. The current flora of the Silesian Upland has been investigated by using the method of mapping of all the species on a grid of equal basic fields: squares with a side of 2 kilometres. A separate list of the flora of each study square was prepared of the basis of floristic notes and phytosociological relevés. For alien plant species population size and type of habitat as well as plant community invaded were recorded. The results of the studies have shown the composition of the spontaneous flora of the region, participation of alien plant species and reflect the spatial and habitat diversity in the area. There was also an attempt to propose the first regional list of invasive alien species, which threatened native flora and vegetation.

11.17.2. Alien invasive plants in natural and semi-natural habitats from Romania

P. Anastasiu[1], G. Negrean[2];
[1]University of Bucharest, Faculty of Biology, Bucuresti, Romania,
[2]University of Bucharest,Botanical Garden Dimitrie Brandza, Bucuresti, Romania.

Based on information from literature, herbaria collections, as well as on field researches, and taking in account the recommended terminology in ecology of plants invasions, we identified 435 alien plants in Romanian Flora. We consider that 38 taxa are invasive in different types of ecosystems. Among these, 24 taxa affect natural and semi-natural habitats. In this paper we discuss the impact of these plants on this kind of habitats from different regions of our country, as well as from some natural reserve: National Park Muntii Macinului, Natural Park Bucegi (important center for endemic species), Natural Park Portile de Fier. So, while some do not produce important modifications, others change the character or the nature of some ecosystems (*Azolla filiculoides*, *Paspalum paspalodes* etc.). Some invasive alien plants are integrated in natural landscape so that, based on them, plants associations that are new for science could be described (*Iva xanthifolia* etc.).

11.17.3. Weeds and invasives in Mexico - What is new?

F. J. Espinosa-Garcia[1], J. Villaseñor-Rios[2], **H. Vibrans**[3];
[1]Universidad Nacional Autonoma de Mexico, Morelia, Michoacan, Mexico, [2]Universidad Nacional Autonoma de Mexico, Mexico, D.F., Mexico, [3]Colegio de Postgraduados, Montecillo, Texcoco, Mexico.

Mexico and adjacent Central America are a center of agricultural origin. It is the home of numerous domesticated plants, and of many widespread weeds, particularly of the tropics. In the past 10 years, the study of the weed flora has advanced considerably, both from regional work, as from the analysis of data in a database of the country's flora. Mexico has almost 3000 registered weed species, out of 23,000 higher plants for the whole country. Only 2.7% (617) are exotic, despite a high level of diaspore pressure for 500 years. We show that a) a positive simple correlation between species richness of native and exotic weeds turns negative if factors that influence diversity in general are excluded, supporting Elton's biotic resistance hypothesis; b) exotic species have smaller average distributions than native weeds; so, most exotic species are not intrinsically superior nor have a enemy escape advantage, or are still in the lag phase; c) families differ considerably in their proportion of native weeds vs. exotics, so differential relative advantages must exist (taxonomic hypothesis). - The presentation also introduces an internet Flora of the weeds of Mexico.

11.17.4. Biotic homogenization of the California flora

M. W. Schwartz;
University of California, Davis, CA, United States.

Biotic homogenization is driven by native species losses and invasive species gains. Patterns of homogenization were investigated for the flora of California. Data from a variety of available databases were aggregated at the county level to examine patterns in county population density and growth as well as floristic change. Examining patterns of rare plant occurrences among these counties revealed that high and medium density counties contained, on average, as many or more rare and endemic species than low density counties. Over 48% of the 962 highly threatened taxa in California are endemic to the high and moderate density counties. Thus, urban and urbanizing counties play a large role in maintaining that part of California's flora that is both unique and threatened with extinction. Examining species losses and noxious weed additions across high density counties, reveals a consistent pattern of low similarity among species that have been extirpated from high density counties and a high similarity among noxious weeds that they all now share. The consequence is that California county floras in urban areas are becoming more homogeneous.

11.17.5. Alien invasion and habitat disturbance: effects on pollination and reproduction in a native boreal forest herb

Ø. Totland, **A. Nielsen**, A. Bjerknes, M. Ohlson;
Norwegian University of Life Sciences, Ås, Norway.

The impacts of alien plant species on pollinator visitation and reproductive success of native species has been little studied, and no studies have examined such impacts in habitats of contrasting disturbance history. We studied how experimental introductions of an alien species (*Phacelia tanacetifolia*) affect pollinator visitation and female reproductive success of a native (*Melampyrum pratense*) in recently logged and in old-growth boreal forest habitats. *Phacelia* significantly increased the number of bumblebees entering plots in both habitat types. However, the alien species had a strong negative impact on visitation rate of the native species in both habitat types. Despite this negative impact on pollinator visitation, the alien had no effect on female reproductive success of the native species in any habitat. Our results show that reproduction may be more robust to alien invasion than pollinator visitation, and that impacts of alien invasion may not differ between habitats of contrasting disturbance history.

11.17.6. Ecological status of the invasive exotic weeds in Shivalik Ranges of Northwestern Himalayas, India

D. R. Batish, R. K. Kohli;
Panjab University, Chandigarh, Chandigarh, India.

Northwestern Himalayas of India have a rich floral diversity. Unfortunately, during the past few years there has been an increase in number of invasive exotic species that have either been introduced deliberately or have entered accidentally. A numbers of factors are responsible for their fast spread such as increasing inter/intra continental links, import/export activities, and climatic changes. It has resulted in a dramatic shift and decrease in the diversity of native flora. Lack of awareness, insufficient information on the species and their respective dimensions of spread and behaviour couple with the lack of coordination and collaboration has further compounded the problem. It is proposed to review the current status of exotic plant species, their range of distribution and impact on the diversity and richness of the native ecosystem health. In addition, some strategies for control of their spread and regular monitoring of the vegetation structure and succession mechanism of the region shall also be discussed.

12.1.1. Elucidating the small RNA component of the transcriptome with massively parallel signature sequencing

P. J. Green[1], C. Lu[1], S. Tej[1], S. Luo[2], C. D. Haudenschild[3], B. C. Meyers[1];
[1]Delaware Biotechnology Institute, University of Delaware, Newark, DE, United States, [2]Solexa, Inc, Hayward, CA, United States, [3]Solexa, Inc., Hayward, CA, United States.

Small RNAs play important regulatory roles in most eukaryotes but only a small proportion of these molecules have been identified. We have developed a novel method for the identification and measurement of small RNAs that provides a substantial advance over existing methods for the analysis of these RNA molecules. This method is based on massively parallel signature sequencing ("MPSS") and can sequence hundreds of thousands of molecules in parallel. From two libraries representing Arabidopsis flower and seedlings, we identified more than 75,000 different small RNA sequences. We are combining experimental and bioinformatics approaches to gain insight about the regulation, genomic distribution and roles of these molecules This powerful genome-wide approach extends miRNA prediction capabilities and is applicable to diverse organisms. Funded by the National Science Foundation.

12.1.2. Antisense transcript and RNA processing alterations suppress instability of polyadenylated mRNA in chlamydomonas chloroplasts

Y. Nishimura, E. A. Kikis, S. L. Zimmer, Y. Komine, D. B. Stern;
Boyce Thompson Institute for Plant Research, Ithaca, NY, United States.

In chloroplasts, the control of mRNA stability is of critical importance for proper regulation of gene expression. The Chlamydomonas reinhardtii strain delta 26pAtE is engineered such that the atpB mRNA terminates with an mRNA destabilizing poly(A) tract, resulting in this strain being unable to conduct photosynthesis. A collection of photosynthetic revertants (suppressor of polyadenylation (spa)) was obtained. Among them, spa19/23 maintained unusual two heteroplasmic chloroplast genomes (PS+ and PS-). Based on RT-PCR, S1 nuclease protection, evidence was obtained that the PS+ genome stabilizes polyadenylated atpB mRNA by generating an atpB antisense transcript. Furthermore, when a 121-nucleotide segment of atpB antisense RNA was expressed in delta 26, in which atpB mRNA is unstable because of the lack of a 3' stem-loop structure, an elevated accumulation of atpB mRNA resulted. Taken together, our results suggest that antisense RNA in chloroplasts can protect otherwise unstable transcripts from 3'->5' exonuclease activity.

12.1.3. Pre-mRNA splicing in plants: SR proteins and interacting modifying proteins

A. Barta, M. Kalyna, C. Forstner, M. Buresova, Z. Lorkovic;
Max f. Perutz Lab.,Medical University Vienna, Vienna, Austria.

Pre-mRNA processing is an important step in gene expression and its regulation leads to the expansion of the gene product repertoire. As SR proteins are the important group of proteins in defining intron borders we have isolated and characterized about a dozen of these important proteins which are organized in several protein families. Characterising their expression pattern by several techniques, differential expression within a family indicate evolution of their different regulation. Ectopic overexpression of particular members of each family show their specific involvement in auxin and sugar metabolism and light /dark responses. By yeast two-hybrid screening several new plant splicing factors could be isolated and their interactions verified by pull-down and immunoprecipitation assay. Interestingly, proteins which fuel the dynamics of spliceosomal assembly, like SR specific kinases and cyclophilins (peptidyl prolyl isomerases) were found by screening and further characterized. Specifically, CypSR64 was found to act early in spliceosome assembly whereas Cyp55 could possibly function at the interphase of transcription and pre-mRNA splicing.

12.1.4. RNA processing in *Arabidopsis* flowering time control

G. G. Simpson[1,2];
[1]Dundee University, Dundee, United Kingdom, [2]Scottish Crop Research Institute, Invergowrie, United Kingdom.

Arabidopsis flowering is repressed by the action of the MADS box transcription factor, FLOWERING LOCUS C (FLC). The accumulation of *FLC* mRNA is controlled by the genetically-defined autonomous pathway. This pathway includes the novel, plant-specific, RNA binding proteins, FCA, FPA and FLK. These novel RNA binding proteins deliver precision to the regulation of *FLC* expression, but how do they function? FCA interacts with the RNA 3' end processing factor, FY. This interaction is required for FCA to autoregulate its own expression and to negatively regulate accumulation of *FLC* mRNA. FCA autoregulates its expression by promoting premature cleavage and polyadenylation within intron 3 of its own pre-mRNA. We are currently characterizing the mechanism by which FPA controls flowering. FPA comprises three RRM-type RNA binding domains and a novel, plant-specific domain found in other plant RNA binding proteins. Genetic studies indicate that FPA controls flowering time independently of FCA.

12.2.1. Physcomitrella patens as a novel tool in plant functional genomics

R. Reski;
Plant Biotechnology, University of Freiburg, 79104 Freiburg, Germany.

Mosses are characterized by a simple body plan, and haploidity of the major tissues. Physcomitrella patens displays homologous recombination in its genome, enabling efficient reverse genetics. An EST database was established covering over 95% of the 30,000 protein-encoding genes. The draft genome will be published later in 2005. Several thousand genes are not known from seed plants, hundreds of them appear as retained genes. The set of transcription factors was identified and compared to the complete set of TFs in Arabidopsis. Efficient protocols for proteomics approaches were established including the genome-wide analysis of reversible protein phosphorilation. Insights from a collection of tagged mutants (75,000) as well as from single knockout-plants will be presented, including in-vivo imaging via CLSM and FRET.
Supported by DFG, BMBF, Fonds der Chemischen Industrie, and BASF Plant Science. Genome sequencing is performed by US DoE at JGI.

12.2.2. Parameters affecting the frequequency of homologous recombination in *Physcomitrella patens.*

D. J. Cove, Y. Kamisugi, A. C. Cuming;
Centre for Plant Sciences, University of Leeds, Leeds, United Kingdom.

Constructs in which a selection cassette is inserted into a length of genomic DNA have been used to target a number of loci, and the resulting transgenics have been analysed by PCR. The frequency of the occurence of homologous recombination (HR) is strongly related to the log. of the length of the homologous sequence and is not affected by the relationship (5' or 3') to the selection cassette, nor do PCR-generated targeting sequences give different frequencies for the corresponding targeting sequences released from plasmids by restriction enzyme digestion. Gene trageting may result in allele replacement with junction sequences consistent with HR having occured in both flanking sequences, but can also result in the insertion of the targeting sequence without replacement of a genomic sequence, by a process that involves not only HR but also non-homologous end joining (NHEJ). Sequence analysis indicates that NHEJ occurs between one or more molecules of the targeting sequence and does not involve the chromosomal sequence.

12.2.3. The genomics of desiccation tolerance in Bryophytes.

M. J. Oliver, P. R. Payton;
Plant Stress Lab, Lubbock, TX, United States.

The molecular, cellular and biochemical responses of plants to water-deficit stress are of major economic importance as we cope with a changing environment. We use the desiccation-tolerant moss Tortula ruralis as an model for studying post-transcriptional gene control, molecular & biochemical responses to abiotic stress, cellular repair mechanisms in plants and as a source of novel tolerance-associated genes. A major advance in our efforts have come with the development of a Tortula unigene set and a Tortula uni-cluster cDNA microarray. Analysis of expression profiles, over the desiccation rehydration cycle, and assessing both transcript abundance and recruitment into the protein synthetic pool has allowed us to develop a comprehensive look at the protection and repair aspects of desiccation tolerance in this bryophyte. Phylogenetic profiling, in this case bioinformatically, coupled with new phylogenetic assessments of desiccation tolerance in the land plants allows us to generate new testable hypotheses concerning the importance of certain genes and gene networks in the evolution of this important trait.

12.2.4. Stress- and ABA- responses in *Physcomitrella patens:* a transcriptomic approach

A. C. Cuming[1], Y. Kamisugi[1], R. S. Quatrano[2];
[1]University of Leeds, Leeds, United Kingdom, [2]Washington University in St. Louis, St. Louis, MO, United States.

Many mosses exhibit a strikingly high level of dehydration tolerance. The model moss *Physcomitrella* is able to withstand dehydrative loss of *ca.* 90% fresh weight and recover. Using a 22,000 feature oligonucleotide microarray designed from the *Physcomitrella* EST database, we have identified networks of genes co-regulated by dehydration, osmotic stress, salt stress and the plant hormone ABA. Analysis of a small number of such stress-regulated genes, encoding homologues of the higher-plant Late Embryogenesis Abundant (LEA) proteins, indicates a common pathway of transcriptional induction through evolutionarily conserved ABRE *cis*-acting promoter sequences. The potential of global transcriptional analysis through microarray studies, in combination with bioinformatic analysis of the emerging *Physcomitrella* genome sequence, is expected to enable the full scope of such gene co-regulatory networks to be revealed.

12.2.5. Phage-type RNA polymerases in *Physcomitrella*

U. Richter[1], E. Decker[2], A. Weihe[1], R. Reski[2], **T. Börner**[1];
[1]Institut für Biologie (Genetik), Humboldt-Universität, Berlin, Germany,
[2]Institut für Pflanzenbiotechnologie, Universität Freiburg, Freiburg, Germany.

Mitochondrial and chloroplast genes of maize and other cereals are transcribed by two different RNA polymerases phylogenetically related to RNA polymerases of bacteriophages. Eudicots, like Arabidopsis and *Nicotiana,* possess an additional phage-type RNA polymerase that is dually targeted to both mitochondria and chloroplasts. Except certain non-green parasitic plants, transcription of chloroplast genes of all lower and higher plants additionally requires a bacterial-type RNA polymerase. Genes for subunits of the bacterial-type RNA polymerase reside in the chloroplast genome with the exception of a nuclear encoded *RpoA* gene in *Physcomitrella patens*. *Physcomitrella* shows another striking difference to angiosperms. The nuclear genome contains two genes for phage-type RNA polymerases, *PpRpoT1* and *PpRpoT2*. GFP-fusions of the transit peptides of the two polymerases revealed that *both* enzymes are dually targeted to mitochondria *and* chloroplasts. Attempts to knock out *RpoT1* in *Physcomitrella* failed, probably because it has an essential function. We obtained, however, knock-out mutants of *RpoT2* that exhibit a surprising phenotype.

12.2.6. Actin dynamics in physcomitrella patens: Role in polar tip growth

R. S. Quatrano, M. Bezanilla, P. Perroud, P. Harries, A. Pan, P. Klueh, J. Cho, D. Cove;
Washington University in St. Louis, St. Louis, MO, United States.

We will describe how we employed two techniques in *P. patens*, i.e. homologous recombination and RNAi, to generate loss of function lines in order to determine the role of two different members of the Arp2/3complex (a seven member protein complex required for nucleating and branching actin filaments) in polar tip growth. We first show that the transcript for ARPC1 and an ARPC4-YFP fusion protein are both localized at the tip of the elongating protonemal apical cell. Knockdown lines of ARPC1 and knockdown and knockout lines of ARPC4 both show abnormal polar tip growth phenotypes -lack of the extension growth. The ARPC1 abnormal phenotype is more severe; caulonmenal cells are not formed resulting in the lack of buds and leafy gametophores. ARPC1 also appears to have a role in adjusting to osmotic stress and in establishing polar outgrowth. Latrunculin B, an actin-disrupting drug, mimics the severe ARPC1 phenotype in wild type protonema. We will discuss how these phenotypes will be used to further our understanding of how the alignment of polar tip growth is controlled. Funding: Helen Hay Whitney Foundation (M.B.); National Science Foundation (IBN 0112461 - R.Q).

12.2.7. Physcomitrella: at the intersection of bryology and pathology

M. A. Lawton, H. Saidasan;
Biotech Center, New Brunswick, NJ, United States.

The ability to manipulate the genome of *Physcomitrella patens* makes it an attractive system for studying genes that regulate programmed cell death (PCD) and associated responses to microbial pathogens. Although the pathology of *Physcomitrella* (and bryophytes) is not well developed, it has the potential to become a model pathosystem for studies in molecular plant pathology. We describe several approaches for developing ‘physcopathology’, including the use of pathogens and elicitors to induce defense responses and PCD. The perception of elicitors by *Physcomitrella* results in changes in secondary metabolites, the activation of defense-response genes and enzymes, and a stereotypical pattern of cellular breakdown. Manipulation of genes that regulate PCD affects both these responses and plant development. These results suggest that *Physcomitrella* can serve as a useful system for studying molecular aspects of PCD, plant defense responses and disease resistance.

12.3.1. Floral morphological character coding and the use of trees.

L. M. Kelly, D. W. Stevenson;
The New York Botanical Garden, Bronx, NY, United States.

Floral morphology has shed much light on phylogenetic relationships of taxa, and conversely, phylogenetic hypotheses have helped us interpret floral morphology. Because modern phylogenetic analysis requires us to explicitly define and code individual characters and character states, the results of phylogenetic analyses allow us to interpret more precisely the evolution of characters, to test the value of characters as evidence, and to refine definitions of characters. We will consider two character systems of the gynoecium that show the relationships between morphological interpretations of characters (as coded in the matrix) and the resulting outcome of the phylogenetic analysis. The concept of pseudomonomery has been assembled based on combinations of morphological and phylogenetic criteria. The phylogenetic interpretations must be removed when characters are coded for an analysis, but the coding and the phylogeny are inextricably linked when we discuss pseudomonomery. Morphological and phylogenetic interpretations of ovary position provide a similar example.

12.3.2. Floral structure and development in Malvaceae-Grewioideae

U. Brunken[1,2], C. Bayer[1];
[1]Palmengarten Frankfurt, 60323 Frankfurt a.M., Germany,
[2]Forschungsinstitut Senckenberg, Department of Botany and Molecular Evolution, 60325 Frankfurt a.M., Germany.

Grewioideae, which include most genera of former Tiliaceae, represent a basal clade within Malvaceae. Their floral structure, especially the androecium, is unique within Malvaceae, where fertile stamens usually occur in antepetalous position, and staminodia in the antesepalous sector, which is interpreted as (ob-)diplostemony. In most Grewioideae the first staminal primordia arise in antesepalous position, followed by antepetalous primordia, which are slightly more peripheral. Additional stamens can arise centrifugally in the antesepalous sectors, less so in antepetalous position. *Sparrmannia* produces exclusively antesepalous stamens. Anatomical features are not always congruent with these ontogenetical observations: Whereas in *Corchorus* and *Trichospermum* only antepetalous traces could be found, there are antesepalous as well as antepetalous traces in *Grewia* and *Sparrmannia*. In *Sparrmannia* the antepetalous traces divide and supply stamens also in antesepalous position. Based on these observations the circumscription and use of the term ‘androecial whorl’ is discussed.

12.3.3. Floral Development and Floral Structure of Dipterocarpaceae

A. Kocyan;
Institute of Systematic Botany, Munich, Germany.

The understanding of floral development within Malvales has become rather extended in the last years. However, one of the families not yet studied so far is the largely South East Asian Dipterocarpaceae. Organ primordia protrude from a strongly flattened floral apex. Sepal initiation is sequential. In Dipterocarpus the first two sepals become conspicuously enlarged later forming the two characteristic wings. The petals arise simultaneously and become contorted. In none of the investigated species a retardation of petal initiation was observed as shown in closely allied Cistaceae (Nandi 1998). Androecium initiation proceeds centrifugally. In Dipterocarpoideae, five episepalous stamens are initiated simultaneously followed by two regular androecial whorls or, in taxa with >15 stamens (incl. Monotoideae, 1 species studied), male organs arise from a ring primordium. The gynoecium arises from three moulds that show a short synascidiate zone, which is also present in the anthetic flower.

12.3.4. Floral diversification in Spermacoce (Rubiaceae): evolutionary steps towards more efficient cross-pollination?

S. Dessein, E. Vaes, A. Vrijdaghs, E. Smets;
Laboratory of Plant Systematics, Leuven, Belgium.

Rubiaceae flowers feature impressive variation in size, shape and colour. The corolla bauplan, nonetheless, shows little variation. Most corollas are 4-5-merous, characterised by early sympetaly, and outgrowths are usually absent. In the Australian representatives of the genus Spermacoce, however, the corolla shows more variation. At the adaxial side of the corolla lobes of many species, outgrowths - called appendages in literature - are present, and in other species the number of corolla lobes is doubled. An ontogenetic study was undertaken in order to investigate the homology among the appendages observed. In addition, the species were studied in the field to illuminate the role of the corolla appendages to achieve more efficient cross-pollination. A phylogenetic hypothesis of the study group based on DNA sequence variation allows us to discuss the floral diversification in a phylogenetic context.

12.3.5. The most polymerous gynoecium among asterids: floral development in *Tupidanthus calyptratus* Hook.f. & Thoms. (Araliaceae)

A. A. Oskolski[1], M. V. Remizowa[2], E. Kudryavtseva[3], D. D. Sokoloff[2];
[1]Komarov Botanical Institute, St. Petersburg, Russian Federation,
[2]Moscow State University, Moscow, Russian Federation, [3]Beth Israel Deaconess Medical Center, Boston, MA, United States.

The peculiar flowers of *Tupidanthus calyptratus* (= *Schefflera pueckleri* (K.Koch) Frodin) are characterized by very numerous floral parts (up to 172 stamens and 138 carpels), a condition of secondary origin unique not only within the order Apiales (where the pentamerous flowers are common and polymery is otherwise much less extreme) but within the asterids as a whole. The pedicels of *T. calyptratus* as well as of closely related *Schefflera* species bear two bracteoles. In *Tupidanthus*, the flower primordium is shaped like a butterfly or bow. The calyx is formed as a tiny ring, and sepal number is thus unclear. The corolla is initiated as a ring-meristem that is transformed into a massive entire tube-like structure with numerous distal lobes. The tube then curves inwards; its abaxial surfaces are postgenitally fused into a calyptra. All the primordia of the numerous stamens appear simultaneously as a single whorl, a mode of androecium initiation that is very rare within the Angiosperms. The carpels, initiated somewhat later than the stamens, likewise form a single whorl. A flat extensive central portion of the floral apex does not take part in the initiation of floral organs.

12.3.6. Flower morphology and development in former Melanthiaceae

M. V. Remizowa[1], D. D. Sokoloff[1], P. J. Rudall[2];
[1]Moscow State University, Moscow, Russian Federation, [2]Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Molecular phylogenetic studies have supported division of the former Melanthiaceae s.l. into four relatively distantly related families: Melanthiaceae s.str. (Liliales), Nartheciaceae (Dioscoreales), Petrosaviaceae (Petrosaviales), and Tofieldiaceae (Alismatales). We have compared floral morphology and development in these families and their relatives. Common characters of all former Melanthiaceae are also present in many other monocots. Some features support the monophyly of each segregated family. However, each family displays significant variation of floral characters, including presence/absence of septal nectaries in Nartheciaceae, variation in ovary position in Petrosaviaceae, unilocular/trilocular ovary and variation in stamen number in Tofieldiaceae. Features supporting ordinal placements are often equivocal. For example, the characteristic calyculus of Tofieldiaceae is similar to the bract whorls in Alismataceae (both Alismatales), but also to the leaf whorl that is inserted below the flower in *Trillium* and its allies (Liliales).

12.3.7. Bridging the basal eudicot and core eudicot boundary. How can we reconcile phylogeny with floral evolution?

L. P. Ronse De Craene[1], L. Wanntorp[2];
[1]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom,
[2]University of Stockholm, Stockholm, Sweden.

Most taxa of the basal eudicot grade, including Gunnerales, share simple dimerous flowers with little or no differentiation between bracts and tepals. The core eudicots have a majority of taxa with pentamerous flowers and a clear distinction between sepals and petals. However, the understanding of the evolution of the perianth in the higher basal eudicots and the lower groups of the core eudicots is crucial for grasping the evolution and the differentiation of petals. It is demonstrated that on the one hand Gunneraceae represent an evolutionary dead-end, with a strong tendency for reduction of the flower linked with wind pollination. It is postulated that progenitors with spiral flowers similar to Berberidopsidaceae gave rise to pentamerous flowers with sepals and petals of a same tepaline origin. A progressive synorganisation of the flower linked with shifts in expression of genes determining organ identity led to a strong resemblance of petals to stamens in several higher orders of the core eudicots. Several reasons are postulated for the absence of any clear morphological links between the basal eudicot grade and the core eudicots.

12.4.1. horizontal gene transfer in the evolution of plant mitochondrial genomes

J. D. Palmer;
Indiana University, Bloomington, IN, United States.

I will first give a brief overview of the remarkable propensity of plant mitochondrial genomes to take up foreign DNA, from the chloroplast and nucleus via intracellular gene transfer and from other plant mitochondrial genomes via horizontal gene transfer. I will then focus on the latter topic, presenting recent work from my lab on the extent, frequency, functional consequences, and mechanisms of plant-to-plant horizontal transfer of mitochondrial genes. Special emphasis will be placed on the role of parasitism in horizontal transfer and on the basal angiosperm *Amborella trichopoda*, whose mitochondrial genome is exceptionally full of foreign genes, acquired from a wide range of angiosperm and moss donors. The implications - both negative and positive - of widespread horizontal gene transfer for the utility of plant mitochondrial genes as phylogenetic and chronological markers will be discussed.

12.4.2. Variation patterns in mitochondrial genes used in plant phylogenetics

J. I. Davis[1], G. Petersen[2], O. Seberg[2], D. W. Stevenson[3];
[1]Cornell University, Ithaca, NY, United States, [2]Botanical Institute, Copenhagen, Denmark, [3]New York Botanical Garden, Bronx, NY, United States.

Mitochondrial genes, or more correctly, genes that usually occur in the mitochondrial genome, frequently exhibit variation patterns suggestive of marked changes in evolutionary rates. This phenomenon also is observed in the nuclear and plastid genomes, but comparisons across major clades of the angiosperms, and among major monocot groups in particular, using genes that have been widely sampled for phylogenetic purposes, suggest that it is more pronounced in the mitochondrial genome than in the plastid genome. Among the various patterns that are exhibited are those that suggest that the rate changes are persistent, and others that suggest episodic events of acceleration and deceleration. RNA editing, though directly inferred in only a few taxa, is correlated with variation patterns that can be used to infer the taxonomic distribution of this phenomenon. These patterns affect the results of phylogenetic analyses. Because they are not confined to the mitochondrial genome, and because this genome provides phylogenetic evidence that is not replicated in others, it would be inadvisable to exclude mitochondrial genes from phylogenetic analyses.

12.4.3. Evolution of RNA editing sites and its impact on phylogenetic signal in plant mitochondrial genes

C. dePamphilis;
Pennsylvania State University, University Park, PA, United States.

We present an analysis of sequence evolution and phylogenetic signal in three mitochondrial genes -cox1, matR, and atp1 - that we have sampled from diverse flowering plant species. Phylogenetic signals are present in these genes that are mostly congruent with chloroplast and nuclear gene phylogenies, and contribute to the resolution of challenging problems in angiosperm phylogeny including origins of parasitic angiosperms and the phylogenetic position of key basal lineages. Several noteworthy phenomena were observed, including horizontal capture of host plant DNA by parasitic plants and evidence of a chimeric atp1 gene containing a portion of a local host plant atp1 gene. Abrupt reversals of the editing status (Riveting) of all editing sites has occurred repeatedly, implying frequent retroprocessing and recombination events involving edited mitotranscripts. These processes could drive high rates of correlated sequence evolution at editing sites, creating processed paralogs and destabilizing traditional concepts of homology. The impact of RNA editing on phylogenetic analysis is examined to revisit predictions made in an earlier study.

12.4.4. Mitochondrial sequences in monocot phylogenetics: new data, new problems

G. Petersen[1], O. Seberg[1], J. I. Davis[2], D. W. Stevenson[3];
[1]Institute of Biology, Copenhagen, Denmark, [2]Cornell University, Ithaca, NY, United States, [3]New York Botanical Garden, New York, NY, United States.

Phylogenetic analyses of the Monocotyledons are based on larger and larger data sets including nucleotide sequence data from all three genome compartments. Incongruence between data sets from the three different genomes helps identify taxa that show anomalous behavior. Analyses of mitochondrial sequences from *cob* and *atp1* in all monocot families point at a number of taxa with divergent sequences, which either placed them on exceptionally long branches or grouped them in peculiar phylogenetic positions. Several processes may explain the divergences including elevated substitution rates, transfer of genes from the mitochondria to the nucleus, and horizontal gene transfer. Whereas an elevated substitution rate in the mitochondrial genes may account for the odd observations in some achlorophyllous taxa (Triuridaceae, Burmanniaceae, Corsiaceae), observations in other groups, e.g., the Liliaceae and the Anthericaceae, most likely are due to transfer of mitochondrial genes to the nucleus.

12.4.5. High frequency of intracelllular gene transfer in grasses and persistence of transcompartmentally duplicated and expressed genes.

H. Ong, J. D. Palmer;
Indiana University, Bloomington, IN, United States.

Two classes of genes, encoding ribosomal proteins and SDH subunits, are lost from the mitochondrial genome and functionally transferred to the nucleus at exceptionally high rates during angiosperm evolution. We focus on two of these genes in grasses, and by greatly increasing their sampling, show that the dynamics of gene transfer, loss and persistence are even more complex than previously recognized. We show that *rps14* was functionally transferred to the nucleus - within the intron of the *sdh2* gene - early in grass evolution. Remarkably, a transcribed and RNA-edited *rps14* pseudogene has been pervasively retained in the mitochondrion for over 50 million years of grass evolution. The *rpl5* gene, usually separated from *rps14* by a single nucleotide, was transferred to the nucleus a minimum of five times in grasses, with a distinct gain of targeting sequences each time, and with retention and expression in many mitochondrial lineages. Our results show that two mitochondrial genes of close proximity can experience different fates of intracellular transfer and that the frequency of functional gene transfer can be even higher than previously estimated.

12.4.6. Exceptionally high substitution rates in Geraniceae and Plantaginacea mitochondrial DNA nad exon regions

F. T. Bakker[1], F. Breman[1], V. Merckx[2];
[1]Nationaal Herbarium Nederland, Wageningen, The Netherlands, [2]Laboratory of Plant Systematics, Katholieke Universiteit Leuven, Belgium.

Nucleotide substitution rates in mitochondrial DNA of Geraniaceae and Plantaginaceae were found to be exceptionally high as compared with other angiosperm mtDNA lineages by Palmer and co-workers in 2000. Rates in nad1 *b* and *c* exons were found to be high enough to distinguish species groups in *Pelargonium* by Bakker & al. in 2000. Palmer & al. had already shown that Geraniaceae and Plantaginaceae have lost their mtDNA introns. In this study we compile DNA sequence data from three exons of the mtDNA nad1 gene for Geraniaceae (i.e. *Pelargonium*, *Erodium*, *Geranium* and the outgroup *Hypseocharis*) and Plantaginaceae (*Plantago* and its sister group *Limosella*) in order to assess the extent and nature of the nucleotide substitution rate acceleration. We also include further outgroups in order to establish where the increase in substitution rate has occurred. Comparison is made with plastid and, if possible, nuclear DNA sequence data in order to show that the rate acceleration is exclusive to mtDNA. Furthermore we compare our findings with mtDNA nad sequence data from other angiosperm groups for which rate accelerations have not been reported (Burmanniaceae, Orchidaceae).

12.4.7. Utility of mitochondrial DNA in plant phylogenetic reconstruction

M. J. Sridharan, O. Dombrovska, Y. Qiu;
University of Michigan, Ann Arbor, MI, United States.

Plant mitochondrial DNA, in comparison to plastid DNA, exhibits two unique features: a high frequency of structural changes and a low substitution rate. They both can be exploited to resolve difficult problems in the land plant phylogeny. We present phylogenetic analyses of basal angiosperms using sequences of mitochondrial genes *atp1* and *matR* and plastid genes *atpB, matK, rbcL,* and *rpoC2*. We evaluate relative contribution of the mitochondrial and plastid genes in resolving various nodes of the basal angiosperm phylogeny. We also present an investigation of distribution of group II introns in the mitochondrial genome of basal land plants as well as a phylogenetic analysis of group II introns in prokaryotes and organellar genomes of eukaryotes. These analyses help to assess informativeness of the genomic structural characters when used to resolve controversial issues in plant phylogeny, and provide an assessment of confidence level of the phylogenetic resolution.

12.5.1. Migration and evolution of arctic plants in response to Quaternary climate changes

C. Brochmann, R. Elven;
National Centre for Biosystematics, Oslo, Norway.

The modern Arctic is a comparatively young biome, formed in response to global cooling in the late Tertiary. The early Quaternary flora was probably recruited from survivors from the arcto-Tertiary forests combined with immigrants from various southern mountain ranges. This floristic mixture has since been repeatedly spatially rearranged and re-mixed in response to numerous cycles of warming and cooling. Here we address recent developments in deciphering and understanding the evolutionary and biogeographic history of arctic and arctic-alpine plants at various scales in space and time. We will summarize recent and ongoing studies at the entire circumpolar (and bipolar) to regional scales. These studies aim to infer origins of arctic plant groups from genus- or section-level phylogenetic and biogeographic analyses, origins of polyploid species complexes from systematic and phylogenetic analyses of markers such as low-copy nuclear genes to unmask their diploid progenitors, and origins of modern single-species distributions formed by postglacial expansion from their most recent glacial refugia, based on phylogeographic analyses of various markers.

12.5.2. Glacial refugia and directions of migrations of arctic alpine plants in Eurasia

A. Tribsch, C. Brochmann;
National Centre for Biosystematics, Natural History Museum, Oslo, Norway.

During the Quaternary large areas in the Arctic were repeatedly and heavily glaciated. Populations of arctic plants must have survived in unglaciated northern refugia and/or in more southerly mountain ranges, most likely in areas that provided suitable habitats all the way through the severe and rapid climatic fluctuations. Palaeoenvironmental and biogeographical data suggest that glacial refugia existed not only in Beringia, but also in other regions, such as in northwestern Siberia. We present phylogeographic/phylogenetic case studies based on cpDNA sequences and nuclear AFLPs markers for *Eritrichium* sect. *Eueritrichium* (Boraginaceae), *Thalictrum alpinum* (Ranunculaceae), *Pedicularis oederi* and related taxa (Scrophulariaceae), and the *Saxifraga stellaris* group (Saxifragaceae). The molecular data, combined with palaeoenvironmental evidence for potential refugia in Eurasia, are used to infer in which parts of northern Eurasia refugia were realized. These refugia may have been of general importance for long-term maintenance of arctic-alpine biota.

12.5.3. Immigration history of rare arctic-alpine plants into the Alps

P. Schoenswetter[1,2], M. Popp[1], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museums and

Botanical Garden, University of Oslo, Oslo, Norway, [2]Department of Plant Biogeography, Institute of Botany, University of Vienna, Vienna, Austria.

A considerable number of plant species of predominantly arctic distribution grow in non-arctic mountain ranges as well, a distribution type referred to as arctic-alpine. There are large differences between such taxa regarding the extent of their distribution area outside the Arctic. Whereas some arctic-alpine species occur frequently in many mountain ranges of the northern hemisphere, others are very rare, sometimes with only a few populations outside the Arctic. Here we address the immigration history of five rare arctic-alpine model taxa (*Carex atrofusca, Carex bigelowii, Juncus biglumis, Minuartia biflora, Ranunculus pygmaeus*) into the European Alps using AFLP fingerprinting and DNA sequencing. We focus on the circumpolar phylogeographical patterns, the source areas for the colonisation of the Alps, the mode of origin of the alpine populations (single vs. multiple introductions) and the phylogeographical structure within the Alps. Some of the rare arctic-alpine plants are critically endangered in the Alps, and conservation strategies will be discussed.

12.5.4. Reticulate evolution and phylogeography in the Arctic: *Saxifraga* section Mesogyne

T. M. Gabrielsen, P. B. Eidesen, R. Elven, C. Brochmann;
National Centre for Biosystematics, Natural History Museum, Oslo, Norway.

Saxifraga section *Mesogyne* is a small, well-defined group of mainly arctic-alpine plant species and is represented in most mountains and arctic regions of the northern hemisphere. We use various molecular markers and flow cytometry to study the origin, evolution, and migration of these saxifrages in relation to the Pleistocene glaciations. We analyse sequences from five non-coding chloroplast DNA regions and 1-2 nuclear DNA regions in addition to AFLP fingerprints. Preliminary phylogenetic analyses indicate that the section is monophyletic, but the origin of the section is not yet resolved. Several chloroplast haplotypes have wide circumpolar distributions, suggesting extensive migration. Most chloroplast haplotypes are species specific, but one widespread haplotype is represented in three species. Analyses of the nuclear sequences suggest that this is the result of hybridization and allopolyploidy, and that at least five species in *Mesogyne* probably have been formed this way. Thus, large-scale migrations and extensive reticulations seem to have dominated the history of *Saxifraga* section *Mesogyne*.

12.5.5. Conmparative worldwide phylogeography of the genus *Arabidopsis* based on plastidic and nuclear DNA markers.

M. Koch, **M. Matschinger**;
Heidelberg Insitute of Plant Sciences, Heidelberg, Germany.

Modern plant systematics has shown that a circumscription of the genus Arabidopsis comprises the former genus Cardaminopsis and Arabidopsis thaliana only. "Cardaminopsis" as treated traditionally comprises three species groups: A. lyrata, A. arenosa, A. halleri. All of them are represented by different subspecies and/or cytotypes. Additionally, several taxa are of hybrid origin such as A. suecica and, as shown here, A. croatica and A. cebennensis. DNA sequene data of nuclear encoded ITS substantiate the existence of these three groups. However, cpDNA haplotype variation based on more than 1,000 samples revealed 5.5% shared haplotypes between species indicating higher levels of interspecific gene flow. Several phylogeographic studies of A. thaliana have been introduced within the last few years. Herein we present the first comparative northern hemisperic phylogeographic framework of the several "Cardaminopsis" species. We characterized high levels of genetic differentiation with more than 140 cpDNA haplotypes. However, pairwise genetic distances are low, indicating pleistocenic migration and in some cases periglacial survival.

12.5.6. Hybridization and adaptive radiation in Australian alpine *Ranunculus*

T. T. Armstrong[1,2], J. E. Ash[2];
[1]Landcare Research, Auckland, New Zealand, [2]Australian National University, Canberra, Australia.

DNA sequence data indicate late Pleistocene dispersal of *Ranunculus* (sect. Acris) from New Guinea to the Australian Alps followed by rapid ecological speciation and morphological divergence. The 8 Australian alpine species hybridize extensively. Hybrid zones are narrow (often < 1m wide), with corresponding clines in morphological transition and allele frequency across ecotones. The species are fully reproductively compatible, with F_1, F_2 and BC hybrids vigorous and fertile. A three-year field trial of parental and hybrid seedlings indicates that hybrid zones are stabilised by intense ecological selection: species perform best in their own habitats; hybrids out-perform parental species within hybrid zones. Adaptive aspects of leaf shape inheritance were investigated using parental lines and hybrid (F_1, F_2 and BC) progeny arrays. Quantitative genetic models revealed polygenic control of traits by independently segregating genes. We propose that adaptations to exploit divergent habitats have acted to isolate lineages via intense natural selection. This study emphasises the importance of selection versus drift for speciation in insular habitats.

12.5.7. North American phylogeography

S. J. Brunsfeld[1], **C. K. Anttila**[2];
[1]University of Idaho, Moscow, ID, United States, [2]San Francisco State Univ., San Francisco, CA, United States.

During the Pleistocene epoch, when ice covered large portions of Eurasia, ice also buried much of northern North America. As in Eurasia, ecosystems were greatly shaped by the presence and absence of ice. Molecular phylogeographic methods reveal the presence of refugia north and south of the limits of North American ice sheets. Arctic and alpine habitats are highly disjunct on the continent, often forming islands of cold-tolerant species that are either closely related or conspecific, and were likely more widespread at the height of the Pleistocene. Ancient vicariance is also responsible for genetic discontinuities on the North American landscape. Such Isolation among plant and animal populations, especially associated with orogeny, usually resulted in higher levels of genetic divergence than that derived from glacial isolation. Molecular tools can also provide the resolution needed to track post-glacial migration patterns and suture zones, The latter are important because they are communities of migrants brought together by different migration waves. The phylogeography of North America has many similarities to that of Eurasia.

12.6.1. Mating systems and speciation in lichen-forming ascomycetes

R. Honegger, S. Scherrer;
Institute of Plant Biology, Zürich, Switzerland.

Speciation processes are poorly understood in lichen-forming fungi. Our team focuses on Teloschistaceae. Phylogenetic analyses of mycobionts (ITS 1 + 2, 5.8S rDNA, hydrophobin, tubulin and mitochondrial genes; C. Eichenberger) and their *Trebouxia* photobionts (ITS 1 + 2, 5.8S rDNA, rbcL gene; S. Nyati) are combined with studies on mating systems in the fungal partner. Changes in reproductive strategies, from cross- to self-fertilization (hetero- to homothallism) or even loss of sexual reproduction, have a strong impact on speciation processes. As mating type genes evolve very rapidly they are difficult to analyse. Sandra Scherrer characterized the mating type genes of a range of *Xanthoria* spp. The distribution of *MAT* haplotypes in natural populations of heterothallic species was explored and the genetics of homothallism in two ubiquitous species investigated. One of these self-fertile species had both idiomorphs (*MAT 1-1* + *MAT 1-2*) per haplotype, the other a HMG box (*MAT 1-2*) only, an exceptional situation among ascomycetes. Genetic diversity within populations of homo- and heterothallic *Xanthoria* spp. and their photobiont was analysed (RAPD-PCR, rDNA).

12.6.2. Migration between continents: Geographic structure in *Porpidia flavocoerulescens* and *Porpidia melinodes*

J. Buschbom;
Institute for Bioinformatics, University of Duesseldorf, Duesseldorf, Germany.

The influence of geography on the structuring of populations of the “species pair” *Porpidia flavocoerulescens* and *P. melinodes* was investigated. The extent of population subdivision was analyzed for populations located in North America, Greenland and Europe using analyses of molecular variance and F_{st}-statistics. Migration rates between sampling localities were estimated using MCMC-based importance sampling approaches to parameter inference.

No clear population subdivision was observed. Haplotypes were shared between continents and geographic regions. The influence of geography on the populations could be best described by a model of isolation-by-distance. The studied epilithic crustose lichens seem to have effective dispersal strategies. The type of dispersed propagules (i.e. ascospores or soredia) does not have a strong influence on the dispersal ability.

12.6.3. Two Group I introns in the 1516 and 1506 positions show a consistent geographical pattern in the *Parmeliaceae*

G. Gutiérrez[1], O. Blanco[2], **A. Crespo**[2];
[1]Universidad de Sevilla, Departamento de Genética, 41080 Sevilla, Spain, [2]Universidad Complutense, Facultad de Farmacia, 28040 Madrid, Spain.

We have studied the primary and secondary structure of 150 Group I introns of nuclear SSU rDNA in more than 60 species of the lichen family *Parmeliaceae* The species studied can be divided into two groups, one showing an intron at the 1506 site and the other at the 1516 position. The two introns differ in sequence and structure and do not occur together. The 1516 introns observed are well conserved in other genera of Lecanorales, whereas the 1506 introns are not present in other Lecanoromycetes. 1506 introns showed significant correlations with a Group I intron at the LSU rRNA of one basidiomycete, with SSU rRNA introns of other ascomycetes and with Group I introns inserted in the SSU rDNA of some chlorophyta species. We have found a distinct correlation between the intron position and the geographic distribution of the species examined. The 1516 introns were found in boreal or temperate lichen species of the small genera *Pseudephebe*, *Asahinea, Parmeliopsis, Vulpicida, Arctoparmelia* as well as *Parmelia, Melanelixia,* etc. whereas the 1506 ones occur in species of the tropical genera *Hypotrachyna* or the oceanic temperate mid-latitude species of *Parmotrema* and *Flavoparmelia*.

12.6.4. Potential distribution modelling and niche characterization of Peltigerales order (lichens) in the Iberian Peninsula

I. Martínez[1], F. Carreño[1], A. Rubio[2], A. Escudero[1], A. Burgaz[3];
[1]Universidad Rey Juan Carlos, Móstoles, Spain, [2]Universidad Politécnica de Madrid, Madrid, Spain, [3]Universidad Complutense, Madrid, Spain.

Most of the species included in the Peltigerales order are associated to well-preserved forests, and some of them are included in national and regional Red Lists. However, there is a lack of regional assessments of habitat suitability that identifies limiting ecological factors for the species. In this work we present a regional model for the distribution of 45 taxa of this order in the Iberian Peninsula. The occurrence in 100 km^2 UTM squares were modelled with broad-scale explanatory variables obtained from thematic digital cartography, climatic data and spatial coordinates. All data were integrated in a GIS tool. These models are relevant in the conservation of the species, because they suggest the limiting factors for these species in the Iberian Peninsula and, they generate predictive maps pointing out both areas in which conservation problems may be probably (suitable areas that are unoccupied), and areas where no data is available but these species are likely to be present. Furthermore, these models can be used as predictive tools in new warming climate scenarios to counteracting measures.

12.6.5. The *Bacidia rosella*-group in the Mediterranean Region.

E. Llop;
Institute of Biology. University of Bergen, Bergen, Norway.

The species concept applied to study *Bacidia* De Not. has been based on central and northern European samples. The revision of Mediterranean material is providing a new outlook on the conception of several species, especially on *Bacidia rubella* (Hoffm.) A.Massal. and *B. rosella* (Pers.) De Not.

Former studies have placed most of the samples with orange to red apothecia and long acicular ascospores in *Bacidia rubella*, while those samples with a pinkish reddish apothecia and longer ascospores used to be included in *B. rosella.* Recently, *B. fraxinea* Lönnr. has been reinstated on the basis of thallus morphology and ascospores size. Afterwards, two new species have been described, *B. parathalassica* Llop & Gómez-Bolea and *B. iberica* Aragón & Martínez. Both species are segregated according to their thallus morphology, apothecial features and ascospore size. Molecular data from the recently described data is not available in order to substantiate its identity; however, morphological characteristics are consistent enough to maintain both taxa.

12.6.6. Unexpected genetic diversification in morphological uniform taxa and exceptional morphological diversification in Cladia and closely related lineages.

N. Hoffmann[1], P. T. DePriest[2];
[1]Institut für Pflanzenwissenschaften, Graz, Austria, [2]Smithsonian Institution, Washington, D.C., DC, United States.

Cladia is a genus of lichenized fungi with most of its species endemic to the Australasian region. In our phylogenetic analysis of partial nuclear and mitochondrial rDNA, the species of the genus Cladia were divided into two clades. The first clade, containing C. aggregata, the type species of the genus, consisted exclusively of the highly similar and hard to distinguish members of the C. aggregata complex. Despite of their morphological uniformity this clade showed unexpected high rates of genetic variation. The opposite observation was made on the second clade. It showed the regularly perforated species of Cladia, such as C. retipora and C. sullivanii paraphyletic relative to species of Heterodea, Notocladonia and Thysanothecium, three lichen genera occurring in the same geographical region. These three genera share many anatomical features with Cladia in general, but have very distinct vegetative morphologies. Their previous treatment as separated genera reflects the striking morphological evolution that has accompanied their diversification.

12.6.7. Towards a new taxonomy for the cetrarioid lichens (Parmeliaceae, lichenized ascomycetes)

I. Kärnefelt, A. Thell;
The Botanical Museum, Lund, Sweden.

The monophyletic group of cetrarioid lichens is phylogenetically analysed using molecular data from three gene regions, nuclear ITS rDNA, betatubulin and GAPDH sequences, together with traditional structural characters and secondary chemistry. The genera, Ahtiana Allocetraria, Arctocetraria, Cetrariella, Flavocetraria, Tuckermanella and Vulpicida, are nested within the three large cetrarioid genera Cetraria, Nephromopsis and Tuckermannopsis. A monophyletic clade of three Tuckneraria species, T. ahtii, T. laureri and T. pseudocomplicata, and 'Cetraria' leucostigma and 'C.' melaloma is nested within Nephromopsis. The status of the genus Tuckneraria, and other segregates within the group, is discussed and different alternatives to solve the taxonomy of the cetrarioid lichens are presented. A brief historical outline and a list of genera and species in current use is presented.

12.7.1. Dating the divergence of angiosperm radiations: progress and prospects

C. D. Bell;
Xavier University of Louisiana, New Orleans, LA, United States.

Integrating these fossils into the tree of living angiosperm taxa remains essential for understanding both the origin of extant angiosperms and the origins of morphological features. Such attempts at integration have been rare for any group of organism; there has been surprisingly little communication between paleobotanists and systematists. We will explore the ways in which angiosperm fossils have been integrated into the phylogenetic framework with extant taxa, with the ultimate goal of forming a comprehensive phylogenetic tree of living and fossil angiosperms. We envision several components for discussion (theoretical and empirical) during this symposium, including: critical evaluation of the fossil record and appraisal of the age of fossils for major clades of angiosperms; construction of a morphological data matrix for fossils and extant angiosperms and the assessment of confidence in fossil placements; integration of fossils into the angiosperm tree with molecular data; exploration of the effects of missing data; and methodologies for the estimation of divergence times.

12.7.2. Dating the Marsileaceae: evolutionary and biogeographical implications

N. Nagalingum[1], K. M. Pryer[1], H. Schneider[2], M. D. Nowak[1], D. Hearn[1], R. Lupia[3];
[1]Duke University, Durham, NC, United States, [2]Albrecht-von-Haller Institute of Plant Sciences, Goettingen, Germany, [3]Sam Noble Oklahoma Museum of Natural History, and School of Geology and Geophysics, Norman, OK, United States.

Marsileaceae is a heterosporous fern clade of about 60 semi-aquatic species in three distinctive genera (*Marsilea*, *Regnellidium*, *Pilularia*). *Marsilea* is by far the most diverse genus (>50 species) and has a cosmopolitan distribution, yet species-level relationships within the genus have been virtually unknown. Here, we present results from the phylogenetic analysis of a six-locus data set of coding and non-coding regions from the plastid and nuclear genomes of Marsileaceae. The fossil record has preserved a rich history of these ferns, mostly in the form of spore microfossils, indicating that Marsileaceae are relative newcomers that diversified during the Cretaceous (ca. 144 mya), at the same time as flowering plants. By integrating critical microfossils as age constraints, we are able to use our molecular data set to determine divergence time estimates for the intergeneric splits and for extant Marsileaceae species. Our phylogenetic hypothesis of extant taxa also serves as an explicit framework to reconstruct the biogeographical history of this group and its putative radiations in Africa and the Americas.

12.7.3. Integrating fossils into molecular phylogenies: examples from Early Cretaceous angiosperms

J. A. Doyle;
University of California, Davis, CA, United States.

Use of fossils to calibrate molecular divergences requires close attention to the concepts of crown group and stem lineage and cladistic analysis of morphology. Synapomorphies seen throughout a crown group provide only a minimum age for its stem lineage; synapomorphies of an extant subgroup are needed for a minimum age of the crown group. Fossils with both crown-group synapomorphies and more plesiomorphic states represent stem relatives; they do not indicate whether the crown group had evolved. Among Cretaceous relatives of Chloranthaceae, *Couperites* fruits with *Clavatipollenites* pollen may be nested within the family or stem relatives. Albian fruits with *Asteropollis* pollen provide evidence for the *Hedyosmum* line and a minimum age for the family, but crown-group *Hedyosmum* may be younger. Barremian-Aptian tetrad pollen can be linked with Winteraceae, but its finer sculpture indicates it is a stem relative. Barremian-Aptian tricolpate pollen may represent crown or stem eudicots, but Albian *Nelumbites* and *Sapindopsis* clearly belong to the crown group (Proteales). Because of its dense record, tricolpate pollen may provide a maximum age for crown eudicots.

12.7.4. Alternatives to the use of fossils for estimation of divergence times.

J. E. Richardson;
Wageningen University, Wageningen, The Netherlands.

The integration of fossil data into phylogenetic trees reconstructed using DNA sequence data from extant taxa is one way of estimating divergence times in these phylogenies. Many recent studies have employed this mode of calibrating phylogenies and have greatly enhanced our understanding of the timing of diversification in angiosperm lineages. However, this approach may be prone to error because of the difficulty in assigning fossils to nodes in the phylogeny and only providing minimum age estimates. Dates obtained by calibrating trees using fossils should ideally be corroborated with evidence from other sources. For some lineages the fossil record is so poor that there is no opportunity to utilize a fossil as an internal calibration point. Constraints on ages could also be based on tectonic events or dispersal of taxa to volcanic oceanic islands of known age. Alternatively, one could utilize the range of published substitution rates for a particular gene and apply these taking into account possible generation time effects. These alternatives are discussed with respect to examples in Rhamnaceae, Annonaceae and mimosoid legumes.

12.7.5. Patterns and rates of evolution in land plants: Fast vs. slow evolving genes.

K. W. Hilu[1], S. Magallon[2], D. Quandt[3];
[1]Virginia Tech, Blacksburg, VA, United States, [2]Universidad Nacional Autónoma de México, Mexico City, Mexico, [3]Technical University Dresden, Dresden, Germany.

Understanding relationships among major clades of land plant provides a solid framework to evaluate rate of phylogenetic splitting and molecular evolution. Here, we examine the impact of mode and rate of gene evolution on phylogenetic reconstruction and estimation of lineage divergence times across land plants. A sample spanning all major extant land plant clades was examined using sequences of slow evolving (atpB, psaA, psbB, rbcL) and rapidly evolving (matK, trnL) plastid genomic regions. Using methods that account for molecular rate heterogeneity, we evaluate effect of fast and slow genomic regions and different optimization criteria on phylogeny reconstruction and divergence time estimation, and compare rates of molecular evolution of these genomic regions across land plants. Our results show good congruence in phylogenetic relationships derived from fast and slow regions, and provide a general overview of the time of origin and diversification of major land plant clades.

12.7.6. Divergence times of phylogenetically basal eudicots

C. Anderson[1], K. Bremer[2], E. Friis[3];
[1]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden, [2]Stockholm University, Stockholm, Sweden, [3]Department of Palaeobotany, Swedish Museum of Natural History, Stockholm, Sweden.

A molecular dating of the phylogenetically basal eudicots (Ranunculales, Proteales, Sabiales, Buxales and Trochodendrales sensu APGII) has been performed using several fossils as minimum age constraints. We have sampled all rbcL sequences available in GenBank for the taxa in focus. Dating was done using Penalized Likelihood, and compared with NonParametric Rate Smoothing. We show that choice of method and fossil constraints has a great impact on the age estimates, and that it is important to use several fossil constraints to yield good age estimates. We discuss the 14 fossils we have chosen to include in this study and present a critical review of other fossils potentially useful in dating studies within the basal eudicots. Our results suggest a rapid diversification during the Early-mid Cretaceous, with all the lineages of basal eudicots emerging during the latest part of the Early Cretaceous. The age of Ranunculales was estimated to 120 myr, Proteales to 119 myr, Sabiales to 118 myr, Buxales to 117 myr and Trochodendrales to 116 myr.

12.7.7. Supertrees, supermatrices and a dated phylogeny of all palm genera

W. J. Baker[1], C. B. Asmussen[2], M. W. Chase[1], J. Dransfield[1], F. Forest[1,3], N. W. Uhl[4], V. Savolainen[1];
[1]Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom, [2]Royal Veterinary and Agricultural University, Copenhagen, Denmark, [3]South African National Biodiversity Institute, Cape Town, South Africa, [4]Cornell University, Ithaca, NY, United States.

The prevalence of palms (Arecaceae/Palmae) in the fossil record has resulted in the frequent assertion that the family is an ancient angiosperm lineage. This perception is, in part, skewed by the fact that palms are especially likely to be successfully fossilised due to the toughness of their organs and has never been explicitly challenged, nor have the ages of the major lineages within the palm family been explored within a solid framework. We have built the first complete phylogenetic tree of all 187 genera of palms using both supertree and supermatrix approaches. Having optimised *rbcL* sequence data from all palm genera across the tree, we have made branches proportional to time using non-parametric rate smoothing and have calibrated the tree with well-authenticated fossils. We use this tree to determine whether or not palms are truly ‘ancient’ and to examine the time frames in which the major radiations of extant palms occurred. By comparing the dated tree with tectonic and palaeoclimatic evidence, we evaluate the constraints and opportunities that may have determined the diversification of the family.

12.8.1. Using phylogenies to realign taxa in an emerging new classification of Leguminosae.

G. P. Lewis;
Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

The Leguminosae currently comprises 727 genera in 36 tribes. A decade of molecular phylogenetic study by several research groups around the globe has led to a substantial advance in the higher level systematics of the legumes and to the construction of a supertree of the family. Many genera and suprageneric groups, as traditionally circumscribed, are not monophyletic. Realignments of a significant number of these are, however, now strongly supported by the accumulating data. Legumes of the World (Lewis, Schrire, Mackinder & Lock, in press) is an illustrated encyclopaedic account of all legume genera placed in a phylogenetic framework. The volume uses published phylogenies to support taxonomic realignments that update the classification of Polhill (1994) presented in the Phytochemical Dictionary of the Leguminosae, and presents hypotheses of relationship for further testing. It also paves the way towards a radical new legume classification.

Examples of the major repositionings of taxa based upon recent phylogenetic research will be presented, together with the implications for the longer term restructuring of the whole family: from genus to subfamily.

12.8.2. Early floral development in Papilionoideae and its phylogenetic interpretation

G. Prenner;
Institute of Plant Sciences, Graz, Austria.

Early floral development of Papilionoideae was studied using scanning electron microscopy, and showed that organ initiation is more diverse than thought until now. While previous studies suggest that floral organs arise uniformly unidirectional from the abaxial towards the adaxial side of the flower, recent observations show variability in this respect. Besides unidirectionality, organ initiation was found to be either sequential, simultaneous, 'modified unidirectional' or bidirectional. Other outstanding features in the papilionoid floral development are initiated but early suppressed bracteoles, and the asymmetric androecium, in which the adaxial antepetalous stamen is formed out of the median plane. While the distinct asymmetry of mature flowers of some Papilionoideae (e.g., *Vigna caracalla*) is a character of the late floral development, androecial asymmetry is already found in early developmental stages. Using molecular phylogenies, I present a first attempt of a phylogenetic interpretation of the different modes of organ initiation as well as a discussion of the systematic relevance of early and late papilionoid asymmetry.

12.8.3. Phylogenetic analysis of floral ontogenetic and molecular characters in the Caesalpinioideae: insights into floral evolution in the basal Leguminosae

A. Bruneau[1], B. B. Klitgaard[2], M. Fougère-Danezan[1,3], S. C. Tucker[4];
[1]Université de Montréal, Montréal, PQ, Canada, [2]The Natural History Museum, London, United Kingdom, [3]Université Paul Sabatier, Toulouse, France, [4]University of California, Santa Barbara, CA, United States.

The paraphyletic basal subfamily Caesalpinioideae comprises 161 genera and 3000 species, and includes some of the most diverse legumes in floral morphology. Recent molecular analyses suggest phylogenetic relationships that question previously held ideas about trends in legume flower evolution. We present a phylogenetic analysis of ~ 70 floral ontogenetic and morphological characters for over 50 representative species of caesalpinioid legumes. The floral characters are combined with *trn*L, *trn*L-F and *mat*K cpDNA sequences. Resolution among major lineages is obtained mostly from the molecular data, but morphological characters help resolve relationships within some clades. Our analyses suggest that bracteole and hypanthium morphology at initiation and maturity are phylogenetically informative and thus under evolutionary constraint, while reduction in petal and stamen numbers occurs in parallel in several clades, suggesting evolutionary lability. Zygomorphy is expressed as a multitude of homoplasious morphs, providing conclusive evidence that the suite of characters that makes up zygomorphy cannot serve as indication of phylogenetic position.

12.8.4. The evolution of bird pollination in Australian pea-flowered legumes

M. D. Crisp, L. G. Cook;
Australian National University, Canberra, Australia.

The papilionoid legumes appear to be ancestrally bee-pollinated and a specific trigger mechanism has been demonstrated in some. In Australia, native bees in several families have been observed as the main or only visitors to pea hosts. Bird-pollinated species are known in multiple genera and tribes and it appears that bird-pollination has arisen several times independently from bee-pollinated ancestors. Comparative analysis of molecular phylogenies will be used to test the hypothesis that bird-pollinated taxa are derived from bee-pollinated ancestors. We will also examine (1) whether the timing of pollinator switches is consistent with the availability of pollinators through the Cenozoic; (2) whether switches to bird-pollination have triggered radiations; (3) whether morphology is a reliable guide to pollination 'syndrome'; (4) whether independently evolved bird-pollination syndrome characters differ; and (5) whether bird-pollination is related to community type.

12.8.5. Evolutionary radiations in the Mimosoideae (Leguminosae)

M. Luckow[1], J. T. Miller[2], D. J. Murphy[3], R. Jobson[1];
[1]Cornell University, Ithaca, NY, United States, [2]Biology Dept., 138 Biology Building, University of Iowa, Iowa City, IA, United States, [3]School of Botany, University of Melbourne, Parkville, Victoria 3052, Australia.

A phylogeny of the legume subfamily Mimosoideae was constructed using molecular data from four chloroplast gene regions (*ndh*F, *mat*K, *trn*L-F, and *trn*K) and morphological characters. This phylogeny is used to examine patterns of evolution in the Mimosoideae. Based on rates of character change, there appear to be several rapid bursts of evolution, correlating with both morphological innovations and habitat shifts. The first radiation represents a shift from rainforest habitats to seasonally dry forests and is presumed to be relatively old as generic-level diversity is high. The second radiation is correlated with reintroduction to the tropical wet habitat as well as movement into southeast Asia. This second burst is presumed to be of more recent origin, exhibiting high levels of species diversity within a few large genera. A shift in chromosome number from x=13 to x=14 seems to be highly correlated with the first radiation event, as do morphological characters such as armature and habit.

12.8.6. Phylogeny, gene duplication, and polyploidy in legumes

J. J. Doyle;
Cornell University, Ithaca, NY, United States.

Polyploidy results in simultaneous apparent duplication of all genes, and thus shapes both individual gene families and whole genomes. Comparison of nuclear and chloroplast gene phylogenies provides reciprocal illumination: individual nuclear gene orthologies can be hypothesized, while the overall pattern provided by chloroplast genes can be corroborated with independent data. Orthologous nuclear genes can then be used to as a source of variation for phylogeny and for comparative mapping of divergent taxa, both of which are relevant for understanding the evolution of polyploidy. The existence of many pairs of homoeologous genes with similar divergence values produces a genomic signature for inferring polyploid events unrecognized from chromosome number alone. Gene family phylogenies can be used to test whether ancient polyploid events were shared among taxa such as *Glycine* and *Medicago*, whose common ancestor was the progenitor of about half of all papilionoid diversity. Phylogenies of nuclear and chloroplast genes within these two genera are keys to understanding patterns of allopolyploidy and autopolyploidy, respectively.

12.8.7. Newly recognised succulent biome: key to the origin and global distribution of Leguminosae?

B. D. Schrire[1], M. Lavin[2], G. P. Lewis[3];
[1]Royal Botanic Gardens, Kew, Richmond, surrey, United Kingdom, [2]Montana State University, Bozeman, MT, United States, [3]Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

Four global biomes predictive of legume distributions are delimited. These include a newly recognised Succulent Biome. A supertree of Leguminosae constructed from existing molecular phylogenies, is converted to a taxon-biome tree by superimposing the biome affinities of c. 730 legume genera. Vicariant analyses are then used to detect a generalised pattern of biome relationships for legumes. A Tertiary Laurasian, rather than Cretaceaous Gondwana, hypothesis for the origin of Legumes is supported both phylogenetically and by fossil evidence, and this is consistent with a Tethys Seaway-wide ancestral distribution, associated with tropical seasonally dry forest. A dry origin for legumes is in accordance with key morphological synapomorphies, a high nitrogen metabolism and the underpinning of the Succulent Biome diagnosing the major nodes in the phylogeny. Tropical wet Rainforest Biome taxa are now shown to be primarily derived from dry biome taxa. The ages of a range of trans-continental legume crown clades show a largely Neogene to Quarternary bias, supporting dispersal rather than vicariance as a predominant explanation for legume distributions.

12.9.1. 30 years of studies in the family Piperaceae

R. Callejas[1], M. A. Jaramillo[2];
[1]Universidad de Antioquia, Medellin, Colombia, [2]Jardin Botanico rio de Janeiro, Rio de Janeiro, Brazil.

Here I explored the taxonomic history of the Piperaceae (black pepper family), starting with F.W. Miquel«s Systema Piperacearum in 1843-1844 through C. de Candolle posthumous key in 1923, and W. Trelease & G. T. Yuncker's monographic treatments for the Neotropics between 1950-1970. Contrasting views on classificatory schemes for Piperaceae proposed by those authors are examined for *Piper* and *Peperomia*, in particular for Paleotropical species of the former genus. A brief account of the importance of sampling, and adequate collections in Piper is provided and a preliminary scheme of classification is proposed for the genus, which takes into account recent phylogenetic analysis, but also data from floral structure and development. Finally I explore the use of tree architecture, seed coat structure, and stem anatomy, characters until now rarely used in Piper for solving the taxonomy of species complex.

12.9.2. Molecular evolution of the matK/trnK region (cpDNA) and evolution of Piperales

S. Wanke[1], T. Borsch[2], M. A. Jaramillo[3], C. Neinhuis[1];
[1]Institut für Botanik, Dresden, Germany, [2]Nees Institut für Biodiverstität der Pflanzen, Rheinische Friedrich-Wilhelms-Universität Bonn, Germany, [3]Laboratorio de Biologia Molecular de Plantas, Universidade Federal do Rio de Janeiro, Brazil.

Piperales (about 3500 species) is one of the largest orders within basal angiosperms. The matK gene and the non-coding trnK intron of some 100 species within Piperales and several outgroups have been sequenced. All families (except Hydnoraceae) and all genera (except Euglypha) are represented. The analyses resulted in maximal support for all major nodes and new insights into the relationships within Piperales. Parsimony and Bayesian inference are highly congruent. The matK/trnK region is widely known for its good phylogenetic signal and its wide range of utility in reconstructing relationships. In most cases, compared to other common regions, this is based on different evolutionary processes on the molecular level. A wide range of micro structural changes (microsatellites, inversions, frame shift mutations and indel events) is discussed as well as the utility in phylogenetics.

12.9.3. Hydnoraceae and its systematic affinities with Piperales

D. L. Nickrent[1], A. Blarer[2];
[1]Southern Illinois University, Carbonale, IL, United States, [2]Institute of Systematic Botany, Zurich, Switzerland.

In a previous investigation, the holoparasitic Hydnoraceae clade (Hydnora, Prosopanche) was placed within Piperales; however, its exact affinity remained unresolved. More recently, a data set of 6 genes (nuclear, chloroplast, mitochondrial) for three outgroup and 16 Piperales taxa was constructed. Branch and bound analysis gave one tree with relationships fully resolved for Piperaceae (5 genera) and Saururaceae (4 genera). In contrast, the Aristolochiaceae (4 genera), Lactoridaceae (Lactoris) and Hydnoraceae clades remained unresolved, even when faster-rate parasites were removed. Aristolochiaceae is composed of two strongly supported clades: Asarum plus Saruma (Asaroideae) and Aristolochia plus Thottea (Aristolochioideae). A sister relationship between Hydnoraceae and the latter received moderate bootstrap support. Morphological divergence and branch lengths on molecular trees indicate a comparatively high degree of evolutionary change in this group, thus we recognize four clades (families): Aristolochiaceae s. str., Hydnoraceae, Lactoridaceae, and Asaraceae.

12.9.4. Phylogenetic relationships of Aristolochiaceae subfamily Aristolochioideae based on molecular and morphological data.

F. Gonzalez[1], S. Wanke[2], C. Neinhuis[2];
[1]National University of Colombia, Bogota, Colombia, [2]Technical University of Dresden, Dresden, Germany.

Recent morphological and molecular studies revealed that the subfamily Aristolochioideae (Aristolochiaceae) has a much more complex internal structure than that suggested by traditional systematic treatments. Based on a representative sampling, a combined molecular and morphological dataset was analysed to clarify the phylogenetic relationships. *Thottea*, a small genus of Asian shrubs branches first, followed by *Isotrema* occurring in Asia as well as North and Central America. The next clade, *Pararistolochia*, from tropical rain forests of Africa and New Guinea, is sister to an extended genus *Aristolochia*. The latter contains two monophyletic clades: pentandrous species from Central America (*Einomeia*) and a group representing mediterranean and paleotropical species (*Aristolochia* s. str.). Their phylogentic position will be dicussed with respect to paraphyletic Central- and South American hexandrous species.

12.9.5. Studies in *Peperomia* (Piperaceae): insights from molecular and morphological approaches

M. Samain[1], L. Vanderschaeve[1], G. Mathieu[1], S. Wanke[2];
[1]Ghent University, Gent, Belgium, [2]TU Dresden, Dresden, Germany.

With approximately 1500 valid species (3000 described), the genus *Peperomia* is one of the largest genera of the Angiosperms. As a result of this huge number of taxa and because of the difficult synonymy, the actual taxonomic knowledge of the genus is quite chaotic. The current infrageneric classification includes some 400 species and is primarily based on fruit morphology. Most species descriptions after 1900 are written without reference to their subgeneric affiliation. Additionally, the monophyly of the infrageneric groups has never been tested.

The overall aims of our work are: 1) to gain insight into the infrageneric relationships based on molecular data from two genomes and morphology; 2) to produce an interactive key to the species via WWW; 3) to revise the genus *Peperomia*. Preliminary results do support the current infrageneric classification on section level but not on subgenus level.

12.9.6. A Phylogenetic Analysis of Canellaceae based on Morphology and DNA Sequences

J. Salazar[1,2], D. P. Little[3], K. C. Nixon[1], A. Jaramillo[4];
[1]L. H. Bailey Hortorium, Dept. of Plant Biology, Cornell University, Ithaca, NY, United States, [2]Departamento de Biología, Universidad Autónoma de Santo Domingo, Santo Domingo, Dominican Republic, [3]The New York Botanical Garden, Institute of Systematic Botany, Lewis B. and Dorothy Cullman Program for Molecular Systematics, New York, NY, United States, [4]Universidade Federal de Rio de Janeiro, Rio de Janeiro, Brazil.

Canellaceae is a small (22 species, 6 genera), tropical and subtropical plant family of aromatic trees (rarely shrubs) found in the Americas, eastern and southern Africa, and Madagascar. Canellaceae traditionally has been used for medicine and other purposes owing to their volatile oils. Most species of Canellaceae are threatened because they are locally or regionally rare, overexploited by humans, or their habitat has been destroyed. A phylogenetic analysis was conducted using morphological data and chloroplast gene sequences. Twenty-one species were sampled_including several undescribed species from Brazil, Costa Rica and the Antilles. The results of this analysis indicate that Canellaceae is monophyletic and sister to Winteraceae. The monophyly of Canellaceae is supported by many characters including monadelphous stamens and parietal placentation. Within Canellaceae, *Pleodendron*, *Cinnamosma*, and *Warburgia* were resolved as monophyletic. However, *Cinnamodendron* was placed in two separate clades, representing a South American group with bicarpellate flowers and few ovules, and an Antillean clade with tetracarpellate flowers and many ovules.

12.10.1. The essential features of CO_2 concentrating mechanisms in plants.

S. von Caemmerer;
Research School of Biological Sciences, Australian National University, Canberra, Australia.

The inefficiencies of C_3 photosynthesis are largely due to the bifunctional enzyme Rubisco. Rubisco has a poor affinity for CO_2 and O_2 acts as a competitive substrate. The oxygenation reaction necessitates the recycling of phosphoglycolate with consequent loss of CO_2. Some photosynthetic organisms have developed ways to increase CO_2 concentration at the site of Rubisco, allowing the enzyme to operate closer to its maximal carboxylation rate and this also reduces oxygenation. The C_4 pathway, with its complex combination of biochemical and morphological specialisation, is an excellent example of such a CO_2 concentrating mechanism. A mathematical model of single cell C_4 photosynthesis with a focus on CO_2 diffusion is used here to explore the key parameters necessary to make the C_4 pathway function efficiently. Attempts are being made to introduce C_4 photosynthetic characteristics into C_3 crop plants by genetic manipulation. The modelling examines the theoretical efficiency of such a photosynthetic CO_2 pump, using available data on CO_2 diffusion characteristics of C_3 leaves.

12.10.2. Single-cell C4 photosynthesis in *Hydrilla*: unraveling key components for a transgenic C4 rice plant

G. Bowes, S. K. Rao, J. B. Reiskind, G. M. Estavillo;
University of Florida, Gainesville, FL, United States.

An understanding of the facultative C_4 system in the monocot *Hydrilla verticillata* can aid the development of transgenic C_4 rice plants because its C_4 and Calvin cycles operate in series in the same "C_3" cell, without Kranz anatomy. Cytosolic PEPC is segregated from rubisco and the decarboxylase NADP-ME in the chloroplasts, where CO_2 is concentrated. Multiple isoforms of PEPC and NADP-ME exist in *Hydrilla*, but *hvpepc4* and *hvme1* encode proteins with characteristics specific to C_4 photosynthesis. CA is also up-regulated in C_4 leaves, presumably in the cytosol to aid PEPC fixation, but we speculate it may be down-regulated in C_4 chloroplasts. Its role and sites(s) are under investigation. To avoid photoinhibition and maintain a favorable NADPH/NADP$^+$ ratio in C_4 leaf granal chloroplasts we postulate OAA (possibly aspartate) is translocated and reduced to malate for decarboxylation. A search for differentially-regulated translocators is ongoing. A preliminary differential display identified about 60 differentially-regulated genes in C_4 *Hydrilla* leaves; 13 were confirmed by northern/RT-PCR analyses. Supported by USDA/CSREES/NRI No. 2002-35318-12540.

12.10.3. Single-cell C4 photosynthesis in terrestrial plants

E. V. Voznesenskaya[1], V. R. Franceschi[2], G. E. Edwards[2];
[1]V.L. Komarov Botanical Institute, RAS, St. Petersburg, Russian Federation, [2]Washington State University, Pullman, WA, United States.

Recently, existence of a unicellular C_4 photosynthesis mechanism was proven for terrestrial Chenopodiaceae species, *Borszczowia* and *Bienertia,* with two unique anatomical subtypes. In *Borszczowia*, organelles are partitioned towards the proximal and distal ends of elongated chlorenchyma cells which function analogous to mesophyll and bundle sheath cells, respectively, in Kranz type NAD-malic enzyme (ME) C_4 species. In *Bienertia*, the peripheral cytoplasm with chloroplasts is connected by cytoplasmic channels to a central cytoplasmic compartment in the center of the vacuole, with numerous chloroplasts and mitochondria which are shown to function analogous to mesophyll and bundle sheath cells, respectively, in classical NAD-ME type. Our results show two chloroplast types with dimorphism in structure, starch storage, and photosynthetic enzymes. This includes location of pyruvate,Pi dikinase in chloroplasts associated with capture of atmospheric CO_2, and compartmentation of chloroplasts containing Rubisco and ADPG pyrophosphorylase along with mitochondria containing NAD-ME and glycine decarboxylase, where C_4 acids donate CO_2 to the C_3 pathway.

12.10.4. Introducing C4 photosynthesis into rice

M. Miyao-Tokutomi, H. Ohkawa, Y. Taniguchi, H. Tsuchida, H. Fukayama;
National Institute of Agrobiological Sciences, Tsukuba, Japan.

C_4 plants have a number of advantages, including high photosynthetic performance and high nitrogen- and water-use efficiencies. To transfer C_4 traits to C_3 plants, enzymes involved in the C_4 photosynthetic pathway were overproduced in the mesophyll cells of rice leaves. Each of four C_4 enzymes, namely, the maize phospho*enol*pyruvate carboxylase (PEPC), the maize pyruvate, orthophosphate dikinase (PPDK), the maize NADP-malic enzyme (NADP-ME), and the sorghum NADP-malate dehydrogenase (NADP-MDH), were successfully expressed at high levels in transgenic rice leaves. Overproduction of any of PEPC, PPDK, and NADP-MDH did not significantly affect either photosynthesis or growth of rice plants, while that of NADP-ME led to serious stunting and leaf photobleaching. Such detrimental effects of the maize NADP-ME could not be overcome by co-overproduction of PEPC, PPDK, NADP-MDH, or a combination of the three. Thus, the rice NADP-ME was adopted instead of the maize enzyme. Quadruple transgenic rice plants had been produced and their homozygous lines are now being analyzed.

12.10.5. Expression of cyanobacterial *ictB* in higher plants enhanced photosynthesis and growth

J. Lieman-Hurwitz[1], L. Asipov[1], S. Rachmilevitch[1], Y. Marcus[2], A. Kaplan[1];
[1]The Hebrew University, Jerusalem, Israel, [2]Tel Aviv University, Tel Aviv, Israel.

Under many environmental conditions plant photosynthesis and growth are limited by the availability of CO_2 at the site of RubisCO. We expressed *ictB*, a gene involved in HCO_3^- accumulation in *Synechococcus* PCC7942, in *Arabidopsis thaliana* and *Nicotiana tabacum*. The transgenic plants exhibited faster photosynthetic rates than the wild types (WTs) under limiting, but not under saturating CO_2 levels. Similar results were obtained in *Arabidopsis* plants bearing *ictB* from *Anabaena* PCC7120. Under low humidity, growth of transgenic *A. thaliana* plants was considerably faster than that of the WT. There was no difference in the amount of RubisCO or its activity (when activated *in vitro*) in the WTs and the transgenic plants. In contrast, the *in vivo* RubisCO activity, without prior activation, was considerably higher; and the CO_2 compensation points was lower in *ictB*-expressing plants than in their WTs. suggesting a higher CO_2 concentration in close proximity to RubisCO. This may explain the higher activation level of RubisCO and enhanced photosynthesis and growth in the transgenic plants. These data indicated a potential use of *ictB* for the stimulation of crop yield.

12.10.6. Glycolate oxidation in the chloroplast: A novel approach for the suppression of photorespiration.

R. Kebeish, K. Thiruveedhi, R. Rosenkranz, R. Bari, F. Kreuzaler, **C. Peterhänsel**;
RWTH Aachen University, Aachen, Germany.

In C3 plants, RUBISCO catalyses both the carboxylation and the oxygenation of Ribulose-1,5-bisphosphate. Carboxylation accounts for net CO_2 fixation whereas oxygenation leads to the loss of CO_2 in the photorespiratory pathway. CO_2 release in the mitochondria during photorespiration results in approximately 25 % loss of the carbon from phosphoglycolate. Moreover, NH3 is lost in this cycle that has to be refixed. Our project aims to introduce a novel method for the partial suppression of photorespiration in C3 plants. For this, a biochemical pathway from E. coli converting glycolate to glycerate was transferred to plant chloroplasts. In a first step, glycolate is oxidized to glyoxylate by a NAD(P)-dependent, but oxygen-independent Glycolate Dehydrogenase. Two molecules of glyoxylate are ligated to one molecule of tartronic semialdehyde (TS) under release of CO_2 that is immediately available for efficient refixation. TS is reduced to glycerate, a component that can be re-integrated into the plant basal metabolism. We will present data on the molecular and physiological characterisation of transgenic plants overexpressing the complete pathway.

12.10.7. Genetic manipulation of the photorespiratory C2 cycle

H. Bauwe, R. Boldt, K. van den Daele, C. Edner, Ü. Kolukisaoglu, A. Richter;
University of Rostock, Rostock, Germany.

The photorespiratory C_2 cycle is indispensable for higher plants to survive in an oxygen containing environment. Moreover, the C_2 cycle represents the major source of internal CO_2 release in C_3 plants and, in course of early C_4 plant evolution, it presumably provided a primary CO_2 concentrating mechanism. The biochemistry and cellular biology of the metabolic processes that make up the C_2 cycle is very complex and, despite long-term research efforts, not fully understood. Its analysis is further complicated by the fact that most of the C_2 cycle enzymes are encoded by gene families but only some by single genes. We will present results from an analysis of *Arabidopsis thaliana* T-DNA insertional mutants that are blocked in individual enzymatic steps including, for example, glycine decarboxylase and hydroxypyruvate reductase. In light of these new data, we will discuss some open questions and recent developments in our understanding of the C_2 cycle.

12.11.1. The role of terrestrial non-vascular vegetation in biosphere-atmosphere exchange

J. Kesselmeier;
Max Planck Institute for Chemistry, Mainz, Germany.

Huge areas of terrestrial surfaces are colonized by a microphytic covering, such as algae, cyanobacteria, bacteria, fungi, lichens and mosses, representing potential carbon sinks as they develop stable micro-vegetation canopies (biological crusts) if untouched. They often represent a dominant vegetation type in semi-arid environments with low primary production. Based on recent measurements in the Negev desert the contribution of biological soil crusts to the potential primary production ranges between 1-7 %. Emission of volatile organic compounds (VOC) between crusts and the atmosphere may contribute to a carbon loss and as well influence atmospheric chemistry and physics. Some VOC species as well as the reduced sulfur compound carbonyl sulfide (COS) are also deposited and consumed. The talk will cover some aspects of the biosphere-atmosphere exchange of carbon, reduced sulfur compounds and volatile organic compounds with particular respect to soil crusts, lichens and mosses.

12.11.2. Carbon sequestrations by Larch Forest Ecosystems

N. Liang, Y. Fujinuma, G. Inoue;
National Institute for Environmental Studies, Tsukuba, Japan.

We routinely measure net ecosystem exchange (NEE) with eddy covariance method at the larch forests in northern Japan, northeastern China and central Siberia. We also partition component CO_2 fluxes, i.e., by utilizing a 24-automated-chamber system for canopy foliage photosynthesis (GPP) and respiration (R_l), a 24-automated-chamber system for stem and branch respiration (R_w), and a 24-automated-chamber system for the understory carbon budget (i.e., 8 chambers for soil efflux, R_s; 8 chambers for heterotrophic respiration, R_h; and 8 chambers for vegetation photosynthesis, R_u). For a 50-year-old larch forest in Japan, three year (2001-2003) averaged NEE was -186 and -500 g C m^{-2} yr^{-1}, ecosystem respiration (R_e) was 1270 and 1095 g C m^{-2} yr^{-1} measured by closed-path and open-path eddy system, respectively. With the chamber approaches, GPP, NPP (net primary production), NEP (net ecosystem production) and R_s was estimated to be about 1275, 677, 130 and 960 g C m^{-2} yr^{-1}, respectively. R_l, R_w, Root respiration (R_r) and R_h was 110, 75, 413 and 547 g C m^{-2} yr^{-1}, witch contributed 8%, 6%, 32% and 43% of GPP, respectively.

12.11.3. *In-situ* emission measurements of volatile organic compounds (VOC) from biological soil crusts (BSC)

B. Wilske[1,2], D. Yakir[1], K. Maseyk[1], J. Burgheimer[3], A. Karnieli[3], E. Zaady[4], G. Schebeske[5], J. Kesselmeier[5];
[1]Department Environmental Sciences and Energy Research, Weizmann Institute of Science, Rehovot, Israel, [2]Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Menglun, China, [3]The Remote Sensing Laboratory, Jacob Blaustein Institute for Desert Research, Ben-Gurion University of the Negev, Sede Boqer Campus, Israel, [4]The Desertification and Restoration Ecology Research Center, Jacob Blaustein Institute for Desert Research, Ben-Gurion University of the Negev, Sede Boqer Campus, Israel, [5]Max Planck Institute for Chemistry, Biogeochemistry Department, Mainz, Germany.

Volatile organic compounds (VOC) emissions from biological soil crusts (BSC) were investigated in the Negev desert, Israel, using dynamic cuvettes on permanent soil borne collars. Air samples from BSC-/soil-enclosures were collected on carbo-cartridges. A gas chromatograph with flame ionisation detection (GC-FID) was used to analyse the samples for more than 20 VOC species including alkanes, isoprene, and terpenoids. Within most sample sequences the amounts of VOC were very variable or not different from reference measurements. However, some samples sequences with BSC showed significant emissions of VOC such as isoprene, octane, octanal, and 1-octen-3-ol. As a rough conclusion these first results of BSC's VOC exchange suggest that (1) their carbon loss due to VOC emission is mostly very low, and (2) significant VOC contributions to processes of biosphere-atmosphere exchange and atmospheric chemistry can be expected only for a limited part of their annual activity period.

12.11.4. Physiological analysis of response of mustard genotypes to sulphur nutrition

A. Ahmad, I. Khan, M. Iqbal;
Hamdard University, New delhi, India.

Sixteen mustard [*Brassica juncea* (L.) Czern. & Coss.] genotypes were grown hydroponically for 35 days in nutrient solution supplemented with 5 µM and 20 µM S, and analyzed for S use efficiency (SUE), plant S concentration and content, and the distribution of S between old and young parts of the shoot. There were marked differences in SUE among mustard genotypes. Pusa Bold was about 2-fold and 7-fold more S-efficient than Pusa Jai Kisan in whole shoot and young-part based SUE, respectively. Interestingly, the older portions of the shoot for most genotypes had higher dry matter production under S deficiency than under sufficient S supply, suggesting that there was a significant inhibition of new shoot growth and transport of photosynthates from source to sink organs under low-S conditions. Sulphur concentrations of both old and young portions of the shoot did not correlate with SUE, but shoot S content was found to be significantly correlated with SUE. Furthermore, S-efficient genotypes distributed more S into young parts of the shoot under S-deficient conditions than did the inefficient lines.

12.11.5. The leaf water uptake role in the water economy of Amazonian tropical trees.

G. K. Cardinot[1], M. Z. Moreira[2], L. S. L. Sternberg[3], D. C. Nepstad[4];
[1]Federal University of Rio de Janiero/IPAM-Amazon Institute of Environmental Research, Belém, Brazil, [2]Centro de Energia Nuclear na Agricultura-Universidade de São Paulo, Piracicaba-São Paulo, Brazil, [3]Department of Biology, University of Miami, Coral Gables, FL, United States, [4]Woods Hole Research Center/IPAM-Amazon Institute of Environmental Research, Woods Hole, MA, United States.

Early studies have shown the importance of dew absorption by leaves in regions where fog is an important component. However, the importance of water uptake by leaves of trees in tropical forests has not been previously considered. We hypothesize here that leaf water absorption in tropical trees might be responsible for the drought tolerance exhibited by Amazonian forest trees. Application of deuterium (ǔD) labeled water and leaf water potential (Ɋ) measurements were carried out in 3 common primary forest tree species at Flona Tapajós (Pará State-Brazil): *Coussarea racemosa*, *Miconia egensis* and *Escheweilera pedicellata* to test whether their leaves or stems absorb water directly. Two leaf irrigation treatments were carried out: leaves were sprayed with ǔD water and branches were exposed to ǔD water (1m from tip) with a moist cotton band. The leaf water ǔD abundance in the sprayed leaves were significantly above background for all 3 species and followed the water potential response with species having the greatest Ɋ response also having the greatest ǔD abundance. These results confirm the role of water absorption by leaves in the recovery of water-stressed plants.

12.11.6. Long-term effects of short-term soil amendments in a sub-alpine grassland

T. Spiegelberger[1,2], O. Hegg[3], K. Hedlund[4], D. Matthies[5], U. Schaffner[1];
[1]CABI Bioscience Switzerland, Delémont, Switzerland, [2]University of Fribourg, Fribourg, Switzerland, [3]University of Bern, Bern, Switzerland, [4]University of Lund, Lund, Sweden, [5]University of Marburg, Marburg, Germany.

Many experiments in grasslands have shown that soil amendments such as fertilization can strongly affect vegetation and microbial composition, but there is a lack of long-term studies assessing over which period ecosystems will be able to recover, once the amendments have ceased. We studied in a controlled, large-scale field experiment in a subalpine pasture in the Swiss Alps the long-term effects of 2-4 years of NPK-fertilization and liming on vegetation and soil microbial communities. Nearly 70 years after the last application, liming still significantly affected vegetation composition and microbial community. The concentration of Ca-ions and pH was higher in limed plots, which was reflected by higher abundances of indicator plant species and PLFAs for low pH in the unlimed plots. We therefore propose that the observed changes in above- and below-ground communities were mediated through changes in soil pH. Our findings suggest that subalpine grasslands are highly sensitive to even short periods of disturbances, and that the recovery rate of certain ecosystem variables can be very low.

12.12.1. The terpene synthase gene family: Tools for ecological and evolutionary studies and metabolic engineering

J. Gershenzon[1], D. Tholl[1,2], E. Pichersky[3], J. Degenhardt[1];
[1]Max Planck Institute for Chemical Ecology, Jena, Germany, [2]Virginia Tech University, Blacksburg, VA, United States, [3]University of Michigan, Ann Arbor, MI, United States.

The remarkable abundance and diversity of terpenoid metabolites in plants and their increasing commercial importance as flavors, fragrances, pharmaceuticals and agricultural compounds have stimulated research on this enormous group of phytochemicals. The incredible skeletal diversity of terpenes is largely due to a major group of enzymes known as the terpene synthases. We are employing genetic and genomic tools to study the terpene synthase genes of Arabidopsis, maize and other species. Sequence comparisons, functional characterization and gene expression studies along with profiling terpene metabolites have provided new information about the ecology, evolution and distribution of terpenes in these species. One striking conclusion is that, although monoterpene (C_{10}) and sesquiterpene (C_{15}) formation in plants was once thought to be associated solely with specialized oil cells, ducts, trichomes or secretory cavities, low levels of these compounds are probably universally emitted in the headspace.

12.12.2. Gain and loss of fruit volatile terpenoids produced by wild and cultivated strawberry species

A. Aharoni[1], A. P. Giri[2], F. W. A. Verstappen[2], C. M. Bertea[2], R. Sevenier[2], M. A. Jongsma[2], W. Schwab[2], H. J. Bouwmeester[2];
[1]Department of Plant Sciences, The Weizmann Institute of Science, Rehovot, Israel, [2]Plant Research International, Wageningen, The Netherlands.

The molecular mechanisms that fruit flavors are gained and lost during evolution and domestication are largely unknown. While the terpenoid profile of cultivated strawberry species is dominated by linalool and nerolidol, fruit of wild strawberry species emit mainly carvyl acetate and myrtenol which are not detected in the cultivated species. Through cDNA microarrays and PCR we cloned genes responsible for the biosynthesis of these terpenoids. Detailed characterization of the different terpene synthases unraveled molecular evolutionary mechanisms which might explain the differences in the volatile terpene profile between wild and cultivated strawberry species. The loss of one metabolite further influenced the fruit flavor as it was no longer available as substrate for the downstream production. This was demonstrated by cloning and characterization of a cytochrome P450 gene, encoding the enzyme catalyzing the C10 hydroxylation of Ŭ-pinene to myrtenol, a typical wild strawberry compound.

12.12.3. Characterization of geraniol synthase and geraniol dehydrogenase, the enzymes responsible for the formation of citral in the glands of sweet basil

Y. Iijima, E. Fridman, E. Pichersky;
Molecular, Cellular, and developmental Biology, University of Michigan, Ann Arbor, MI, United States.

The monoterpene fraction of the lemon-scented sweet basil (*Ocimum basilicum*) cv. Sweet Dani consists mostly of citral (a mixture of geranial and neral), with lower levels of geraniol and nerol. These compounds are stored in glands found on the leaf epidermis. Geraniol synthase (GES) activity, generating geraniol from geranyl diphosphate, was shown to be localized exclusively or almost exclusively to glands. A GES cDNA was isolated based on analysis of a glandular trichome EST database, and the sequence of the protein encoded by this cDNA shows some similarity to sequences of other terpene synthases. We have also isolated a basil cDNA encoding NADP-dependent geraniol dehydrogenase (GEDH) and characterized the enzyme it encodes. GEDH is capable of oxidizing geraniol and nerol in equal efficiency. Prolonged incubation of geraniol with GEDH *in vitro* produces not only geranial and its *cis*-isomer neral, but also nerol. The reduction of neral (which is likely produced by keto-enol tautomerization of geranial) by GEDH explains the small amounts of nerol found in basil glands, since no enzyme is known to catalyze the formation of nerol directly from geranyl diphosphate.

12.12.4. The terpene synthase family in *Zea mays* and its role in defense against herbivory

J. Degenhardt, T. G. Köllner, C. Schnee, J. Gershenzon;
Max Planck Institute for Chemical Ecology, Jena, Germany.

Terpenes constitute the largest group of plant products and display an extreme chemical diversity. In an effort to understand the genetic and molecular basis of terpene diversity as well as the ecological function of the complex terpene blends, we started to study maize terpene biosynthesis. We identified a large and diverse gene family encoding terpene synthases which each form multiple terpene products from a prenyldiphosphate substrate. Comparison of the terpene synthase *in vitro* activities with the terpene blends released by maize plants indicates that five differentially regulated multiproduct terpene synthases are sufficient to produce the complex maize sesquiterpene hydrocarbon blends. The characterization of structure-function relationships between the terpene synthases TPS4 and TPS5 revealed that the formation of products with stereospecific differences is determined by only four amino acids. Further mechanisms increasing the diversity of maize terpene biosynthesis are based on the allelic distribution of active and inactive enzymes in maize lines. We are currently evaluating the ecological role of specific terpenes in maize defense.

12.12.5. Unraveling the wizardry of terpene biosynthetic enzymes

J. Chappell[1], S. Takahashi[1], B. Greenhagen[1], Y. Zhao[2], P. O'Maille[3], J. Noel[3], R. Coates[2];
[1]University of Kentucky, Lexington, KY, United States, [2]University of Illinois, Urbana, IL, United States, [3]Salk Institute, San Diego, CA, United States.

Many plants respond to pathogen attack by the synthesis and secretion of anti-microbial compounds. For example, solanaceous plants produce anti-microbial terpenes that inhibit germination and growth of several fungal species. The production of these chemicals has been interpreted as an important defense response. We have also hypothesized that an understanding of the mechanisms responsible for the biosynthesis of the anti-microbial terpenes should provide a means for engineering the generation of novel and more efficacious compounds. Towards that goal, we have elucidated a 2-step biosynthetic pathway for capsidiol, an anti-microbial sesquiterpene di-alcohol. The pathway consists of a synthase that catalyzes the cyclization of farnesyl diphosphate to a bi-cyclic hydrocarbon structure, followed by the action of a P450 hydroxylase that introduces hydroxyl functions with stereo- and regio- specificity. Using several different approaches, we have mapped functional features of the respective enzymes, and used this information to evolve novel catalytic activities for the generation of unique chemical entities.

12.12.6. cDNA isolation and functional expression of Linalool Synthase from *Nicotiana alata*

C. Ganz, B. Piechulla;
University of Rostock; Dept. of Biological Sciences, 18059 Rostock, Germany.

Flowers of *Nicotiana alata* (Solanaceae) emit a broad range of volatile organic compounds (VOCs), comprising primarily mono- and sesquiterpenes and aromatic esters. Linalool, an acyclic monoterpene, is a major component emitted from *N.alata* flowers during the night. A cDNA encoding a monoterpene synthase was isolated via RT-PCR from petals. The nucleotid sequence of this terpene synthase consists of 1629 bp encoding a protein of 542 amino acids. The protein sequence is similar to other monoterpene synthases from different plant families. The heterologous expression of the tps clone allowed purification and characterization of this enzyme. It converts geranyl diphosphat into linalool and is therefor designated Linalool Synthase (LIS), although the protein shows highest identity at the amino acid level to an Ŭ-terpineol synthase from *Vitis vinifera*. The *lis* gene is only expressed in petals and anthers, not in other flower and plant tissues. High transcript levels during night correlate with the nocturnal emission.

12.13.1. 'Green' fingerprints of climate change

G. Grabherr[1], **G. Walther**[2];
[1]Institute of Ecology and Conservation Biology, Vienna, Austria,
[2]Institute of Geobotany, Hannover, Germany.

Climate is a major determinant for the phenology, physiology, distribution and interactions of plants. With the world's recent increase in global average temperature, these processes are supposed to be affected in a perceptible way. An ever increasing number of recently published studies strongly suggests that the last thirty years of warmer temperatures have had a substantial influence on seasonal patterns and the distribution of plants and vegetation types. Common features of such "green" fingerprints of climate change are presented and discussed in terms of its implications for community structure, trophic interactions and ecosystem consequences. Though climate impact research has made some progress, it still suffers from the lack of long time series of standardised observations. There is an urgent need to establish global networks for ground based ecological monitoring such as GLORIA, the Global Observation Research Initiative in Alpine environments.

12.13.2. global change and the bioclimatology of grasses pollination optimum

P. Comtois, B. Escamilla-Garcia, C. Bapikee;
University of Montreal, Montreal, PQ, Canada.

Grasses are the most cosmopolitan allergophytes. A large part of aerobiological researches have been devoted to produce forecasts using regression analyses between daily airborne pollen counts and meteorological factors. However, in these studies, the bioclimatology and eco-physiology of Grasses pollination were forgotten. By studying the aerobiology of Grasses pollen in Montreal for the past 19 years we were able to show that both seasonal total and maximum daily value (/m3) presented a decreasing trend, which could be correlated to a similar trend for rain fall, putting some doubt to the popular belief that global change will induce more allergy symptoms. By drawing frequencies curves of pollen abundance for different meteorological condition categories, we were able to visualize Grasses pollen behaviour: with temperature, the profile was negatively asymmetrical, meaning that, in Montreal, there is always a deficit of temperature for Grasses pollen; for relative humidity and wind speed, the profile was symmetrical, meaning that both have specific optimum; while for rain, it was parabolic, both arms representing rainout and washout processes.

12.13.3. Changing vegetation patterns at the alpine-nival ecotone of the Eastern Alps - the last 10 years on Mount Schrankogel/Tyrol

H. Pauli, M. Gottfried, K. Reiter, C. Klettner, G. Grabherr;
Universität Wien, Institut für Ökologie und Naturschutz, Wien, Austria.

Comparisons of historic data with records from recent investigations provided evidence that vascular plant species richness has increased on high summits of the Alps during the 20th century. This upward migration of alpine plants was most likely caused by the observed climate warming since the 19th century. Stimulated by these finding, an extensive monitoring network of 1000 one-square metre permanent quadrats was established on Mount Schrankogel in the Tyrolean central Alps at altitudes between 2900 and 3450 m a.s.l. in 1994. In 2004, a representative selection of 400 of these 10-year-old plots were re-investigated. Some pioneer species of alpine grassland were remarkably expanding or have established at new sites, while others have disappeared or showed a decreased cover. The extent of changes appeared to be dependent on the topographic position and thus on the snow cover duration.

12.13.4. Climate change and its impact on cloud forests: Fire as a major determinant in the subalpine zone of Kilimanjaro

A. Hemp;
Dept. of Plant Physiology, University of Bayreuth, Bayreuth, Germany.

The vanishing glaciers of Kilimanjaro attract broad interest. Less conspicuous but ecologically far more significant is the associated increase of frequency and intensity of fires on the slopes of Kilimanjaro, which lead to a downward shift of the upper forest line by several hundred meters as result of a drier (warmer) climate since the last century. During the last 70 years Kilimanjaro has lost nearly half of its forest cover, in the upper areas caused by fire, on the lower forest border mainly caused by clearing. The loss of 150 km2 of cloud forest - the most effective source in the subalpine fog interception zone - caused by fire during the last three decades means a considerable reduction in water yield. In contrast to common belief, global warming does not necessarily cause upward migration of plants and animals. On Kilimanjaro the opposite trend is under way, with consequences more harmful than those due to the loss of the showy ice cap of Africa's highest mountain.

12.13.5. Plant and environment in the subnival belt of the Caucasus

G. Nakhutsrishvili;
Institute of Botany of the Georgian Academy of Sciences, Tbilisi, Georgia.

Subnival belt (2900-3700 m) is quite well formed in Georgia. It is distinguished by high degree of endemism (including generic endemism) compared with the Alps. It is also distinguished by participation of Caucasian-West Asian geographic elements. Plants are distributed sporadically in the subnival belt in a form of separate individuals as well as nanocoenoses. The facilitation phenomenon is a feature of the belt, i.e. plants typical of the subnival belt shelter plants of other belts. Observations made with the support of the GLORIA-EUROPE project have shown that there are two tendencies of plant adaptations to severe winter conditions: plants protected by snow cover and plants without snow cover. We suggest that the latter must be connected in part with the global warming, considering that upper borders of distribution of certain species have already ascended by approximately 50-80m.

12.13.6. Climate change and its impacts: facts and fiction

L. Nagy[1], S. Dullinger[2];
[1]McConnell Ecological Research, Edinburgh, United Kingdom, [2]VINCA - Institut für Naturschutz und Ökologie, Vienna, Austria.

Much of current thinking about global warming and its environmental impacts is based on assumptions and computer models. These assumptions and model outputs are carried forward as facts into successive cycles of research through scientific publications and form the basis for training new generations of scientists. Whilst accepting that science is not about finding the truth but about testing hypotheses by the application of scientific methods, foremost logic, it is argued that uncritical acceptance of 'computer output reality' is counterproductive to progress. A critical overview is presented of evidence-based vs. assumption- and computer simulation-based research on the impacts of climate change (temperature warming, changing precipitation) and nutrient input from atmospheric deposition on alpine plants and ecosystems. Following a discussion of the characteristics of alpine habitats and the ecological principles governing species co-existence, conclusions from field observations, experiments, historical evidence and model predictions are compared.

12.13.7. Short-time effects of simulated climate change on epiphytic communities of tropical cloud forest

J. H. Jacome, M. Kessler;
Albrecht von Haller Institute of plant science. Department of Systematic Botany, Göttingen, Germany.

In order to address how climate change might alter epiphyte communities in tropical cloud forests and if this response will take place at community or specific level, we transplanted complete epiphytic bryophyte communities in the Bolivian Andes. We moved 60 branches with epiphyte communities from 3000 m to 2700 m and 2500 m, simulating temperature increases of 1.5ºC and 2.5ºC. Controls were transplanted at 3000 m. On each branch we recorded the cover of each species at the start and after a year, and calculated Sorensen`s similarity values comparing the composition across time. Communities moved to lower elevations changed faster than communities at their original elevation. At specific level, some species increased while others decreased. According to these results, it is possible to suggest that epiphyte communities may be already reacting to climate change and that future community composition will depend on the individual response of each species.

12.14.1. The past, present and future of botanic gardens

D. Gibbs[1], P. Wyse Jackson[1,2];
[1]Botanic Gardens Conservation International, Richmond, United Kingdom, [2]National Botanic Gardens, Glasnevin, Dublin 9, Ireland.

The reasons for establishing and the primary objective of botanic gardens have evolved and changed over time: from early European university teaching and research gardens to economic trade focused gardens of the colonial era to today's diversity of missions and objectives. The last fifty years have been marked by a period of remarkable growth in the number, the role and the distribution of botanic gardens. The BGCI *Garden Search* contains online information on over 2,400 botanic gardens operating in 167 countries today.

The *International Agenda for Botanic Gardens in Conservation*, developed by BGCI and the botanic garden community, provides a global framework for the development of individual garden's strategies within a common goal of stemming the loss of biodiversity. It is the *International Agenda* and the *Global Strategy for Plant Conservation* that will help shape the future of botanic gardens. Through the GSPC, botanic gardens have an opportunity to play an important role in connecting work on biodiversity conservation to the issues of sustainable development, the alleviation of poverty and achievement of the Millennium Development Goals.

12.14.2. The International Association Of Botanic Gardens

J. Hernández Bermejo;
IABG, Jardín Botánico de Córdoba, Córdoba, Spain.

Since its independent constitution in 1981, IABG has represented a basic structure with continental networks, promoting the European-Mediterranean association in Hamburg 1982, and the Asiatic one in Nanjing 1988. In the Nancy Conference (1984), IABG and IUCN did not find an effective mechanism for conservation cooperation, so IUCN promoted its BGCS, later the independent BGCI. In Wuxi, China (1993), BGCI and IABG signed an agreement to promote common initiatives, congresses and workshops. IABG did never try to organize a formal membership but is devoted to promote new networks. It always kept a message, including not only conservation but also social commitment and natural and cultural heritage. IABG and BGCI lead their actions towards this last line in the core of the EU, and created the European Consortium. In Barcelona 2004, IABG endorsed the Spanish network document "*Botanic Gardens: an increasing value*", and encouraged the UNESCO recognition of a World Day of Botanic Gardens.

12.14.3. The history, conservation challenges and future tasks of the Botanical Garden at National Museum of Natural Science, Taichung, Taiwan

S. Chiu[1], T. Yang[1], C. Peng[2,1], C. Li[1];
[1]Department of Botany and Botanical Garden, National Museum of Natural Science, Taichung, Taiwan Republic of China, [2]Institute of Botany, Academia Sinica, Taipei, Taiwan Republic of China.

The Botanical Garden at National Museum of Natural Science carried out the design and the plan in March, 1994 and was opened to public in July (established by January,) 1999. It includes a 4.5-ha open field for the varied and representative native vegetations at the low altitude of Taiwan, a 33 m tall hexagonal climatron for displaying the tropical rainforest, an exhibition greenhouse for ferns or special floral exhibits, the nursery area for conservation as well as research, and the herbarium (TNM) for specimens. Due to the roles of this Garden containing recreation, conservation, education, exhibition, public service and research, it combines the great challenges to fulfill all the missions and achievements. In passing 5 years, over 1,800 species of growing plants, 200 species in seed banks, 20 special exhibits, 3 symposia, 100 educational events and achieving 110,000 specimens. The optical daily records exceeded 5000 visits per day for special exhibit in January 2005. The future perspectives crucially focus on the management of species diversity, recording phenology, conservancy projects, exhibit improvement and institutional cooperation.

12.14.4. Developing an action plan for Fushan Botanic Garden, Taiwan--- A dream for people who appreciate biodiversity

W. Chiou;
Taiwan Forestry Research Institute, Taipei, Taiwan Republic of China.

The Fushan Botanic Garden (FBG), located in northeastern Taiwan and occuping1097 ha, was established in 1990 and opened to the public in 1992. The FBG is established mainly for conservation, education, and research. This report aims to develop an action plan for FBG to implement these objectives. SWOT analysis was used to develop this action plan. To achieve the conservative objectives, FBG should enhance the communication with the local government and aboriginal people; monitoring populations of vulnerable plants; prioritize, collect, grow, and display the conserved plants; integrate the *in* and *ex situ* conservation actions. To achieve the education objectives, FBG should enhance the volunteer's organization; train the guiders of travel agencies; promote the awareness of the importance of biological diversity to visitors, students, teachers, policy makers, and staffs through plant display, proper interpretation, and symposium or workshop; involve school teachers and experts to develop adequate education programs. The action plan should also be evaluated after a period of time to ensure their feasibility.

12.14.5. Innovation of site layout for *ex-situ* conservation in botanical gardens

S. He[1], X. Li[2], H. Yu[3], Y. Gu[1];
[1]Nanjing Botanical Garden, JP & CAS, Nanjing, China, [2]Nanjing Agricuture University, Nanjing, China, [3]Nanjing Botanical Garden, JP & CAS and Nanjing Agriculture University, Nanjing, China.

In Nanjing botanical Garden there was a *Taxus chinensis* living collection of only 11 individuals, 5 male and 6 female, introduced in 1950's. After 45 and more years a new population of 461 plants originated from the collection occurred in the neighboring natural woods. Among all individuals 23 plants were more than 2 m high in 1999. Based on this fact and similar appearance of some other species authors suggested that small *ex-situ* conservation collection can developed into a new and large population if the integrate ecological conditions, environments with rich biodiversity in both physical and biological aspects, are provided. The current living collections in botanic gardens are basically or totally under cultivated conditions and they are substantially *ex-situ* cultivation but not *ex-situ* conservation because of lacking of appropriate ecological conditions. So that the layout of *ex-situ* conservation site should be changed and a site mixed with cultivated land and wild field is needed. It could bring about a revolutionary reform in botanic gardens.

12.14.6. The botanical gardens in Kew and Vienna and their role in scientific biodiversity research to provide tools for conservational decisions on Meliaceae (mahogany family)

A. N. Muellner[1], R. Samuel[2], M. W. Chase[1];
[1]Royal Botanic Gardens, Kew, Surrey, United Kingdom, [2]University of Vienna, Vienna, Austria.

Pantropical Meliaceae (order Sapindales) have overwhelming economic and scientific-medicinal importance in both Europe and the USA, and one quarter of their species are listed as "threatened" in the IUCN 2003 Red List and are key target taxa in campaigns of international conservation groups. Taxonomic boundaries at and above species level in the family are, however, still largely unclear. Collections and expertise at the botanical gardens in Kew and Vienna provide valuable background for a project on Meliaceae and their links to conservation. We present the objectives and first results of the two-year (2004-2005) EU project "Threatened Biodiversity in Meliaceae: Urgent Need for a New Taxonomic Framework for Conservation" currently underway at RBGK. The project focuses on *Aglaia* (Southeast Asia, Australia and Pacific islands) and *Cedrela* (Central and South America). Objectives include contributing to the clarification of taxonomic delimitation at species level, creating the basis for setting up IUCN Red List assessments for target species, and evaluating hypotheses about the timing and causes of speciation.

12.14.7. International Plant Exchange Network (IPEN): A model for plant material transfer among Botanic Gardens

T. Helminger[1], W. Lobin[2], M. von den Driesch[2], F. Klingenstein[2], B. van den Wollenberg[3], M. Delmas[4], M. Kiehn[5], K. Laine[6], F. Schumacher[5], S. Waldren[7];
[1]Musée national d'histoire naturelle, Luxembourg, Luxembourg, [2]Botanische Gärten der Universität, Bonn, Germany, [3]Utrecht University Botanic Garden, Utrecht, The Netherlands, [4]Museum National d'Histoire Naturelle, Paris, France, [5]Botanischer Garten der Universität Wien, Vienna, Austria, [6]Oulu Botanic Gardens, Oulu, Finland, [7]University of Dublin, Botany Department, Dublin, Ireland.

Since the Convention on Biodiversity (CBD) asserted the sovereign rights of the countries over their genetic resources in 1992, Botanic Gardens that naturally depend on plant material transfer among each other face a completely new legal situation. The International Plant Exchange Network (IPEN), established by Botanic Gardens in order to comply with the CBD, covers only plant material transfer between Botanic Gardens and for non-commercial purposes. Botanic Gardens that want to join the network must adopt the IPEN Code of Conduct and use its common documents for plant material transfer. The benefit of participation in IPEN lies in the harmonized and simlified plant material transfer among members, without the need for individual material transfer agreements. Moreover the IPEN numbering system guarantees traceability and transparency: all plant material entering the network is given a unique and individual IPEN-number, containing the ISO-code of the country of origin and the acronym of the Botanic Garden introducing that plant material.

This Botanic Garden is obliged to keep record of all information regarding the origin of this individual accession.

12.15.1. Root system and water supply of plants in extremely arid conditions

I. O. Baitulin;
Institution of Botany and Phytointroduction, Almaty, Kazakhstan.

The plants of extremely arid regions have high absorb water properties of roots and water regulation by abilities. The roots of many hyperxerophytes has water reserve formation - root tubercle (Scorzonera pusilla Pall.), thickening (species of a Calligonum), sometimes such as a root crop (Ferula caspica M.B), develop plentiful quantity epemeral roots in the damp period, have abilities to absorb inter condensation moisture. Some kinds develop root system reaching up to a level of earth waters (Alhagi pseudoalhagi (M.B.)Desv.or up to the zone of their capillary raising (Ceratoides latens J.F.Gmel.), even overcoming dry horizonts of soil (Kochia prostrata L.Schrad). Species of plants, which roots do not reach these depths, have no a constant source of water supply during the whole period of the development, experience parched period and running in a status anabiosis or semianabiosis (species of a Artemisia from section Seriphidium).

12.15.2. Root growth and environment

L. Kutschera[1], I. Baitulin[2];
[1]Pflanzensoziologisches Institut, 9020 Klagenfurt, Austria, [2]Institute Botany & Phytointroduction, 480070 Almaty, Kazakhstan.

Field investigations on about 1.100 taxa showing morphology of the whole plant and on 900 showing anatomy of the root were done mostly in temperate zones of Europe including alpine regions, but also in subtropical and in desert areas outside Europe. Based on this the mechanism of geotropic growth was investigated by experiments in laboratory. The results are: The movement of water vapour by gravity inside and outside of plants is of great importance for their direction growth. Duhamel de Monceau explained this in 1758. The upward growth is connected with water supply for the elongation growth from inside, the downward from outside. Therefore the shoot covered with cuticula grows mostly upwards, the root without downwards. The root grows downwards, even in case of environmental resistance by higher and changing water supply, horizontally by less or constant water supply, and upwards by its lack. The root body is protected by root cap against too early water uptake. Due to environmental impact the root cap becomes often asymmetric. Consequently the uptake and loss of water including soluble substances within the root body are asymmetric too.

12.15.3. Structure of root endodermis within relationship between genetic and environment

A. Lux;
Faculty of Natural Sciences, Comenius University in Bratislava, Bratislava, Slovakia.

The endodermis is the most important part of the root cortex. The whole root cortex might be designated as a root buffer zone, especially under stress conditions. The endodermis, and to some extent the exodermis, represent apoplastic barriers. This function is a consequence of cell wall modifications in the first and the second developmental state. Improved technique for vizualization of endodermis was developed. The development of endo- and exodermis influences the ion uptake processes of the root. The relationship between the accumulation and translocation of, and sensitivity to, cadmium and endodermal anatomy exists in willow clones. Moreover, the proportion of root apoplastic barriers, exo- and endodermis to other root tissues is increased in clones with higher tolerance to Cd ions. Endodermis at the third state protects the stele and vascular tissues in older root parts, and its function is already mostly mechanical. The extensive impregnation of endodermal cell walls by silicon takes place in some species during this state. Endodermal silicification has an impact on cell wall extensibility and the role in drought tolerance in some species is also shown.

12.15.4. Globalization of root demographics and function

A. J. M. Smucker;
Michigan State University, East Lansing, MI, United States.

The functional dynamics of root growth and associated microbial contributions to nutrient and water uptake require additional comparisons of root demographics and their life spans within soil profiles across geopolitical boundaries. Root contributions of carbon into the soil matrix enhance soil aggregate strength and improve additional root growth. Combinations of these feed-back associations with functional root dynamics across multiple long term ecosystems would provide valuable belowground information when cataloged by multinational scientific teams who compare specific species across soil and climatic landscapes. Comparative root functions require similar sampling and analytical protocols before libraries of spatial variabilities across numerous ecosystems can be developed. Soil models and root image processing are poised to initiate evaluations of functional root dynamics across many geopolitical boundaries. This new global root knowledge would provide essential information needed to increase the production and sustainability of food and fiber and to quantify root contributions to terrestrial carbon sequestration on planet Earth.

12.15.5. Responses of roots to soil water: Scaling from individual roots to global rooting depths

H. Schenk;
California State University Fullerton, Fullerton, CA, United States.

Recent advances in research on gravitropic and hydrotropic root growth have allowed plant scientists to predict rates and directions of individual root growth and the spatial distribution of root systems, using data on the spatial and temporal distribution of soil water and using cost/benefit models of root growth. At a larger scale of populations and communities, optimization models that maximize plant water acquisition in the presence of root competition have yielded promising results. Insights gained from this research at smaller scales now allow us to scale up and predict global patterns of vertical root distributions. A simple soil-water balance model was used to successfully predict vertical root distributions under a wide variety of global vegetation types. The prediction that vertical root distributions are related to the soil water balance was further tested by using global root data sets to test for statistical relationships between rooting depths and seasonal patterns and long-term means of precipitation and evapotranspiration, as well as soil texture. The resulting empirical models were used to create global maps of predicted rooting depths.

12.15.6. The carbon cost of root function in boreal forests

H. Å. Persson;
Department of Ecology and Environmental Research, Box 7072,
Swedish University of Agricultural Sciences, 750 07 Uppsala, Sweden.

Studies on root biomass, growth and turnover are notoriously more difficult than studies of aboveground growth processes. Data from various European forest stands suggest annual turnover rates of 2-4 times the average fine-root biomass (see below). The root function is extremely costly and is enhanced by a high carbohydrate supply. The aboveground capacity to supply carbohydrates by photosynthesis governs the long-term root and mycorrhizal growth rate. Roots can grow in any direction even upwards (Kutschera et al. 2004). Roots occupying favourable soil regions tend to grow at the expense of others. Carbohydrates are stored at high levels in the fine roots; starch levels of 25-30% are frequently found. Tree roots can persist in the soil and survive for several years even when photosynthesis is restricted. References Kutschera L, Haas, D, Sobotik M. and Lichtenegger E (2004). 12.15.7. Effects of grazing on root biomass and demography in a Alpine grassland

S. Baronti[1], G. Lanini[1], F. Ponti[2], P. Stefani[3], A. Raschi[1];
[1]CNR, Firenze, Italy, [2]Università di Bologna, Bologna, Italy, [3]Università della Tuscia, Viterbo, Italy.

An experiment was undertaken to determine the effects of grazing on root production, mortality and decomposition in a mountain grasslands, and to assess the patterns of biomass allocation to roots under different environmental conditions and different management options. In fact, the vast majority of literature data concentrate on short-term studies and indicate that clipping consistently retards root growth; yet, field studies are few and contradictory, and tend to indicate that grazing has little effect on grassland belowground production. The experiment was conducted throughout a 1-year-period in a high mountain cow farm ("malga") in Trentino (Northern Italy), at a height of 1700 m a.s.l using minirhizotrons installed in soil. Fine root production and mortality varied seasonally, with greatest production in sprig and greatest mortality in winter. Root biomass was reduced sharply with depth and, in the ungrazed area, it was less abundant at the 5-10cm depth, and more abundant at 10-20cm, in comparison to the grazed area.

12.15.8. Development of roots of juvenile European Beech and Norway Spruce individuals under ozone stress in the crown and *Phytophthora citricola* infestation in the soil

G. Luedemann[1], R. Matyssek[1], F. Fleischmann[2], J. B. Winkler[3], T. E. E. Grams[1];
[1]Department of Ecology / Ecophysiology of Plants, Technische Universität München, Freising, Germany, [2]Department of Ecology / Pathology of Woody Plants, Technische Universität München, Freising, Germany, [3]Department of Environmental Engineering, National Research Center for Environment and Health, Neuherberg, Germany.

Root development is affected by air pollutants like O_3 and plant pathogen infections. Because plants respond to O_3 in a similar way as they respond to a pathogen attack, we hypothesised that juvenile beech and spruce under enhanced O_3 concentration are less susceptible to the root pathogen *Phytophthora citricola.* A two-year phytotron experiment was conducted with 32 planting containers, each hosting 10 beech and 10 spruce saplings. A natural climate was reproduced with ambient and twice-ambient O_3 regimes in combination with an inoculation treatment with *P. citricola*. Quantitative PCR was performed to verify infection. Root length, fine and coarse root biomass, tips per root length, root to shoot and fine to coarse roots relations were determined in beech and spruce to analyse effects by O_3 as well as the pathogen. Beech root development was reduced under enhanced O_3 or under *P. citricola* infection, but effects were not additive. Spruce root development was only reduced by combined stresses. We conclude that susceptibility to *P. citricola* under enhanced O_3 conditions is increased in spruce but decreased in beech.

12.16.1. The virtual information world: challenges for libraries

G. L. McDaniel;
New York Botanical Garden, Bronx, NY, United States.

Even while resources and access are expanding, librarians and information specialists face increasing challenges. The speaker will outline various types of electronic resources such as databases, electronic publications, scanned text and digitized herbarium specimens. Three main areas of challenges to libraries will be discussed: identifying and collecting electronic resources, providing access to the electronic resources for users, and preserving or archiving these resources. How can librarians find out what databases have been created or which texts have been scanned and converted into digital format? How can or should libraries provide access to these resources for their users? How do libraries ensure that once an electronic resource has been created users will always have access to it? What are some of the financial demands of handling electronic resources, and how can libraries manage these demands and maintain other library functions?

12.16.2. The African Plants Initiative: digitising and data-sharing through Aluka

S. Demissew[1], E. Nic Lughadha[2], G. Smith[3];
[1]Addis Ababa University, Addis Ababa, Ethiopia, [2]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [3]National Botanical Institute, Pretoria, South Africa.

The African Plants Initiative (API) is a new network of institutions holding important collections of herbarium specimens of African plants and related materials. API partners commit to database and produce high resolution images of all their type specimens pertaining to African plants in the first instance and selected additional material of particular interest, including species of economic importance and regional or local endemics as well as non-specimen resources such as illustrations, texts and archival materials. The network has grown rapidly since its inception in mid-2003 and now includes 24 partner institutions in 15 countries in Africa, Europe and the US. By January 2005, more than 44,000 African specimens had been digitised by API partners, and it is envisaged that the majority of the estimated 300,000 African types in herbaria worldwide will have been digitised by mid-2006. The materials will be made available collectively by Aluka, a new, not-for-profit initiative aiming to increase access to scholarly resources from the developing world, beginning in Africa, based on the successful model developed by J-STOR (http://www.jstor.org/).

12.16.3. Visual plants - a tool for local and web-based access to information of single images, specimen and species of plants

H. Dalitz[1], J. Homeier[2];
[1]Institute of Botany, Stuttgart, Germany, [2]Plant Ecology, GÃ¶ttingen, Germany.

Huge progress in biodiversity information systems on the web is evident and a very helpful source of information about specimen and species distribution. But access to the internet is still restricted to members of so-called developing countries. Visual Plants tries to fill this gap being an on-site tool for information retrieval and at the same time a web-based system. Information stored is hierarchically organized showing information for each single image, the specimen and the species. Additionally basic information about families is provided.
Visual Plants (visualplants.de) can be used as a tool for the visual determination of plants using basic (and mostly vegetative) characteristics of the specimen which is photographed in the field, scanned as fresh material or digitized as a herbarium specimen. It is already used in two research frameworks like the DFG funded research unit 402 "Functionality in a Tropical Mountain Rainforest: Diversity, Dynamic Processes and Utilization Potentials under Ecosystem Perspectives" (www.bergregenwald.de) and the BMBF funded framework BIOTA-East (www.biota-africa.org/1024/frames/biota-africa.htm).

12.16.4. The Solanum PBI project: taxonomy in the electronic information age

L. Bohs[1], S. Knapp[2], M. Nee[3], D. Spooner[4], J. Bennett[2], L. Walley[2], J. Clark[1,5];
[1]University of Utah, Salt Lake City, UT, United States, [2]Natural History Museum, London, United Kingdom, [3]New York Botanical Garden, Bronx, NY, United States, [4]University of Wisconsin, Madison, WI, United States, [5]Smithsonian Institution, Washington, DC, United States.

We have begun a multi-institutional, multidisciplinary project to complete a species-level treatment of the genus Solanum (Solanaceae) by the year 2008. Solanum, with approximately 1500 species, is one of the largest and most economically important plant genera (it includes tomato, potato, and eggplant, among others). Our project, funded by the NSF PBI (Planetary Biodiversity Inventory) program, provides species descriptions, interactive keys, a nomenclature index, a photo and illustration archive with images of type specimens, an illustrated glossary, and a searchable database of herbarium specimens for all taxa in the genus. This information is disseminated electronically on our Solanaceae Source website. This project will create a globally accessible information source that will link libraries, collections, and electronic resources containing Solanum data. Such virtual resources are the way of the future in taxonomic research, in which far-flung and historical sources of information are synthesized. We expect this project to provide a model for other large scale taxonomic endeavors and for the electronic distribution of biodiversity data.

12.16.5. The Biologia Centrali-Americana Centennial: a vision for digital access to taxonomic information

A. L. Weitzman[1], C. H. C. Lyal[2];
[1]National Museum of Natural History, Smithsonian, Washington, DC, United States, [2]Natural History Museum, London, United Kingdom.

A major problem for access to biodiversity information is the many forms and places where it is stored. While data standards for storage and exchange of taxonomic names and specimen data are relatively stable, literature is still generally not accessible electronically or, if it is, the format is not one that enables interoperability with other data types. Research and products of a wide variety are hindered by the lack of easy access to taxonomic literature. The BCAC project aims to create a model to resolve these issues. The project will make a major taxonomic resource for Mesoamerica, the 58 biological volumes of *Biologia Centrali-Americana*, available in JPEG and PDF formats on the web and as a fully searchable resource. The model will be appropriate for all taxonomic literature and will enable interoperability with specimen databases, taxonomic authority files, and other datasets made available on the web. In addition to integrating literature and other data sources, the method opens possibilities of generating further web products including checklists from multiple publications available in this form and a way of speeding production of taxonomic products.

12.16.6. PRISMA: Web integration of heterogeneous taxonomic information sources

W. Fajardo[1], E. Gibaja[1], F. Pando[2], R. Perez-Perez[1];
[1]University of Granada, Granada, Spain, [2]Real Jardin Botanico, CSIC, Madrid, Spain.

We will describe in this paper a tool developed to handle data for of heterogeneous sources. At present, there are number information sources which although having related contents are dealt with independently: on one hand, the GBIF initiative, which aims to provide access to data from a vast number of [sources/data providers] under a common format, has manage side-by-side data from different types of collections, observations, surveys , etc. On the other hand, organizations such as Species 2000 intents to provide the nomenclatural backbone to enable the users with road map to all those names those appear in the primary data sources. The integration of names, concepts and specimens / observations is one of the biggest challenges of the management of biodiversity data. In this contribution we tackle the problem using (multi-agent system, ontology, probabilistic approaches, etc) to provide to the user a way to obtain meaningful responses from distributed biodiversity information systems.

12.16.7. Creating a digital information environment for USDA plant germplasm collections

J. H. Wiersema[1], D. E. Herendeen[2];
[1]United States Department of Agriculture/Agricultural Research Service, Systematic Botany & Mycology Laboratory, Beltsville, MD, United States, [2]United States Department of Agriculture/Agricultural Research Service, National Agricultural Library, Acquisitions and Serials Branch, Technical Services Division, Beltsville, MD, United States.

A collaborative project between librarians and botanists in USDA to integrate or link USDA databases containing information on USDA germplasm accessions of agronomic and horticultural plants is underway. Databases to be integrated are the Germplasm Resources Information Network (GRIN) and AGRICOLA of the National Agricultural Library (NAL), with additional USDA resources also involved. GRIN contains essential data on nearly 500,000 accessions and over 40,000 species, including passport, evaluation, descriptive, and taxonomic data, and useful data on agricultural plants in general. AGRICOLA is a database of ca. 4 million agricultural citations created by NAL and its cooperators describing information encompassing all aspects of agriculture and allied disciplines. Two elements controlled in both datasets that form the basis for this integration are scientific names and plant introduction (PI) numbers. This cross-linkage provides benefits to both databases and their users, including an increased user base, tracking of germplasm utilization, direct access to needed bibliographic or taxonomic information, and improved taxonomic standardization.

12.17.1. A landscape approach to the study of gene flow in plant populations

V. L. Sork[1], D. Grivet[1], P. E. Smouse[2];
[1]University of California, Los Angeles, CA, United States, [2]Rutgers University, New Brunswick, NJ, United States.

Gene flow is a major determinant of plant genetic structure, and genetic structure analyses of plants at varying scales yield particularly useful insights concerning contemporary and historical gene flow. We will present a case study of wind-pollinated California valley oak, Quercus lobata, to illustrate several points about how to add a landscape perspective to population genetics. (1) We will examine contemporary pollen flow in Valley oak, using the TwoGener pollen pool structure method, and will test the assumption of isotropic pollen flow (no directionality), using spatial autocorrelation analysis. (2) We will deploy a seed pool structure analysis to identify the scale of contemporary seed movement, illustrating with seed transport by acorn woodpeckers. (3) We will use spatial autocorrelation analysis of adult Valley oak genotypes to estimate the scale of the historical neighborhood. (4) We will explain the spatial distribution of chloroplast microsatellite haplotypes in California valley oak with respect to historical patterns of colonization and seed movement. These studies illustrate the insight we gain by examining gene flow in real landscape.

12.17.2. landscape genetics on different scales of space and time

A. R. Templeton;
Washington University, St. Louis, MO, United States.

A new genetic variant initially exists in only one place at one time. DNA replication allows this variant to travel from one generation to the next and to spread through space. The strategies that work best in revealing how genes spread through space and time depend upon the spatial/temporal scale of the study. At small spatial scales, high levels of pre-existing genetic variation, such as those provided by microsatellites, are needed because the mutational process is not a major factor on a short time scale. Insight into the movement of genes through the landscape can be achieved by coupling microsatellite surveys with traditional population ecology studies. As the geographical and temporal scale of the study goes up, the mutational process becomes important, and phylogeographic approaches become increasingly informative. At intermediate spatial and temporal scales, both phylogeographic and microsatellite approaches are informative and complement each other. At the largest temporal scales, phylogeographic and coalescent approaches become the primary tools for analysis.

12.17.3. Genetic diversity and population structure of *Geum urbanum* L. (Rosaceae) in fragmented agricultural landscapes

C. Baessler, S. Klotz, W. Durka;
UFZ - Centre of Environmental Research Leipzig-Halle, Halle (Saale), Germany.

As a consequence of natural distribution of suitable habitats and anthropogenic fragmentation processes, many species occur in spatially structured populations. In the agricultural landscapes of Central Europe arable intensification resulted in major landscape transformations. Decreasing area of habitats and increasing isolation have severe effects on the viability of populations inhabiting the agro ecosystem. Avoidance of the unsuitable matrix and altered dispersal distances between habitat fragments may lead to increased inbreeding, thus to reduced genetic diversity.

We studied the population structure of *Geum urbanum* L. as influenced by land use intensification and landscape fragmentation by means of microsatellites. We compare genetic population structure with GIS generated landscape metrics. The survey was conducted in three differently structured landscapes of Germany. Despite being mainly self-pollinated, *G. urbanum* populations were genetically diverse, irrespective of population size. Populations where highly differentiated. Single events of long dispersal can be traced by multilocus genotypes found in different populations.

12.17.4. SSRs in fragmented *Primula vulgaris* populations indicate the importance of a network at landscape level on fitness

A. Van Geert, F. Van Rossum, K. Van Puyvelde, L. Triest;
Vrije Universiteit Brussel, Brussel, Belgium.

Primula vulgaris is a self-incompatible, perennial herb with two floral morphs: pins and thrums. In Flanders, (northern Belgium) the species is rare and declining. It is restricted to a network of fragmented populations in areas of intensive agriculture. Habitat fragmentation resulting from human disturbance reduces the size of populations and increases their isolation. The possible consequences are increased random genetic drift and inbreeding, and reduced gene flow between populations. This can lead to genetic erosion and increased genetic divergence between populations. We studied both adults and first year seedlings of *Primula vulgaris* populations for microsatellite loci at the landscape level. . The genetic differentiation between adults and seedlings, as well as the significant effects of population characteristics and of the surrounding network of populations on the genetic diversity and the fitness will be discussed.

12.17.5. Why are some plant species restricted to river corridors?

M. Burkart[1], V. Pasqualetto[2], M. van Kleunen[2], M. Fischer[2,1];
[1]Botanic Garden, University of Potsdam, Potsdam, Germany, [2]Institute of Biochemistry and Biology, University of Potsdam, Potsdam, Germany.

The restricted distribution of some plant species to river corridors (RC) has often been attributed to dispersal by water. Here, we present results showing that also soil and flooding conditions contribute to this distribution pattern. In a common garden experiment, we compared the performance of 18 species that are restricted to RC and 26 species that are not restricted to RC in NE Germany. Plants were grown in one non-RC (garden soil) and two RC environments (RC soil, flooding). The performance of all species was best in the non-RC environment. However, the performance of species restricted to RC was lower than the performance of the other species. This applied to both soil environments but the difference was less pronounced on the RC soil. Moreover, the species restricted to RC had a higher reproductive performance than the other species when they had been flooded. Our study suggests that one of the reasons that some species are restricted to RC is their competitive inferiority in non-RC environments but that in RC these species can compete successfully due to their better tolerance of RC-specific conditions.

12.17.6. Landscape genetics of *Stenocereus stellatus* (Cactaceae) in an edaphic cronosequence of Tehuacan-Cuicatlan Valley, Mexico

A. Cornejo[1], M. Martinez-Garcia[2], J. E. Campos-Contreras[2], A. Valiente-Banuet[1];
[1]Instituto de Ecologia, UNAM, Mexico, Mexico, [2]Facultad de Estudios Superiores-Iztacala, UNAM, Mexico, Mexico.

Genetic structure of *Stenocereus stellatus*, a columnar cacti with both sexual and asexual reproduction, in an edaphic cronosequence of Tehuacan-Cuicatlan Valley was analyzed. We tested whether, due to humidity gradient in the four soils: 1) the subpopulations were genetically differentiated and 2) clonal recruitment had affected spatial distribution of genotypes in arid soils. The analysis was made using 75 RAPD markers. AMOVA showed a significant genetic divergence between the two subpopulations of humid soils and two arid ones (ū $_{ST}$= 0.16, P < 0.001). Clonal recruitment determined the spatial distribution only in humid soils, according to isolation by distance model. Although the gene flow was high (Nm = 4.29), subpopulation divergence is probably due to seed recruitment through windows of opportunity as well as high recruitment of ramets in humid soils. Probably seed or ramets recruitments are not allowed in arid soils, long time ago. If the patterns of recruitment observed in humid soils occurred in the arid ones during the past, soils development could play an important role in the genetic structure and spatial distribution of genotypes of *S. stellatus*

12.17.7. Linking intra-specific diversity and habitat suitability - a case study using *Pinus cembra* L.

N. E. Zimmermann, F. Gugerli;
Swiss Federal Research Institute WSL, 8903 Birmensdorf, Switzerland.

Predictive habitat modeling is a means to explore the potential suitability of a landscape for a target species. By this, statistical models are formulated that allow expressing the suitability of any location in a landscape as a function of spatially explicit environmental predictors. We explore the potential of using habitat suitability of *Pinus cembra*, simulated as a function of proximal bioclimatic predictors, for explaining genetic diversity. We sampled 48 individuals at 20 locations throughout the Swiss Alps and assessed the number of chloroplast haplotypes per site, as well as the haplotypic diversity. We first analyzed the power of bioclimatic predictors to explain haplotypic diversity, and then we analyzed how much the predictive power changed when adding habitat suitability of *P. cembra* for explaining its local haplotypic diversity. We used ordinary least squares regression as well as generalized linear models. The statistical powers found may help to refine hypotheses of genetic diversity pattern as influenced by population processes and its effects on pollen and seed gene flow.

13.1.1. Molecular evolution of flower color determining genes: a model for the study of adaptive evolution

M. T. Clegg, M. L. Durbin, K. E. Lundy, D. M. Toleno;
University of California, Irvine, CA, United States.

The methodological difficulties associated with linking single gene change to adaptive phenotypic change are notorious, yet this is a central goal of evolutionary genetics. Flower color is a phenotype that simplifies many of these complexities. Well-established biochemical pathways and extensive molecular characterization of pathway genes illuminate some of the causal connections between genes and phenotypes. Flower color is also a trait that has a direct affect on reproductive fitness and is therefore likely to be subject to strong selection. A plant genus that exhibits a rich array of floral color adaptations associated with speciation is the morning glory genus (*Ipomoea*). We present a comparative analysis of gene expression for flower color determining genes and we consider patterns of molecular evolution for pathway genes. Shifts in flower color phenotype among closely related species are frequently associated with changes in the regulation of gene expression rather than mutations in structural genes. We also show that structural genes in the pathway exhibit complex shifts in rates of molecular evolution throughout the evolution of the genus *Ipomoea*.

13.1.2. Population genomic studies in *Arabidopsis* and rice

M. Purugganan;
North Carolina State University, Raleigh, NC, United States.

Population genomic analyses allow us to survey variation within genomes for evidence of selection, as well as to examine adaptation in a genomic context. High-throughput acquisition of sequence data, as well as the sequencing of entire plant genomes, has made population genomic approaches possible. We have been attempting to characterize the genetic basis of adaptation in Arabidopsis thaliana and Oryza sativa. Both of these selfing plant species have served as model genetic systems, and the availability of genomic resources in these species allow us to examine adaptation in a genomic context. This talk will discuss two studies. First, we will discuss a dissection of high-diversity genomic regions in A. thaliana, which may contain balanced polymorphisms. Second, we will examine levels and patterns of polymorphisms in the rice genome. Both these studies will illustrate approaches in identifying genomic regions that may contain genes underlying adaptive traits in plant species.

13.1.3. Gene expression variation in natural populations of *Arabidopsis*

U. Lagercrantz;
Evolutionary Functional Genomics, Uppsala University, Uppsala, Sweden.

The relative importance of changes in coding versus regulatory sequences in adaptation and evolution is still unclear. Partly for technical reasons, most experimental work has focused on changes in protein coding sequences, for which rigorous model-based testing has been developed. Still, changes in gene expression are likely to constitute an important component of phenotypic evolution. A challenge for future research is to characterise variation in gene expression within and between species, and the underlying variation in regulatory sequences. We have initiated microarray studies of gene expression variation within and between plant species in the Brassicaceae family, with the aim to quantify gene expression in natural populations, and to assess to what extent this variation is important for adaptation. We will present data on global transcriptome variation between populations of *A. thaliana* and *A. lyrata*, as well as between the two species. We are also searching for gene expression differences that are associated with variation in apparently adaptive phenotypic variation (i.e., variation in flowering time, cold acclimation and trichome density).

13.1.4. Sequence diversity in maize (*Zea mays* L.): transposable elements, regulatory variation and heterosis

M. Morgante[1], S. Radovic[1], S. Brunner[2], G. Pea[3], M. Pe'[3], A. Rafalski[2];
[1]Universita' di Udine, Dipartimento di Scienze Agrarie ed Ambientali, Udine, Italy, [2]DuPont Crop Genetics Research, Wilmington, DE, United States, [3]Università degli Studi di Milano, Dipartimento di Scienze Biomolecolari e Biotecnologie, Milano, Italy.

The extensive lack of collinearity among allelic maize genomic segments has recently been described. Two types of phenomena are responsible for this observation: presence/absence of LTR-retrotransposons and presence/absence of genic fragments. Retrotransposons that are not shared between inbred lines appear to have inserted into the maize genome significantly more recently than those that are shared, revealing an active movement of high copy number elements in very recent evolutionary times. The genic fragment polymorphisms are also due to recent insertions of non autonomous elements of the *helitron* class. It has often been postulated that transposable elements are still actively reshaping genomes: the maize genome is in constant flux in that transposable elements continue changing both the genic and non-genic fraction of the genome, profoundly affecting genetic diversity. In addition to the non colinearity we have detected extensive *cis*-regulatory variation in maize genes. We will discuss the implications of the allelic non collinearities for regulatory variation, heterosis and evolution of novel gene functions.

13.1.5. Genome-wide analyses of the evolutionary impact of transposable elements

D. R. Hoen, N. Juretic, T. E. Bureau;
McGill University, Montreal, PQ, Canada.

Once dismissed as purely selfish, the inherent ability of transposable elements to move and replicate enables them to participate in a variety of phenomena, from genome plasticity to new gene formation. As the single largest constituent of many genomes, investigations of transposons must often be conducted at genomic scales. We have undertaken large scale analyses of the genomes of several completely sequenced organisms, including rice and Arabidopsis. We review current understanding of transposons' role in evolution and describe challenges and rewards of genome-wide transposon studies. Challenges include devising methods to deal with the repetitive, diverse, and degenerate characteristics of transposons. Rewards include characterizing important evolutionary phenomena such as transposon-mediated gene duplication ("transduplication"), selfish gene "domestication", host gene capture, and phenotypic impacts of new insertions.

13.1.6. Opposing evolutionary dynamics on linked genes in a disease resistance pathway in wild tomato

L. E. Rose;
University of Munich - LMU, Planegg, Germany.

Understanding the evolution of genetic pathways requires investigating how selection is acting on each individual component of the pathway. I have investigated the selective forces which have shaped the evolution of two genes required for resistance to a bacterial pathogen of tomato, *Pseudomonas syringae* pv. *tomato* in a natural population of the self-incompatible tomato species, *Lycopersicon peruvianum*. The two genes are *Pto,* which has been identified as the receptor for the pathogen ligand, and *Prf,* which is closely linked and required for activating the resistance response once the pathogen has been detected. Of fifteen genes surveyed, *Pto* had the highest amino acid polymorphism, consistent with either relaxed selective constraint or the maintenance of amino acid variation by some form of balancing selection. In contrast, the low level of amino acid polymorphism at *Prf* is consistent with purifying selection operating at this locus. These results represent a first step towards understanding how potentially opposing selective pressures are reconciled at the molecular evolutionary level.

13.1.7. Molecular evolution of the gene NORK in the model legume *Medicago truncatula*: positive darwinian selection in a mutalism.

T. Bataillon[1,2], S. de Mita[3], J. Ronfort[3], S. Santoni[3], M. Maynadier[3], I. Hochu[4], J. Prosperi[3], A. Tsitrone[3];
[1]Bioinformatics Research Center, Aarhus C, Denmark, [2]INRA- UMR 1097 "Diversité & Génomes des Plantes Cultivées", Montpellier, France, [3]INRA-UMR 1097 "Diversité & Génomes des Plantes Cultivées", Montpellier, France, [4]INRA-UMR 1097, Montpellier, France.

Understanding the selective constraints of partner specificity in mutually beneficial symbiosis is a significant, yet largely unexplored, prospect of evolutionary genomics. These selective constraints can be explored through the study of nucleotide polymorphism at loci controlling specificity. The membrane-anchored receptor NORK (nodulation receptor kinase) of the model legume Medicago truncatula controls early steps of root infection by two symbiotic microorganisms: nitrogen-fixing bacteria and endomycorrhizal fungi. We analyzed the diversity of the gene NORK in a set of inbred lines sampled from natural populations. Tajima's D and Fay and Wu's H revealed no departures from the neutral model. We analyzed divergence using sequences from the closely related species M. coerulea and found an excess of non-synonymous changes contributing to this divergence. Maximum-likelihood analysis of a molecular phylogeny of legume species indicated that some sites, likely located in the receptor domain of the protein, evolved under positive selection. These results as well as patterns of linkage disequilibrium a region of ~120 kb flanking NORK will be discussed.

13.2.1. Epidermal patterning in *Arabidopsis*: Trichomes as a model

M. Hülskamp;
Botanical Institute III, Köln, Germany.

The spacing of trichomes in the leaf epidermis of Arabidopsis thaliana is a well-studied epidermal patterning system. The spacing of trichomes is established by a conserved gene casette consisting of a myb R2R3 factor, a basic helix loop helix factor and a WD40 protein. These proteins act together to promote trichome development and are counteracted by single-repeat myb factors that are believed to move between cells to mediate cell-cell interactions. The logic of the system is assessed by several approaches: First, the genetic interactions and the expression of the involved genes are analysed. Second, the promoters of positive and negative factors are compared to determine qualitative and quantitative differences. Third, the cell-autonomy is analysed using the Cre-Lox system. Forth, the relevance of the cell-autonomy or non-autonomy is tested by manipulating the autonomy of the individual proteins.

13.2.2. Integrating molecular systematics, morphology and anatomy towards understanding evolution of Kranz anatomy in the genus *Flaveria* (Asteraceae)

A. D. McKown[1], J. Moncalvo[2], N. G. Dengler[1];
[1]University of Toronto, Toronto, ON, Canada, [2]Royal Ontario Museum, Toronto, ON, Canada.

For most C_4 plants, Kranz anatomy represents a critical set of structural features that facilitates C_4 photosynthesis. Many studies describe Kranz anatomy; however, little is known how these anatomical characteristics have evolved in relation to each other and to C_4 biochemistry. One of the best models for studying C_4 evolution is the small New World genus *Flaveria* (Asteraceae) which includes C_3 and C_4 species, in addition to species classified as biochemically intermediate (C_3-C_4or C_4-like). To date, anatomical studies of *Flaveria* are limited and a complete phylogeny does not exist. We use molecular (cptrn L-F, nrITS and nrETS DNA sequences) and morphological data to reconstruct the phylogeny of *Flaveria*. We then mapped Kranz anatomy and vein pattern data from a comparative leaf anatomy study of *Flaveria* species (C_3, C_4, C_3-C_4, C_4-like) onto the phylogeny. The results indicate that C_4 (or C_4-like) photosynthesis has evolved independently within two clades of this genus. Moreover, these data suggest that evolution of Kranz anatomy traits proceeded in a step-wise manner within each clade.

13.2.3. Gilding the lily: the evolution and development of specialised petal cell shapes

B. J. Glover;
University of Cambridge, Cambridge, United Kingdom.

Specialised epidermal cells with particular forms interact to enhance the attractiveness of flowers to their pollinators. We have been working on the development of several specialised cell types in the Antirrhinum petal, which are linked through the activity of a small group of MYB transcription factors. We are now extending this work to investigate the evolution and development of specialised petal cell shapes in other species, including basal Angiosperm groups and species with a range of pollination systems, including buzz pollination. This work also involves assays of pollinator behaviour in response to different petal cell types. We have also recently begun work on the roles of specialized petal cells in producing the fly-mimicking “beetle spots” of *Gorteria diffusa*. These spots are composed of localised anthocyanin deposition and specialised papillate cell shapes.

13.2.4. Morphology of pumpkin leaf trichomes and their ecophysiological roles

D. Kolb, G. Zellnig, B. Zechmann, M. Müller;
Institute of Plant Sciences, Graz, Austria.

Plant trichomes are involved in a high number of different functions like secretion processes, control of water loss, protection from heat, etc; especially glandular trichomes show high functional amplitudes. Leaves of Styrian oil pumpkin (*Cucurbita pepo* L. var. *styriaca* Greb.) develop three glandular trichome types (I, II, IV) and one non-glandular (III) trichome.

The structural differences of these trichomes were studied by means of light and electron microscopy. Histochemical staining reactions and cadmium experiments were carried out in order to get more detailed information about the major functions and secretion processes of the trichomes.

The light microscopical data showed differences in the ontogenesis and histochemistry of the trichomes, as well as in the secretion processes. Ultrastructural analyses gave continuative information and indicated changes in the vacuolar deposition and altered plastids depending on the cell type and secretion stage. Treatment with cadmium did not induce ultrastructural changes and no indication for the involvement of these trichomes in detoxification processes could be found.

13.2.5. Regulation of egg cell identity in the female gametophyte of *Arabidopsis*

R. Gross-Hardt[1], C. Kägi[1], U. Grossniklaus[2];
[1]Center for Plant Molecular Biology (ZMBP), Tübingen, Germany,
[2]Institute of Plant Biology, Zürich, Switzerland.

In plants the egg cell is formed by a separate haploid generation, the female gametophyte. The female gametophyte of *Arabidopsis* develops from a single haploid spore. This spore divides mitotically to give rise to seven cells, one of which is the egg cell. We study the mechanisms that underlie the specification and regulation of egg cell identity. We made use of an egg cell specific marker line and screened for mutants with a deregulated expression of the egg cell marker.

The *lachesis* mutant expresses the egg cell marker ectopically in cells neighbouring the egg cell. Morphological, molecular and functional data indicate that the respective gene is necessary for restricting egg cell identity to the egg cell only. In addition, our data suggests that cell-cell communication is vital for the specification of different cell types in the female gametophyte. A phenotypic characterisation of the mutant and the potential function of the encoded protein will be discussed.

13.2.6. The role of spatial constraint on the ontogenesis of stomata: a case in Velloziaceae

M. M. Amaral[1,2], R. Mello-Silva[1,3];
[1]University of Sao Paulo, Sao Paulo, Brazil, [2]Fapesp, Sao Paulo, Brazil, [3]Fapesp/Cnpq, Sao Paulo, Brazil.

The stomatal types have long been used as characters in systematics. However, identical stomata can have distinct origin, and a similar ontogenetical pattern can form different stomata. Stomatal ontogenesis of four Velloziaceae species, *Nanuza plicata* and *Vellozia epidendroides* (tetracytic), and of *V. glauca* and *Barbacenia riparia* (paracytic), were investigated. The stomata follow the perigenic development. The subsidiary cells arise from oblique divisions of neighbor cells of the GMC, which are elongated parallel to the longer axis of the stoma. Polar cells show wide variation, following the shape and size of the epidermal cells in the vicinity, and so cannot be called subsidiary cells. High concentration of GMCs forces the development of short polar cells, leading to an apparently tetracytic stomata; low concentrations allow the elongation of the polar cells, thus leading to true paracytic stomata. The space available between the GMCs can interfere in the final configuration of the mature stomata. Therefore, the four species were considered braquiparacytic and the former stomatal classification in Velloziaceae must be questioned.

13.3.1. Processes of evolution in the flora of southern South America

B. B. Simpson[1], H. M. Meudt[2];
[1]The University of Texas, Austin, TX, United States, [2]Massey University, Palmerston, New Zealand.

The flora of southern South America has developed from indigenous elements, taxa that arrived from Australasia, Africa, or North America, as well as neotropical elements that moved into the high latitudes. The timing of the establishment of non-native taxa depended on the development of suitable habitats. Likewise radiations of non-native and indigenous taxa depended on the shifting patterns of geology and climate that determined the temporal and spatial patterns of the habitats we now see in southern South America. The relative importance of vicariance and dispersal as the factor determining the influx of taxa depended on habitat and to some extent life history. Recent molecular phylogenetic studies have shown that many of the elements in the southern flora are the result of radiations of native stocks but for herbaceous and shrubby taxa shared with Australasia, Africa, and North America, long-distance dispersal appears to have been the dominant mode of movement between areas.

13.3.2. Phylogenetic and biogeographic patterns in the endemic South American subtribe Myrciinae (Myrtaceae)

E. J. Lucas, E. M. Nic Lughadha, M. W. Chase;
Royal Botanic Gardens, Kew, Surrey, United Kingdom.

Myrtaceae distribution reflects ancient land links between Australia and South America, with centres of diversity on both continents. It has been proposed that Myrtaceae progenitors arose in Gondwana previous to the separation of Africa, radiating in what is now Australia. Subsequent land bridges joining Australia, Antarctica and South America allowed the family to extend its distribution to the latter continent. Phylogenetic relationships of Myrciinae (the only subtribe of Myrtaceae endemic to South America) reconstructed using *psbA-trnH*, ETS and ITS sequence data support this theory. Indications are that Australian taxa are sister to South American taxa while monophyletic Myrciinae is nested within the South American clade. Short branch lengths at generic and subtribal levels in Myrciinae suggest a rapid and early radiation in this group. Some genera difficult to assign to subtribe on account of their anomalous morphology have disjunct distributions restricted to a few temperate localities (e.g., on either side of the Andes and the Juan Fernandez islands). It has been suggested that these taxa are unspecialised early branches from Myrtaceae ancestors.

13.3.3. Speciation of *Hypochaeris* (Asteraceae) in South America: a model for continental adaptive radiation

K. Tremetsberger[1], T. F. Stuessy[1], C. M. Baeza[2], E. Urtubey[3];
[1]Department of Systematic and Evolutionary Botany, Institute of Botany, Vienna, Austria, [2]Departamento de Botánica, Universidad de Concepción, Concepción, Chile, [3]División Plantas Vasculares, Museo de La Plata, La Plata, Argentina.

The herb *Hypochaeris* (Asteraceae, Cichorieae) has diversified into c. 40 species in South America after dispersal from NW Africa in the Pliocene or Pleistocene. It has colonised all regions of the continent except the moist tropics, being found in subantarctic regions in Argentina and Chile northward into subtropical Brazil, and even further north into the high Andes as far as Venezuela. Species occur from sea level to more than 5,000 m in different habitats. Morphologically these species exhibit a wide variety of forms, ranging from large-leaved herbs 1 m tall to rosette-leaved species only a few centimeters high. Amplified fragment length polymorphism (AFLP) data help differentiate parallel lineages that have evolved rapidly in response to different ecological conditions. The pattern in *Hypochaeris* of South America, therefore, is of rapid speciation via adaptive radiation on a broad continental scale. The young age of the entire group (c. 1 million years) suggests that this radiation might also have been impacted by Pleistocene glacial cycles.

13.3.4. Nothofagus biogeography and the Gondwana break-up

A. Backlund[1], U. Swenson[2];
[1]Uppsala University, Dept. of Medicinal Chemistry, Div. of Pharmacognosy, Uppsala, Sweden, [2]Swedish Museum of Natural History, Botany Department, Stockholm, Sweden.

The break-up sequence of Gondwana played an important role for biotic distribution in the Southern Hemisphere, resulting in vicariance events. In vicariance biogeography, areagrams have been used in order to find and explain such events. Areagrams may also convey on biogeographic information to the extent that alternative and unsupported palaeogeographic hypotheses may be enforced as alternative area relationships. Extinctions and dispersals are biological realities, albeit often difficult to assess, that may unfortunately distort the biogeographic signal, leading to an incomplete description of past distribution, and subsequently flawed areagrams.

By reconciling phylogenies with hypotheses of area relationships and optimising fossil data on the reconstruction, hypotheses of vicariance, dispersals, and extinctions can be tested. Fossils then become indispensable tools as evidence of past distribution and shall not be underestimated. The only palaeogeographic hypothesis explaining Nothofagus known past and present distribution, including that in Antarctica, is the current accepted model of Gondwana break-up.

13.3.5. Genetic diversity and differentiation within and among Chilean populations of *Araucaria araucana* (Araucariaceae) based on AFLP markers and allozyme variability.

E. A. Ruiz[1], G. Fuentes[1], R. Samuel[2], F. González[1], C. Toores[1], M. Mardones[1], J. Becerra[1], T. Stuessy[2], M. Silva[1];
[1]University of Concepción, Concepción, Chile, [2]University of Vienna, Vienna, Austria.

Genetic diversity within and among Chilean *Araucaria araucana* populations was estimated using AFLP markers and allozyme variability. Both kind of data were congruent, indicating that *A. araucana*'s genetic variability is relatively high compared with other biologically similar species. Most of the total variation was nested within populations, but a considerable interpopulational variation was obtained. Intrapopulational variation was considerably higher in Coastal population. Populational differentiation was highest between the north Andean population and the remaining populations. The patterns of actual genetic variation could be influenced by historical factors such as tectonic and paleoclimatic changes that occurred in southern South America. Different areas in Coastal and Andes Mountain remained as refuge during the Pleistocene Glaciations. From these areas the glaciated surface was recolonized. We discuss about genetic variability from a conservation point of view for *Araucaria araucana* forest in Chile.

13.3.6. Biogeographic history of *Nothofagus*- the molecular story

M. Knapp[1], K. Stöckler[1], D. Havell[2], F. Delsuc[1,3], F. Sebastiani[4], P. J. Lockhart[1];
[1]Allan Wilson Centre for Molecular Ecology and Evolution, Institute of Molecular BioSciences, Massey University, Palmerston North, New Zealand, [2]Universal College of Learning, Palmerston North, New Zealand, [3]Département de Biochimie, Université de Montréal, Montréal, PQ, Canada, [4]Dipartimento di Biotecnologie Agrarie, Università degli Studi di Firenze, Firenze, Italy.

Southern Hemisphere biogeography is now dominated by many examples of transoceanic dispersal. Even within the genus *Nothofagus* (Southern Beeches), which has become iconic for ancient Gondwanan relationships that date back to the Cretaceous era, dispersal has been proposed for some species. This view is consistent with recent results from molecular clock analyses of Australian and New Zealand Southern Beech species. Nevertheless, different molecular clock divergence time estimates for South American and Australian *Nothofagus* lineages appear to be consistent with the timing of the break-up of Gondwana. This raises the possibility that at least some Southern Hemisphere relationships can be explained by vicariance. Thus our results indicate that the biogeographic history of Southern Beeches is more complex than envisaged under opposing polarised views expressed in the ongoing controversy over the relevance of dispersal and vicariance for explaining plant biodiversity.

13.3.7. Molecular phylogenetics and historical biogeography of *Oreobolus* (Cyperaceae)

J. Chacon[1], S. Madrian[1], M. W. Chase[2], J. J. Bruhl[3];
[1]Universidad de los Andes, BogotÃ¡, Colombia, [2]Royal Botanic Gardens Kew, London, United Kingdom, [3]University of New England, Armidale, Australia.

Nuclear ITS and plastid trnL intron and trnL-F intergenic spacer regions were sequenced for 13 species of Oreobolus (Cyperaceae) from throughout its distribution range (South America, Australasia, and Hawaii), plus the monotypic genus Schoenoides; Costularia laxa was used as outgroup. Phylogenetic trees were produced for the datasets separately, as well as combined. We estimated species divergence times by enforcing a molecular clock on the combined tree, using the appearance of O. furcatus in Hawaii, no earlier that 5.1 mya, as a calibration point. Our results support the monophyly of the South American species with the southern O. obtusangulus as sister to the rest. This South American clade is sister to the Australian O. pumilio, and the remaining Australasian and Hawaiian species form a basal grade. Schoenoides oligocephalus is embedded within Oreobolus. The topology of the combined analysis indicates a recent (5.5--6 mya) origin of the South American clade, followed by a northward biogeographical progression of species along the Andes.

13.4.1. Concepts matter: characters as units of evolutionary change

G. P. Wagner;
Yale University, New Haven, CT, United States.

If organisms would be completely integrated wholes, biology as an analytical science would not be possible. Perhaps even evolution by mutation and natural selection would be impossible. In this contribution I will be arguing that the existence of well defined, quasi-independent characters is as fundamental to biology as the existence of species. Hence, for biology understanding the genetic/developmental organization of characters, their evolutionary origin and mode of evolution are important research objectives. The research questions associated with this field, among others, are: 1) what are the genetic/developmental mechanisms that constitute morphological character as quasi-independent units of evolution? 2) how does one recognize the existence and the limits of characters? 3) why are characters stable in the face of adaptive evolutionary change? 4) what are the mechanisms that lead to novel characters (evolutionary novelties)? 5) what are the constraints on character evolution, and what are their causes? I will discuss examples to illustrate research approach to address these questions.

13.4.2. Complexes of characters provide important insights into the function and evolution of pleurocarpous mosses

L. Hedenäs;
Swedish Museum of Natural History, Stockholm, Sweden.

Whether characters evolve independently or in more or less stable complexes has implications for phylogenetic analyses and for our understanding of their biological functions. Pleurocarpous mosses have important complexes of correlated states related to the spore capsule, its peristome, and calyptra. These complexes may include more than 20 states. Spore dispersal apparently depends on a much more intricate set of many co-evolving morphological structures than any found gametophyte function. Some of these complexes of states can be explained by the phylogenetic history of the taxa having them. Such complexes, and those that evolved repeatedly as a more direct response to the habitat, are all correlated with specific habitats and are therefore likely to be functional under extant environmental conditions. Wind speed, air humidity, and substrate moisture for spore germination are likely to be important factors for explaining the function of complexes of capsule and calyptra structures.

13.4.3. Reconstructing common ancestors using mapping of qualitative and quantitative characters: a case study of Apiaceae tribe Scandiceae

K. Spalik[1], A. Wojewódzka[2], S. R. Downie[3];
[1]Department of Plant Systematics and Geography, Warsaw University, Warszawa, Poland, [2]Warsaw University Botanic Garden, Warszawa, Poland, [3]Department of Plant Biology, University of Illinois, Urbana-Champaign, IL, United States.

We have reconstructed general fruit appearance for the ancestors of Scandiceae subtribes Scandicinae, Torilidinae and Daucinae, as well as of their major subclades. We considered all qualitative and quantitative traits that unambiguously characterise general fruit morphology and anatomy, including the shape and size of the fruit and its appendages and internal structures. Quantitative traits were re-coded as ordered characters based on the analyses of their distributions. All characters were mapped on the tree inferred from rDNA ITS sequences and the character states for the ancestors of particular subtribes, major clades, and genera were inferred. These reconstructions were generally unambiguous for most clades recognised in Scandicinae and Torilidinae, but not for Daucinae. Based on these ancestral character sets drawings of fruits were prepared. Such a visualisation may provide heuristically valuable insight into the evolution of plant form and function, and be better than the standard analysis of character evolution. However, since it depends much on the accuracy of ancestral character reconstruction, its utility is somewhat limited.

13.4.4. A contribution to solving the problem of morphological character states

B. K. Kirchoff, S. Richter, D. Remington;
University of North Carolina, Greensboro, NC, United States.

A contribution to the problem of creating morphological character states can be made by applying insights from cognitive psychology to the character state creation task. Psychologists have identified two visual processing modes. Analytic visual processing involves attending to distinct, separate features of a trait (e.g., septa, locules, and ovules of an ovary). Holistic processing involves attending to global features such as overall shape (Gestalt), or to interdependent aspects such as the distance between features. Preliminary evidence suggests that holistic processors are able to create character states with higher inter-investigator agreement (higher reliability), and higher agreement with an independent assessment of phylogeny (greater validity), than analytic processors. Holistic visual processing can be stimulated by training. To construct character states, photographs of traits are sorted into hierarchical groups. The results are hypotheses of the relationships among taxa based on a specific set of traits (a specific character). These hypotheses can be coded for phylogenetic analysis by using matrix representation with parsimony.

13.4.5. A penalty of using anonymous dominant markers (AFLPs, ISSRs, and RAPDs) for phylogenetic inference

M. P. Simmons[1], L. Zhang[1], K. Müller[2];
[1]Colorado State University, Fort Collins, CO, United States, [2]Nees-Institut für Biodiversität der Pflanzen, Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany.

AFLPs (and to a lesser extent ISSRs and RAPDs) are increasingly being used for phylogenetic inference among closely related species, using both distance and parsimony analyses. The justification that is generally given for using these characters is that nucleotide sequences lack sufficient variation among the sampled taxa. Presence/absence characters for each AFLP allele treat all absences as homologous to one another. This is analogous to coding four nucleotides at a given position as four separate characters. When only two alternative alleles for each locus occur in the study group, this character coding is not particularly problematic because any change between alleles simply gets weighted twice. The problem arises with three or more alleles. We conducted a simulation study to quantify how severe the negative effect of using presence/absence characters of individual bands is for phylogenetic inference relative to standard multistate characters. We examined alternative tree topologies, relative branch lengths, numbers of characters, rates of evolution, and numbers of alternative alleles, using both parsimony and Nei-and-Li distance analyses.

13.4.6. Homology and character states in morphological and molecular data

B. D. Mishler[1], E. De Luna[2];
[1]University and Jepson Herbaria, Berkeley, CA, United States,
[2]Instituto de Ecologìa, Xalapa, Mexico.

Phylogenetic analysis inherently consists of two phases. First a data matrix is assembled, then a phylogenetic tree is inferred from that matrix. The first phase of phylogenetic analysis is the most important; but paradoxically, by far the largest effort in phylogenetic theory has been directed at the second phase. Our goal is to examine each of the logical elements in the assembly of the data matrix: the rows (what are OTUs?), the columns (what are characters?), and the individual entries (what are character states?). There is never a given set of OTUs or characters to begin a phylogenetic analysis with. Furthermore, there is a reciprocal relationship between OTUs and characters. OTUs need to be constructed of semaphoronts using character evidence, and characters need to be discovered and evaluated, during each analysis. A good taxonomic character shows greater variation among OTU's than within -- each must be a system of at least two discrete transformational homologs, or character states. This variation must be heritable and independent of other characters. These principles of character analysis apply to all sources of data, whether morphological or molecular.

13.4.7. Geometric spaces and quantitative methods for the similarity test of homology and character state identity

E. De Luna[1], B. D. Mishler[2];
[1]Instituto de Ecologia AC, Xalapa, Mexico, [2]University and Jepson Herbaria, Berkeley, CA, United States.

Assessment of morphological homology consists of comparability statements and conjectures of character states as potential taxic and transformed homologues. Statistical analyses are used in the test of similarity of homology for character state identity. Measurements or coordinates of fixed or varying "morphs" constitute clouds of vector points respective to a multidimensional geometric space configured by multiple axes. Identification of the same phylogenetic state (taxic homology) or recognition of sufficiently different states (transformational homology) is a statistical question about structure of correlations and variance in such vector space. We use analyses of variance to test if there is a statistically significant association of the quantitative feature (a character state) with the a priori discrete groups (species as sampling units). Multiple comparison tests are used to discover which groups of means are significantly different from each other. We exemplify this approach with mosses, orchids, bromeliads, diatoms and bats. Conjectures of character states are still hypotheses of primary homology, which need to be tested for congruence.

13.5.1. Northern Hemisphere deciduous forest disjunctions, with special reference to Dipsacales

M. J. Donoghue, S. A. Smith;
Yale University, New Haven, CT, United States.

In recent years there has been a significant increase in the number of phylogenies for disjunct taxa, which has improved our understanding of phytogeographic connections in the Northern Hemisphere. We will review phylogenetic work to date and examine how temperate deciduous forests of the Northern Hemisphere have assembled during the Tertiary. Our discussion will focus particularly on ancestral areas, examine the timing of divergences, general patterns and possible causes, and compare with selected animal clades. Multiple examples of several Northern Hemisphere disjunction patterns are present within the Dipsacales (Asteridae). These patterns will be discussed and special emphasis will be given to *Viburnum* (Adoxaceae) and *Lonicera* (Caprifoliaceae), case studies that will provide the opportunity to present and discuss a database we are developing to assemble and analyze our knowledge of Northern Hemisphere biogeography.

13.5.2. Northern Hemisphere tropical lineages, with special emphasis on Leguminosae and Cucurbitaceae

S. S. Renner[1], M. Lavin[2];
[1]Ludwig Maximilians University, Munich, Germany, [2]Plant Science and Plant Pathology, Montana State University, Bozeman, MT, United States.

Molecular phylogenetic studies involving dense sampling at the species level within the legume and Cucurbitaceae families (worldwide) are revealing a remarkable level of geographic and ecological phylogenetic structure. Many intracontinental and transcontinental crown clades appear of Neogene to Quaternary age, pointing to migration across Beringia or the North Atlantic. Similar patterns exist in other families that today have disjunct tropical ranges. These patterns plus paleobotanical data (esp. new fossils) and phylogenetic studies that include molecular dating, reveal a picture of the boreotropics (Wolfe 1975) that includes seasonally dry biota bordering the Tethyan seaway, from Southeast Asia west to the Gulf of Mississippi and through North America, as well as mixed forests of a taxon composition that we are only beginning to fathom. Our contribution will focus on components of the Laurasian thermophilic flora that are predicted by molecular phylogenies, but are not yet found in the fossil record.

13.5.3. Tertiary intercontinental disjunctions in the phytogeographic history of the Northern Hemisphere

S. R. Manchester;
Florida Museum of Natural History, Gainesville, FL, United States.

The fossil record reveals patterns of intercontinental disjunction among Tertiary woody seed plant genera that help to explain modern phytogeographic ranges in the Northern Hemisphere, for example: East Asia-western North America (Amersinia, Craigia, Davidia, Deviacer, Dipteronia, Florissantia, Trochodendron, Tetracentron); Europe-North America (Buzekia, Cedrelospermum, Cruciptera, Eostangeria, Tetraclinis); Europe-Asia (Banisteriocarpum, Buxus, Podocarpium, Pteroceltis). Some formerly pan-north temperate taxa are now either disjunct between North America and East Asia, or endemic to one of these regions (Carya, Cercidiphyllum, Comptonia, Liriodendron, Metasequoia,

Sequoia). Some of the Eocene Euro-North American genera are now confined to East Asia (Diplopanax, Platycarya Mastixia, Tapiscia) or to Asia plus Africa (Alangium, Ensete, Pyrenacantha, Tinospora). European Tertiary genera now confined to tropical America include Anacardium, Ceratozamia,Tetrapterys, and Matudaea. The timing and directionality of the exchanges with Africa and South America remain to be documented.

13.5.4. Colonisation dynamics and the tempo of tree evolution in the northern hemisphere

R. J. Petit[1], G. G. Vendramin[2];
[1]INRA, Cestas, France, [2]CNR, Florence, Italy.

Phylogenetic and phylogeographic studies point to heterogeneous rates of molecular evolution across lineages in all kingdoms. This DNA sequence rate heterogeneity is attracting more and more interest, and mechanistic models based on generation time, metabolism, population size, diversification rate... are being actively developed. Here, I explore the idea that mutation rates are inversely related with the geographic stability of the corresponding lineages, using case studies relying on interspecific and intraspecific phylogenies of forest trees and shrubs from the northern hemisphere. In particular, I ask if species or populations within species that have experienced long-term geographic stability (geographic relicts) typically have more ancestral characters than their more invasive counterparts. The results suggest that data on the tempo of molecular divergence could be better valorised in historical biogeographic studies.

13.5.5. Patterns of morphological differentiation among intercontinental disjunct plants in the Northern Hemisphere

J. Wen[1,2];
[1]Field Museum of Natural History, Chicago, IL, United States,
[2]Smithsonian Institution, Washington, D.C., DC, United States.

I examine patterns of morphological differentiation in several intercontinental disjunct genera: *Aralia*, *Carpinus*, *Corylus*, *Dendropanax*, *Kelloggia*, *Oplopanax*, *Panax*, *Phryma*, *Prunus, Rhus* and Altingiaceae in a phylogenetic framework. There is evidence for higher rate of morphological differentiation at the junction between the tropics and the temperate region (e.g., in *Aralia*, Altingiaceae and *Prunus*). *Aralia*, *Panax* and *Carpinus* have highly distinct morphological groups in North America, whereas their species in Asia are morphologically complex, with several species complexes difficult to differentiate. Molecular data in conjunction with fossil evidence suggest a young age of these species complexes. In the same groups, there is evidence for highly distinct lineages in Asia. This morphological pattern supports eastern Asia as an active speciation pump as well as a relict "museum." Several disjunct genera are morphological highly distinct from their closest relatives, yet the disjunct species have differentiated little. Morphological similarity of the disjuncts may be attributed to either young age, or stasis, depending upon the lineages.

13.5.6. The ecological context of evolution, speciation, and extinction in Northern Hemisphere disjunct plant genera

R. E. Ricklefs[1], H. Qian[2], Q. Guo[3];
[1]University of Missouri-St. Louis, St. Louis, MO, United States, [2]Illinois State Museum, Springfield, IL, United States, [3]US Geological Survey, Jamestown, ND, United States.

Disjunct genera in eastern Asia (EAS) and eastern North America (ENA) illustrate independent evolution in regions having similar climates differing in geography. We investigate conservatism of physiological traits by comparing temperature and precipitation extremes within the ranges of genera in each region, and relate ecological breadth to species richness. Herbaceous genera exhibit stronger correlations between EAS and ENA, compared to woody genera, in response to climate variables and in area of geographic distribution. Primarily temperate genera that extend their distributions into the tropics differ between EAS and ENA, suggesting idiosyncrasy in adaptation to new environments. Rate of diversification is uniformly higher in EAS, presumably due to the greater topographic and geographic complexity of the region. With additional phylogenetic and ecological work, these disjunct genera will become an important model system for investigating diversification and adaptation in plants.

13.5.7. Comparison of rates of speciation and molecular evolution in Eastern Asia and Eastern North America

Q. Y. Xiang;
North Carolina State University, Raleigh, NC, United States.

Although similar in climate and floristic composition, eastern Asia (EAS) has twice as many species as eastern North America (ENA) in genera occurring in both regions. To explore causes underlying the diversity anomaly, rates of net speciation and molecular evolution between EAS-ENA sister clades were compared. Results from analyses of ten angiosperm genera and ITS sequence data revealed a pattern of greater species diversity and higher ITS substitution rate in the EAS counterparts. The results imply greater net speciation and accelerated molecular evolution in EAS. Fossil evidence from the compared genera does not suggest greater species extinction in ENA, supporting the idea that accelerated speciation in EAS, promoted by its highly dissected topography, is an explanation for the greater species diversity in EAS. The close relationship between rates of ITS evolution and species richness further suggests a link between rates of species production and nucleotide substitution. This hypothesis is further tested in *Cornus* with molecular data from other genes.

13.6.1. Bryophyte phylogeny: pushing the molecular and morphological frontiers forward.

K. S. Renzaglia[1], J. Shaw[2];
[1]Southern Illinois University Carbondale, Carbondale, IL, United States,
[2]Duke University, Durham, NC, United States.

Revolutionary new concepts of bryophyte relationships have emerged from molecular phylogenetic analyses conducted since the onset of the 21st century. For example, sequence data contradict the historical notion that isophylly in leafy liverworts is plesiomorphic and that simple thalloid liverworts are monophyletic. Also contrary to traditional views, is the concept that *Leiosporoceros* is genetically distinct from other hornworts, and that *Oedopodium* is sister to the peristomate mosses. Substantial increases in comparative ultrastructural and anatomical data likewise have provided new insights on interrelationships. Because of this recent deluge in evolutionary studies on bryophytes, it is an opportune time to examine contemporary morphological knowledge in light of novel molecular hypotheses. Accordingly, this presentation will reevaluate the evolution of structural and developmental design in bryophytes, especially within the monosporangiate sporophyte. Examination of bryophytes is essential to identify structural innovations that accompanied land invasion and to resolve the evolution of more complicated body plans in tracheophytes.

13.6.2. A comprehensive molecular phylogeny of liverworts (Marchantiophyta)

L. L. Forrest[1], E. C. Davis[2], D. G. Long[3], B. J. Crandall-Stotler[1], R. Wilson[4], J. Heinrichs[4], A. Clark[3], M. L. Hollingsworth[3];
[1]Southern Illinois University Carbondale, Carbondale, IL, United States, [2]Duke University, Durham, NC, United States, [3]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom, [4]University of Göttingen, Göttingen, Germany.

Sequence data from three chloroplast genes (*rbc*L, *rps*4 and *psb*A), one nuclear gene (the ribosomal LSU) and one mitochondrial gene (*nad*5) were assembled for ca. 180 species (120 genera) of liverworts, providing the most comprehensive molecular data matrix for the group to date. Phylogenetic analyses of these data provide support for the monophyly of the liverworts, and resolve critical nodes along the backbone of Marchantiophyta. The earliest diverging lineage comprises the controversial taxa *Haplomitrium* and Treubiaceae. A Blasiaceae/complex thalloid clade resolves as sister to all remaining liverworts. The leafy liverworts do not resolve as monophyletic: the separation of the Aneuraceae/Metzgeriaceae from all other simple thalloids, and their placement within the 'leafy' clade as sister to the enigmatic leafy genus *Pleurozia*, as suggested in earlier molecular phylogenies, is also supported by this far larger data set. Within both the complex thalloid and the 'leafy' clades, however, there is little support for lineages.

13.6.3. Progress and Challenges in Reconsctructing Hornwort Phylogeny

R. J. Duff[1], K. S. Renzaglia[2];
[1]University of Akron, Akron, OH, United States, [2]Southern Illinois University, Carbondale, IL, United States.

Despite recent interest in the hornworts, taxonomic boundaries at nearly every level remain controversial. Molecular sequence data has been obtained from a plastid (*rbc*L) and mitochondrial (*nad*5) gene for more than 30 hornwort species representing eight named generic segregates. Phylogenetic analyses of these sequences reveal a number of hierarchical relationships that are not reflected in current classifications. In particular these analyses suggest three divergent lineages of hornworts which include: 1) the monotypic genus *Leiosporoceros*, 2) members of *Anthoceros* and *Folioceros* and 3) all of the remaining hornwort genera. Both morphologically and genetically distinct from all other hornworts, *Leiosporoceros* generally is resolved as sister to the hornworts however divergent rates of RNA editing among lineages of hornworts in both chloroplast and mitochondrial sequences create challenges for phylogenetic reconstruction. The third group includes a number of surprising relationships including the presence of at least one previously unrecognized group consisting of members usually ascribed to the genus *Phaeoceros*.

13.6.4. Inversions and length mutations in chloroplast DNA and their phylogenetic utility

D. Quandt[1], M. Stech[2], K. Müller[3], C. Löhne[3], K. W. Hilu[4], T. Borsch[3];
[1]Technische Universität Dresden, Dresden, Germany, [2]Freie Universität Berlin, Berlin, Germany, [3]Rheinische Friedrich-Wilhelms-Universität, Bonn, Germany, [4]Virginia Tech, Blacksburg, VA, United States.

Non-coding DNA and fast evolving coding regions often display impressive degrees of length variation. Although these regions are widely used in phylogenetic analyses, their mutational dynamics and resulting patterns of variability are still incompletely understood. Length variation is analysed in several datasets with dense sampling for bryophytes (trnT-F, psbT-H, atpB-rbcL) or basal angiosperms (trnT-F, petD, trnK/matK) and compared across land plants (trnT-F, psbT-H, trnK/matK). It appears that inversions are largely associated with hairpins. Depending on their structural positions, inversions are often highly homoplastic unlike other kinds of microstructural changes (e.g., simple sequence repeats). Utilizing secondary structures and minimum free energy models, slipped-strand mispairing as a potential mechanism that creates duplications is evaluated for different structural situations.

13.6.5. Infra-specific molecular phylogeography of bryophytes

T. Hedderson[1], J. Shaw[2];
[1]University of Capetown, Private Bag, South Africa, [2]Duke University, Durham, NC, United States.

Recent advances in DNA technology, along with the development of coalescent theory, provide very powerful tools for the study of population and speciation processes in bryophytes. They provide opportunities for testing hypotheses regarding population history and demography as forces shaping observed patterns of distribution and abundance as well as of genetic variation. We review coalescent theory with a particular emphasis on the opportunities and challenges that bryophytes offer. Areas that we particular focus on include i) species concepts and their relationship to gene genealogies, ii) the influence of past climates on distribution patterns, iii) conservation genetics, and iv) inferences about mating systems and reproductive biology. We review data from studies of bryophytes (mosses, liverworts, hornworts) that include sampling from multiple populations within species, and utilize molecular data based on nucleotide sequencing and various approaches to DNA fingerprinting.

13.6.6. The Moss Diversity Project: Haplolepideae (Dicranidae)

C. J. Cox[1], B. Goffinet[2], J. Shaw[1];
[1]Duke University, Durham, NC, United States, [2]University of Connecticut, Storrs, CT, United States.

As part of the Moss Diversity Project we focus in this paper on the relationships and diversity of Haplolepideae (Dicranidae). The Dicranidae are a major lineage of arthrodontous mosses with a unique peristome architecture, consisting of (when typical) a single ring of peristome teeth, with positional homology to the endosome of diplolepidous mosses. Phylogenetically the Dicranidae are most closely related to the diplolepidous-alternate peristomate mosses (Bryidae), and are typical classified into 238 genera containing approximately 4,000 species. We analysed chloroplast rps4, mitochondrial nad5 intron, and partial nuclear large ribosomal subunit sequences of 103 genera of Dicranidae and 20 outgroup taxa. Maximum likelihood and Bayesian analyses reveal strong support for many clades, however, few of these clades are reflected in the traditional taxonomy of the group. The Pottiaceae, Grimmiaceae s.l., and Calymperaceae are, in general, supported as phylogenetic groups, while others, such as the Dicranaceae, Ditrichaceae, and Rhabdoweisiaceae are polyphyletic. We contrast levels of molecular and taxic diversity within the Dicranidae.

13.6.7. *Physcomitrella patens* as a powerful model organism for EvoDevo studies: functional analysis of moss homologs of the floral regulator FLO/LFY

T. Tanahashi[1,2], N. Sumikawa[1], M. Kato[2], M. Hasebe[1];
[1]National Institute for Basic Biology, Okazaki, Japan, [2]Univ. of Tokyo, Tokyo, Japan.

Physcomitrella patens is an excellent moss model because of the feasibility of efficient gene targeting, which enables us to analyze gene functions of interest. To get insights into the evolution of flowers, the function of *PpLFY* genes, *P. patens* homologs of the floral regulator *FLO/LFY* genes, were analyzed. We generated disruptants of *PpLFY* genes, which hardly formed sporophytes though gametangia were normally differentiated. Confocal laser scanning microscopy demonstrated that fertilization occurred in *PpLFY* disruptants but zygote development was arrested at the single-cell stage. Crosses between the disruptants and wild-type strain supported these observations. Thus *PpLFY* genes regulate the first cell division of zygote and such a role is different from those of other *FLO/LFY* genes in angiosperms. The very rare sporophytes of the *PpLFY* disruptants showed mostly normal organogenesis, but had abnormalities in the pattern of cell division, suggesting *PpLFY* genes are necessary for proper cell division throughout sporophyte development. Other insights into the evolution of plant development using the *P. patens* model system are briefly reviewed.

13.7.1. At the edges of Cyperworld...

P. Goetghebeur;
Ghent University, 9000 Gent, Belgium.

Although our phylogenetic understanding of Cyperaceae continues to improve, attention is drawn to several unresolved morphological problems.
Mapanioids. Do we see spikelets or spikes or spicoids ? And what about the plicate lateral "hypogynous scales", and the unseen oddities in *Chrysitrix* ? Are there really terminal flowers in *Scirpodendron* ? (Yes !) *Caricoids*. Might there be a morphological link from scirpoids to caricoids ? (Yes !) *Fimbristyloids*. How to understand the adaxial "floral" scale in *Nelmesia* ? *Cyperoids*. The laterally flattened ovary of *Pycreus*, *Kyllinga*, *Queenslandiella* - is it unique or a parallelism or a convergence ? *Schoenoids*. The spikelet rachilla is a monopodium or a sympodium ? And are the flowers thus lateral or terminal ? (Well, ...) *Sclerioids*. How can we link the (seemingly ?) terminal flower in Bisboeckelereae with the pseudolateral ones in *Scleria* ? What are the "complex" prophylls in Trilepideae ? All these point to a brilliant future for morphological studies !

13.7.2. Phylogeny of Cyperaceae based on DNA sequence data: current progress and future prospects

D. A. Simpson[1], A. M. Muasya[2], X. Zhang[3], K. Ghamkhar[3], J. J. Bruhl[3], K. L. Wilson[4], A. Marchant[4], M. W. Chase[1];
[1]Royal Botanic Gardens Kew, Richmond, Surrey, United Kingdom, [2]East African Herbarium, National Museums of Kenya, Nairobi, Kenya, [3]Botany, Centre for Ecology, Evolution and Systematics, University of New England, Armidale, Australia, [4]Royal Botanic Gardens, Sydney, Australia.

The family Cyperaceae is composed of 108 genera and c.5500 species and has an almost cosmopolitan distribution. Phylogenetic studies of the family, using DNA sequence data, have steadily increased over recent years. These have usually targeted particular groups within the family. At the Monocots III conference in 2003 a phylogeny of Cyperaceae based on rbcL data was presented. Since then further taxa have been sampled for rbcL and data are now available for a large majority of the genera. In addition a trnL-F dataset has been assembled, with representative taxa from across the family. Analyses based on these datasets, run separately and in combination, will be presented with a discussion of subfamily and tribal recognition. Recent molecular work that has been carried on taxa in tribes Abildgaardieae, Arthrostrylideae, Schoeneae and Scirpeae will be highlighted. Priorities for future work will be discussed.

13.7.3. Small is beautiful in Scirpeae

S. Dhooge, P. Goetghebeur;
Ghent University, 9000 Gent, Belgium.

The tribe Scirpeae comprises 11 genera. These genera are nowadays more or less well-defined, but this was not always the case. *Scirpus* of all genera has long been treated as a dustbin genus grouping Cyperaceae without clear diagnostic features. As better phylogenetic tools became available, the description of this genus became much more restricted. Still the affinity of some scirpoid species is not at all clear. From the Andes, a number of diminutive scirpoid species are known that are characterized by a single terminal spikelet or a small head of spikelets. An intensive study of the morphology, anatomy and molecular phylogeny resulted in the description of a new genus *Zameioscirpus*, a new circumscription of *Phylloscirpus* and a new species in *Oreobolopsis*. The minimal morphological differences between *Oreobolopsis* and *Trichophorum* and the results from a molecular analysis suggest that the species of *Oreobolopsis* should be recombined in *Trichophorum*, of which however more species from Eurasia should be studied first.

13.7.4. An overview of the Rhynchosporeae (Cyperaceae)

W. W. Thomas[1], A. C. Araujo[2], M. V. Alves[3];
[1]The New York Botanical Garden, Bronx, NY, United States, [2]Universidade do Valle do Itajaí, Itajaí, SC, Brazil, [3]Federal University of Pernambuco, Recife, PE, Brazil.

The genera *Rhynchospora* (ca. 300 species) and *Pleurostachys* (ca. 32 species) form a distinct clade within the Cyperaceae and are most diverse in tropical America. While *Pleurostachys* is exclusively found in forests, *Rhynchospora* is ecologically diverse, occurring in savannas and forests as well as more specialized habitats such as black-water rivers and short-lived annuals. Kükenthal, in his 1949-51 monograph of *Rhynchospora*, recognized two subgenera, five supra-sectional taxa, and 29 sections; he recognized *Pleurostachys* as distinct from *Rhynchospora*. Current research includes revisions of *Pleurostachys* and *Rhynchospora* sections *Pluriflorae* and *Longirostres* as well as studies of anatomy and cytology. Preliminary phylogenetic analysis of *trn*L-F plastid gene suggests that *Pleurostachys* is distinct and that, within *Rhynchospora*, a large clade comprising much of subgenus *Haplostylis* is distinct. Subgenus *Rhynchospora*, however, and the remaining sections of subgenus *Haplostylis* are poorly resolved but show some evidence of clustering into clades resembling some of Kükenthal's supra-sectional groupings.

13.7.5. What is a genus in Cypereae?

A. M. Muasya[1,2], D. A. Simpson[3], M. W. Chase[3], P. Goetghebeur[4], E. Smets[5];
[1]National Museums of Kenya, Nairobi, Kenya, [2]Laboratory of Plant Systematics, K.U.Leuven, Leuven, Belgium, [3]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [4]Department of Biology, Ghent University, Ghent, Belgium, [5]Laboratory of Plant Systematics, K.U.Leuven, Leuven, Belgium.

Cypereae comprises 900 species in 19 genera. *Cyperus* is the largest genus (550 species), while 13 of the genera have under five species. Most genera are diagnosed by few characters, causing difficulties in delimitation and varying generic concepts. Ongoing DNA studies support Cypereae as monophyletic and comprising the *Cyperus* and the *Ficinia* clades. The *Cyperus* clade, with predominantly distichous glume arrangement, is not monophyletic and two groups resolved differ in the presence or absence of Kranz anatomy, but with no defining morphological characters. The *Ficinia* clade has spherical glume arrangement, but some taxa with distichous glume arrangement have been included in *Cyperus*. *Hellmuthia*, previously included among the Mapanioideae due to presence of two floral scales, is resolved among the *Ficinia* clade. Oddly, *Scirpus ficinioides* and *S. falsus* are included in *Ficinia* clade, yet these taxa have bristle-like perianth. The DNA results reveal character evolutionary patterns, point to the need for revising tribal circumscription and support the unpopular taxonomic view of merging the 15 genera belonging to the *Cyperus* clade into one genus.

13.7.6. Homology problems in cyperoid flowers: a floral ontogenetic approach.

A. Vrijdaghs[1], P. Goetghebeur[2], E. Smets[1];
[1]Laboratory of Plant Systematics, K.U.Leuven, 3001 Leuven (Heverlee), Belgium, [2]Research Group Spermatophytes, Ghent University, 9000 Gent, Belgium.

In Cyperaceae, two large subfamilies, Mapanioideae and Cyperoideae, can be distinguished, as suggested by recent molecular phylogenetic analysis (Simpson et al. 2004). A theoretical cyperoid flower consists of two whorls of each three perianth parts, a diplostemonous androecium, and a tricarpellate gynoecium. In all cyperoid taxa, however, there is a tendency to reduce the number and/or modify the shape of the floral parts. This has caused controversy about the interpretation of cyperoid inflorescences, flowers, and floral parts. We present SEM images of the floral ontogeny of *Scirpus*, *Eriophorum*, *Eleocharis*, *Fuirena*, *Dulichium*, *Cyperus*, *Scirpoides*, *Ficinia*, and *Schoenus*, showing that all flowers studied in Cyperoideae orginate according to the same *Scirpus*-like ontogenetic pattern. Our results allow us also to understand the nature of the perianth parts in *Eriophorum* and *Fuirena*, and of the hypogynous stalk in *Ficinia*. Moreover, our results clearly show that in all the cyperoid genera studied, the spikelets consist of an indeterminate rachilla, with lateral empty or flower subtending glumes.

13.7.7. It's a flower, it's a spikelet: the guessing game in Cyperaceae - How do we resolve floral homology in the sedges?

J. J. Bruhl[1], J. H. Richards[2], K. L. Wilson[3];
[1]Centre for Ecology, Evolution and Systematics, University of New England, Armidale, Australia, [2]Florida International University, Miami, FL, United States, [3]Royal Botanic Gardens, Sydney, Australia.

Uncertainty about flower and inflorescence homology exists across Cyperaceae. Of particular interest are homology of the flower, spikelet and associated bracts of Cyperaceae and similarly-named structures of Juncaceae. Principles that should guide investigation of cyperaceous reproductive homologies are that evidence should be considered within the broader context of phylogeny and floral homology of monocots and that multiple lines of evidence (corroboration) are necessary. Essential contributions are (1) comparative studies of spikelet development, as well as mature morphology, in diverse species; (2) mapping of characters onto robust phylogenies; and (3) use of gene expression techniques, as in the grasses. Because of their sister-group relationship to the rest of the family, as well as controversies about homology of their spikelets, mapaniids are a priority. We present our work on spikelets in this clade, esp. *Exocarya sclerioides* where inflorescence units appear monopodial.

13.8.1. Progress in Malpighiales phylogeny: new insights from eight genes

K. J. Wurdack[1], C. C. Davis[2];
[1]Smithsonian Institution, Washington, DC, United States, [2]Ecology and Evolutionary Biology, University of Michigan Herbarium, Ann Arbor, MI, United States.

Malpighiales include 29 families previously assigned to 13 different orders sensu Cronquist. While the monophyly of most families within the order has been established, interfamilial relationships are largely unclear. Our phylogenetic analyses of DNA sequence data from 8 genes (plastid *atpB*, *matK*, *ndhF*, and *rbcL*; nuclear 18S and *PHYC*; and, mitochondrial *nad1B-C* and *matR*) spanning nearly 120 malpighialean taxa is beginning to resolve many of the major subclades within the order. These data further support the recent addition of Rafflesiaceae s.s. and *Centroplacus*, exclusion of Peridiscaceae, sister relations of Elatinaceae+Malpighiaceae and Putranjivaceae+Lophopyxidaceae, and inclusion of *Paradrypetes* in Rhizophoraceae s.l. New findings show Podostemaceae apparently nested within Hypericaceae, and a well-supported sister relationship between Phyllanthaceae and Picrodendraceae. The implications of these new results for the evolution of morphological characters, the problems of horizontal gene transfer, and for biome evolution will be discussed.

13.8.2. Phylogeny, character evolution, and classification of the Flacourtiaceae/Salicaceae complex

M. H. Alford;
The Ohio State University, Columbus, OH, United States.

Recent phylogenies drawn from DNA sequence data have affirmed the polyphyletic nature of the angiosperm family Flacourtiaceae, and a taxonomic rearrangement has been proposed which places most of the taxa into two major families, Achariaceae and Salicaceae. Presented here is a more robust phylogeny of one of these families, the Salicaceae *sensu lato*, which includes Salicaceae *sensu stricto*, the monotypic Scyphostegiaceae, and the majority of the former Flacourtiaceae (>80% of the species). Phylogenetic relationships were inferred from morphological data gathered for all genera and DNA sequence data gathered for 89% of the genera. A new classification is proposed based on this phylogeny that optimizes morphologically homogeneous groups. Samydaceae are resurrected as a family, Scyphostegiaceae are maintained as traditionally circumscribed, and a modified but more homogeneous Salicaceae, including part of the non-cyanogenic Flacourtiaceae, are introduced. *Ahernia* is moved to Salicaceae, Phyllobotryeae are moved to Achariaceae, and a new family near Malvales is created for *Gerrardina*.

13.8.3. Molecular phylogeny of Malpighiales and Euphorbiaceae, and evolution of ovule and seed coat characters

T. Tokuoka[1], H. Tobe[2];
[1]Graduate school of Human and Environmental Studies, Kyoto, Japan,
[2]Graduate school of Science, Kyoto University, Kyoto, Japan.

Molecular phylogeny of Malpighiales and Euphorbiaceae is investigated to clarify relationships within the order and the family using sequence data from three plastid DNA rbcL, atpB, and matK and one nuclear 18S rDNA. Parsimony analyses of Malpighiales based on 106 genera in 24 families resulted in two most parsimonious trees. The monophyly of Euphorbiaceae and the other groups of families were well supported, and four genera (Pera etc.) with a tracheoidal exotegmen, which were previously placed in Acalyphoideae, diverged at the first branch within Euphorbiaceae. Using the four genera as an outgroup we conducted analyses of 74 genera of three subfamilies in Euphorbiceae and obtained two most parsimoniouos trees. Their strict consensus tree showed that Suregada diverged at the first branch, followd by tribe Adenoclineae, the rest of Crotonoideae, the rest of Acalyphoideae, and Euphorbioideae. Both Euphorbioideae and Acalyphoideae (except for the four genera used as the outgroup) are monophyletic, and that Crotonoideae are paraphyletic. We also found that the major clades were supported well by anatomical evidence of ovule and seed coat.

13.8.4. Phylogeny and Evolution of the Passiflorineae

S. Krosnick[1], M. H. Alford[1], S. Vanderplank[2], J. V. Freudenstein[1], D. J. Hearn[3];
[1]The Ohio State University, Columbus, OH, United States, [2]Rancho Santa Ana Botanic Garden, Claremont, CA, United States, [3]Duke University, Durham, NC, United States.

The relationships among the families of Malpighiales are poorly resolved. One group of families, however, is consistently recovered in phylogenetic analyses based on chloroplast *ndhF* and mitochondrial *matR*, albeit poorly supported. This group encompasses the taxa with parietal placentation (plus Goupiaceae) in Malpighiales and is referred to as suborder Passiflorineae. Presented here is a phylogeny of Passiflorineae at the generic level based on both morphological and molecular data sets. Like previous phylogenies, this analysis indicates a close relationship between Passifloraceeae, Malesherbiaceae, and Turneraceae and between Samydaceae, Scyphostegiaceae, and Salicaceae. It also indicates a close relationship between Achariaceae *sensu lato* (including the cyanogenic part of the former Flacourtiaceae) and Violaceae. The distribution of character states for cyanogenic glucosides, anther dehiscence, and wood anatomy corresponds well with this phylogeny. The monophyly of Achariaceae *sensu lato* is addressed, as well as the evolution of corona, stamen number, and sexual systems.

13.8.5. Wood evolution in the novel eudicot order Malpighiales

P. Gasson[1], S. Jansen[1], P. Rudall[1], J. Palmer-Wilson[1], K. Parrish[1], A. M. W. Mennega[2];
[1]Royal Botanic Gardens Kew, Richmond, Surrey, United Kingdom,
[2]Nationaal Herbarium Nederland, Heidelberglaan 2, 3584 CS Utrecht, The Netherlands.

The Malpighiales represents "a bewildering assemblage of highly specialised groups as well as many primitive elements" according to Chase *et al.* (2002). This variety is reflected in their wide range of habit and habitats and diverse wood anatomy. Here we review new and published information on the wood anatomy of Malpighiales, particularly the important timber families Chrysobalanaceae, Clusiaceae, Euphorbiaceae, "Flacourtiaceae" and Salicaceae. Some families (e.g. Malpighiaceae and Passifloraceae) include lianas with anomalous secondary growth. Other characters with phylogenetic potential include vessel distribution, vessel perforation plate type (simple, scalariform or both types), vestured pits, vessel-ray pitting, axial parenchyma patterns, ray structure and type of cell inclusions (silica bodies, calcium oxalate crystals). We evaluate wood evolution in Malpighiales by plotting some of these wood characters onto recent molecular cladograms at the order and family levels.

13.8.6. Phylogeny of the flaxes: Evolutionary relationships in the Linaceae and *Linum*.

J. R. McDill[1], M. Repplinger[2], B. B. Simpson[1], J. W. Kadereit[2];
[1]Section of Integrative Biology and The Plant Resource Center, The University of Texas at Austin, Austin, TX, United States, [2]Institut für Spezielle Botanik und Botanischer Garten, Johannes Gutenberg Universität, Mainz, Germany.

Linaceae, best known for the useful fibers and oils from the cultivated flax, *Linum usitatissimum*, is a widespread family with 13 genera and 300 species, ranging from diminutive temperate annuals to woody tropical trees and climbers. The position of Linaceae in Malpighiales has been clarified in large-scale phylogenetic analyses, but relationships within the family have not been addressed. To determine the circumscription of monophyletic Linaceae and the relationships of the large, cosmopolitan genus *Linum* to the other temperate genera, especially the segregates from *Linum*, we sampled all 13 Linaceae genera and the 5 sections of *Linum*. Phylogenetic analyses of *rbc*L sequences in the context of the Malpighiales show that the tropical genera of Linaceae subfamily Hugonioideae subtend the monophyletic temperate subfamily Linoideae. Within Linoideae, analyses of *trn*K 3' and *trn*L introns, *trn*L-F spacer, and nuclear ITS show that *Linum* is not monophyletic: the blue-flowered linums are sister to the yellow-flowered linums, *Hesperolinon*, *Sclerolinon*, *Radiola* and *Cliococca*. The central Asian *Tirpitzia*, *Reinwardtia*, and *Anisadenia* are basal in the Linoideae.

13.8.7. Phylogeny and character evolution in Clusiaceae and their immediate relatives.

V. Bittrich[1], **M. H. G. Gustafsson**[2], P. F. Stevens[3], P. Sweeney[4];
[1]IB-UNICAMP, Campinas, Brazil, [2]University of Aarhus, Risskov, Denmark, [3]University of Missouri, St Louis; Missouri Botanical Garden, St Louis, MO, United States, [4]University of Missouri, St Louis, MO, United States.

Three subfamilies of Clusiaceae have been recognised based on their morphology. After extensive sampling, molecular data have been used to evaluate their status and relationships, and also those of Podostemaceae and Bonnetiaceae. The monophyletic Clusioideae and Kielmeyeroideae are likely sister taxa. Molecular data show that Hypericoideae, or part of them, are sister to the aquatic Podostemaceae. The morphological evolution of this complex is studied in detail using a data base of over 125 characters. Within Clusioideae, the monophyly of the Neotropical Clusieae, with arillate seeds and a non-fasciculate androecium, has strong support. The Pantropical Garcinieae and Symphonieae are close molecularly, yet very different in androecium and stigma structure. The Pantropical Kielmeyeroideae show notable variation in embryo morphology and oli/resin-secreting anther glands. Stigmatic variation is of particular interest in Hypericaceae, Bonnetiaceae and Podostemaceae. Germination, seedling morphology, leaf margin, and position of cork cambium in both stem and root, are among other character systems whose evolution is discussed.

13.9.1. Phylogenetic structure of Poaceae (R. Br.) Barnhart subfamily Pooideae Benth. based on sequence data of four chloroplast-encoded genes (*mat*K, *ndh*F, *ndh*H, and *rbc*L)

R. J. Soreng[1], J. I. Davis[2];
[1]Smithsonian Institution, Washington, DC, United States, [2]Cornell University, Ithaca, NY, United States.

Pooideae phylogenetic structure was evaluated by cladistic analysis of over 100 genera of Pooideae and ca. 40 outgroups. With taxa from all tribes of Pooideae and several unusual genera sampled for the first time, a robust structure for relationships among related subfamilies and tribes is as follows: Ehrhartoideae (Bambusoideae Pooideae), and within Pooideae; Brachyelytreae ((Lygeeae Nardeae) (Phaenospermateae (Stipeae ((Brylkinieae Meliceae) (Diarrheneae (Brachypodieae ((*Littledalea* (Bromeae Triticeae))(Aveneae Poeae). Asian genera, *Duthiea* and *Sinochasea*, formerly Aveneae or subfam. Arundinoideae *s.l.*, align in a clade with the Asian *Phaenosperma*, and the Australian *Anisopogon*. *Ampelodesmos* aligns among sampled Stipeae, including: *Trikeraia*, *Hesperostipa*, *Oryzopsis s.s.*, *Nassella*, and *Timouria*. *Psammochloa*, hitherto Stipeae, aligns with *Bromus*, but *Littledalea* does not. Poeae *s.l.* includes 2 cpDNA clades corresponding in part to Aveneae and Poeae, but several lineages are switched, and Hainardieae are included within Poeae *s.s.* Pooideae classification is revised, and morphological and biogeographic patterns are considered.

13.9.2. Evolutionary analysis of the Poaceae subfamily Pooideae tribal complex Aveneae-Poeae: systematic and biogeographic implications

P. Catalán[1], A. Quintanar[2], L. Gillespie[3], L. A. Inda[1], J. G. Segarra-Moragues[1], A. Archambault[3], J. Müller[4], M. Olonova[5], R. Soreng[6], S. Castroviejo[2];
[1]University of Zaragoza, Huesca, Spain, [2]Real Jardín Botánico, CSIC, Madrid, Spain, [3]Canadian Museum of Nature, Ottawa, ON, Canada, [4]University of Jena, Jena, Germany, [5]Tomsk State University, Tomsk, Russian Federation, [6]Smithsonian Institution, Washington, DC, United States.

Phylogenetic analysis of the sister tribes Aveneae and Poeae has clarified the evolutionary boundaries of their major lineages and their interconnections. Sampling included a large generic representation of Poeae (75%) and Aveneae (67%). Parsimony and Bayesian reconstructions based on ITS and *trn*TF sequences recover a similar topology, distinguishing: i) a Loliinae s. l. + close allies clade, where the main genus *Festuca* is paraphyletic diverging into a grade of basal broad-leaved *Festuca* lineages and a supported clade of recently evolved fine-leaved *Festuca* lineages; ii) a Poinae s. l. clade, where the main genus *Poa* is monophyletic if other minor genera are included within it and if subgen. Andinae is removed; iii) an Aveneae core clade, formed by the most recently evolved sister clades Koeleriinae /Aveninae and Agrostidinae, plus a series of other less related lineages. Most reconstructions recover a closer relationship of Poinae to Aveneae than to its cotribal group Loliinae though these relationships are weakly supported. Separating the Aveneae and Poinae core clades is a series of intermediate lineages including a mixed group of Aveneae + Poeae taxa.

13.9.3. Reticulate evolution and origins of northern hemisphere allopolyploid *Elymus* (Triticeae)

R. J. Mason-Gamer;
University of Illinois at Chicago, Chicago, IL, United States.

The wheat tribe, Triticeae, is recognized for its complex evolutionary history. Its reticulate history is implicitly demonstrated by extensive conflict among diploid gene trees, and explicitly confirmed by the presence of numerous allopolyploid combinations. *Elymus* is a large, widespread, entirely allopolyploid genus that includes at least one *Pseudoroegneria* genome, combined with genomes from one or more of several other genera from the tribe. Molecular phylogenetic analyses have been useful for clarifying the evolutionary origins of *Elymus* species, with data from most of the tetraploids usually confirming cytogenetic hypotheses of origins. Data from multiple chloroplast and nuclear genes suggest that the origin of hexaploid *Elymus repens* is more complex, possibly combining (1) allopolyploidy involving *Hordeum*, *Pseudoroegneria*, and an unknown donor, and (2) introgression from *Taeniatherum* and a species from outside of the tribe.

13.9.4. Incongruence and the phylogeny of the Triticeae (Poaceae)

O. Seberg, G. Petersen;
Institute of Biology, Copenhagen, Denmark.

The Triticeae includes some of the world´s most important cereals, wheat (*Triticum),* barley (*Hordeum*), and rye (*Secale*), plus a wide variety of important forage grasses. Despite its economic importance the phylogeny of the tribe remains largely unsettled. The vast majority of the species are allopoly-ploids, with an apparently known history, but the relationships of their diploids progenitors are obscure. Nearly all phylogenies of the Triticeae (Poaceae), which have been based on more than a single data set, show a high level of incongruence between different data partitions. The contribution of individual data sets from different genome compartments are explored in this analysis based on eight data sets, viz. nucleotide sequences from three plastid genes (*rbc*L *ndhF*, and *rpo*A), one mitochondrial gene (*cox*II), two single-copy nuclear genes (DMC1 and EF-G), one multi-copy nuclear region (ITS), and morphology.

13.9.5. Phylogeny and biogeography of Bromeae

J. M. Saarela[1], P. M. Peterson[2], S. W. Graham[1];
[1]Department of Botany and UBC Botanical Garden & Centre for Plant Research, University of British Columbia, Vancouver, BC, Canada, [2]Department of Botany, National Museum of Natural History, Smithsonian Institution, Washington, DC, United States.

Tribe Bromeae (Poaceae: Pooideae) comprises a single genus, *Bromus*, with ~160 species distributed widely in temperate regions. Phylogenetic analyses of nuclear (rDNA internal transcribed spacers) and plastid (*trn*L intron and *ndh*F) data identified several lineages with weak to robust support, some corresponding to traditionally recognized taxa (e.g., sects. *Bromus* and *Genea*). However, there is some evidence of incongruence between the nuclear ribosomal region and the plastid genome. In addition to augmenting our original taxon sampling, we are surveying additional plastid loci and the external transcribed spacer (ETS) region of nuclear rDNA to obtain better resolved and supported trees from these linkage groups, as a first step in clarifying any intergenomic conflict. Several major clades are supported by unambiguous indels; one in the *trn*T-*trn*L spacer, for example, supports a clade of some North American taxa in *Bromopsis*, a section with little plastid DNA sequence variation. We also provide an overview of how the new phylogenetic data impact upon our understanding of the biogeography and morphological diversity of the major lineages of *Bromus*.

13.9.6. Speciation in *Hordeum* (Triticeae): The interrelation of biogeography and ecology

F. R. Blattner, S. S. Jakob;
IPK, Gatersleben, Germany.

The barley genus Hordeum L. occurs with 31 species in the meridional and temperate regions of the northern hemisphere, South America, and South Africa. The center of diversity of the genus is southern South America where ten diploid and six polyploid species occur. Phylogenetic analysis of three nuclear loci revealed a rapid and relatively recent radiation within this area during the last 4-2 million years. The combination of the nuclear phylogeny with genealogical data of chloroplast haplotypes resulted in the resolution of repeat long-distance dispersals and major vicariance events as mechanisms contributing to allopatric speciation in this group. Ecological differentiation took place within and between two major South American species groups. In these groups species possess different habitat preferences with regard to humidity, salinity, and elevation, supporting the view of ecological niche differentiation. The Eurasian species groups were affected by far reaching extinctions during the Pleistocene, which aggravated the differences in Hordeum species numbers between Old and New World.

13.9.7. Biogeography and classification of New World Pooideae (Poaceae)

P. M. Peterson, S. J. Pennington, R. J. Soreng;
Smithsonian Institution, Washington, DC, United States.

Of the 3851 native species of grasses in the New World, 1340 are members of the Pooideae. In our classification of the Pooideae we recognize eight tribes, 17 subtribes and 83 genera as native to the New World. Over 60% of the Pooideae belong to the Poeae tribe (827 species), including four of the five largest genera: *Festuca*

(209), *Poa* (175), *Calamagrostis* (132), and *Agrostis* (67). The other, *Nassella* (Stipeae) has 115 species. The Pooideae is the largest subfamily of grasses in the New World with less than 2% of these species being pervasive. Argentina (476 species/122 endemics) and the USA (432/135) have the richest Pooideae flora, followed by Chile (296/54), Canada (246/7), Peru (230/66), Mexico (211/71), and Bolivia (207/23). The Pooideae represent over 70% of the grass flora of Canada and Chile, as opposed to approximately 45% for Argentina and the USA. The subfamily is completely or nearly absent from Belize, El Salvador, Nicaragua, and the Guiana Shield. High species diversity that is mutually exclusive occurs in temperate to subtropical regions of the USA in North America and in the pampas region of Argentina, Paraguay, Uruguay, and Brazil in South America.

13.10.1. Alpine plant reproductive biology: the emerging picture

M. T. K. Arroyo[1], I. Till-Bottraud[2];
[1]Facultad de Ciencias, Universidad de Chile, Santiago, Chile,
[2]Laboratoire d'Ecologie Alpine, CNRS, Universite Joseph Fourier, Grenoble, France.

In alpine communities above treeline, increasingly colder temperatures are paralleled by altitudinal changes in pollinator composition and decreases in flower visitation rates. We will evaluate the advances made, and gaps in knowledge required to determine whether alpine floras exhibit fundamental differences in: breeding systems, pollination mechanisms, levels of genetic variation and floral characteristics, in comparison with their lowland counterparts. While obligately outbreeding systems decrease in frequency with elevation on some mountains, the reverse trend has also been found. Some alpine species are strong selfers and have limited genetic variation whereas others show considerable genetic variation indicative of significant outcrossing. Generalist and specialist pollination systems can co-occur in the alpine, but broad comparisons show that connectance is not necessarily high. Increased flower longevity at higher elevations seems to be common trend - it might not only allow compensation for low pollination rates, but also explain low pollinator density per se.

Research financed by: FONDECYT 1020956, 7020956, ICM P02-051

13.10.2. Is there a typical alpine flower?

Ø. Totland[1], J. Grytnes[2], W. Eide[2];
[1]Norwegian University of Life Sciences, Department of ecology and natural resource management, N-1432 Ås, Norway, [2]University of Bergen, Department of Biology, N-5007 Bergen, Norway.

Flowers of alpine species are often said to be more brightly coloured and larger than flowers of low-land species, the proposed reason being that alpine plants must be particularly showy to attract the few pollinator individuals that exist in alpine habitats. Moreover, alpine species are believed to have structurally simpler flowers that can be effectively pollinated by a wide array of pollinators. However, in reality we know little about how floral traits of alpine species differ from those of species occurring in other habitats.

We examined if alpine species have special flowers by comparing flower size, colour and morphology of alpine, costal and south-eastern species in Norway.

With the exception of one notable floral feature, there were no indications suggesting that there exist a typical alpine flower, at least in Norway. In general, floral traits of alpine species could be special if a species filtering process based on floral traits occurred *before* species migrated to the alpine, or if selection acted strongly on floral traits *after* migration to the alpine. Apparently, none of these two processed have occurred.

13.10.3. Variations in flowering phenology in alpine ecosystem: its importance as a selective force

G. Kudo;
Environmental Earth Science, Hokkaido University, Sapporo, Japan.

Flowering schedule of alpine plants is basically determined by climatic conditions and snowmelt regimes at micro scale. Spatiotemporal variations in flowering timing and duration of individual species strongly influence the reproductive situations. Flowering in early season often results in pollen limitation due to low activity of pollinators under cool conditions. Late flowering, whereas, results in failure of seed set due to limited season length. Segregation of flowering season may isolate the gene flow through pollination process among adjacent local patches, resulting in a fragmented or genetically differentiated structure of populations within local areas. At community level, a snowmelt gradient creates a complex and diverse flowering structure. This may be beneficial for flower visiting insects, but it may cause severe pollination competition among co-flowering plants. Thus, patterns of flowering phenology act as an important selective force on alpine plants.

13.10.4. Adaptive peaks or evolutionary traps: are alpine plants victims of their own success?

C. Galen[1], M. T. Brock[2];
[1]University of Missouri-Columbia, Columbia, MO, United States,
[2]University of Minnesota, St. Paul, MN, United States.

Brief growing seasons, cold temperatures, and high winds prevail above timberline. Alpine plants have traits that allow them to flourish despite these limitations. I use two examples to argue that such traits will reduce the capacity of alpines to tolerate aspects of global change. 1. Flower heliotropism is mainly limited to plants of alpine and arctic habitats. Heliotropism in the snow buttercup, *Ranunculus adoneus*, has a favorable impact on flower carbon balance and seed growth under current alpine conditions. However, when ambient temperature is increased experimentally, heliotropism exacts a carbon cost in respiration compared to stationary controls. Results suggest that solar tracking will have a net energetic cost under warmer conditions. 2. Alpine plants typically are dwarfed in stature. Low stature is thought to resist lodging under high winds above treeline. Seed bearing stalks are shorter in the alpine dandelion, *Taraxacum ceratophorum* than in its exotic congener *T. officinale*. Because seed dispersal in dandelions depends on height, exotics have an advantage over alpine natives in colonization of open disturbances and may replace them over time.

13.10.5. Collective sustaining of pollinators by globeflowers

L. Despres;
University of Grenoble, Grenoble, France.

Cooperation among unrelated individuals challenges the individualistic-based Darwinian view of evolution, which predicts that free-riders benefiting from the common resource without paying its cost should invade. Globeflowers are exclusively pollinated by flies whose larvae feed on their seeds. Although all plants benefit from mutual cooperation to sustain the pollinator population, a cheating individual could do even better by exploiting the cooperative efforts of others, without paying the price of rearing pollinator larvae. Here we document individual versus population conflict in globeflowers in sustaining their pollinating flies throughout the range of this arctic-alpine European plant. Despite considerable variability in ecological conditions and pollinator densities across populations, the percentage of seeds lost to pollinators remains strikingly stable over time and space. The stability of the interaction relies on density-dependent competition among larvae co-developing in flower heads.

13.10.6. Insectivorous carnivores negatively affect pollinator visitation and reproductive output in alpine plants.

A. A. Muñoz;
Departamento de Botánica, Universidad de Concepción,, Concepción, Chile.

Studies on plant-pollinator interactions have largely neglected the potentially negative effects of predators of pollinators on seed output. Pollinator anti-predatory behavior may affect flower visitation patterns, pollen transfer, and plant reproduction. I discuss experimental evidence showing lizards to reduce pollinator visitation and seed output in an Andean shrub. The lower alpine belt holds a high density of lizards and low shrubs interspersed among lizard-inhabited rocks. Lizard exclusion resulted in a 2-4 fold enhancement of the visitation rates of the most frequent pollinators of this shrub, the duration of visits, and seed output. In a natural experiment, fly visits were 9 times shorter, and visitation rates and seed output were 2-3 times lower on shrubs adjacent to lizard-occupied rocks compared to those distant from rocks. Our results show lizards to alter pollinator behavior and elicit strong top-down negative effects on seed output. Such effects may be especially important in the alpine, where pollinator activity can be low, and pollen limitation occurs.

13.10.7. Seed banks and seed germination in the alpine zone

B. Erschbamer;
Institute of Botany, University of Innsbruck, Innsbruck, Austria.

The investigation of seed banks, seed persistence, and germination strategies becomes more and more important as these traits are essential for the explanation of life histories and ecosystem functioning and probably also for the evaluation of climate change impacts in the future. During the last decades, a considerable amount of papers showed that seed banks exist in alpine soils, being important drivers of regeneration. The aims of the present contribution are (1) to highlight the importance of alpine seed banks, (2) to describe short and long term persistence of alpine seeds, (3) to answer the question if seed size, shape and mass are important in determining the alpine seed bank behaviour, and (4) to compare seed banks and germination strategies along primary succession. Data from the central alpine glacier foreland of the Rotmoosferner (Ötztal, Tyrol, Austria) are shown. It was suggested that early colonizers - in contrast to later successional species - will not build a seed bank. This hypothesis can be rejected for the study site in the Central Alps.

13.11.1. Seasonal adjustments in photosynthesis and photoprotection

W. W. Adams III, C. R. Zarter, V. Ebbert, K. E. Mueh, V. S. E. Amiard, B. Demmig-Adams;
University of Colorado, Boulder, CO, United States.

Overwintering herbaceous species typically maintain fully functional photosynthetic electron transport systems and rely primarily on flexible zeaxanthin-dependent thermal energy dissipation for photoprotection. In contrast, many evergreens exhibit prolonged and pronounced reductions in photosynthetic electron transport capacity during winter, coupled with sustained high levels of zeaxanthin-dependent thermal energy dissipation. Under more extreme conditions at higher elevations, all major evergreen components of the Rocky Mountain subalpine ecosystem (conifers and a broad-leafed ground cover) exhibited strong and lasting photosynthetic downregulation. During the vernal upregulation of photosynthesis, both photosynthetic capacity and the degree of sustained energy dissipation varied from day to day with changing environmental conditions. The role of particular proteins in these seasonal adjustments, including D1, PsbS in flexible dissipation, and Elips and/or Hlips in sustained dissipation, will be examined. Differences in photosynthetic adjustment between apoplastic and symplastic loaders will also be considered.

13.11.2. Wintertime influences on net ecosystem CO_2 exchange in a high-elevation, subalpine forest

R. K. Monson;
University of Colorado, Boulder, CO, United States.

Wintertime conditions affect the exchange of CO_2 between ecosystems and the atmosphere through influences on tree photosynthesis and soil respiration. Although wintertime photosynthesis is downregulated, wintertime soil respiration continues at a relatively high rate, resulting in the loss of up to 60% of the carbon sequestered by the ecosystem the previous summer. Winter soil respiration rates are dependent on the depth of the late-winter snow pack, which in turn influences beneath-snow soil temperatures. Wintertime loss of sucrose from plant roots, perhaps due to mechanical disruption during soil freezing, supplies carbon substrate for microbial activity and soil respiration. During the spring snowmelt forest net CO_2 uptake reaches its maximum annual rate, due to the combination of warm air temperatures, which promote high rates of photosynthesis, and low soil temperatures, which promote low rates of soil respiration. The evergreen growth form allows subalpine conifers a “quick start” to photosynthesis at the end of winter; permitting them to minimize the developmental constraint to seasonal photosynthesis that is exhibited by deciduous trees.

13.11.3. Snow-induced hypoxia - a keynote towards the descent of birch treelines in snowy regions

D. Gansert;
Institute of Ecological Plant Physiology and Geobotany, Duesseldorf, Germany.

On snowy mountains in humid northeastern Asia the descent of the birch treeline by 800 m below the thermal upper distribution limit is discussed in terms of a synergistic effect of oxygen and carbohydrate deficiency during bud break. In spring, hypoxia under compressed snow hampers oxidative respiration and thus, causes ATP deficiency in the parenchymatous tissues of the wood-body. The impact of hypoxia on tree survival will increase when most reserve carbohydrates have been consumed so that enhanced ATP demand of live tissues during bud break cannot be further compensated. Thus, on condition of prolonged snow cover deciduous treelines may occur where metabolic compensation of hypoxia limits anabolism during the early season. This hypothesis of hypoxia-induced carbohydrate limitation regards oxygen supply to the woody cormus as a key factor for the establishment of birch treelines in snowy, periodically water-logged subalpine and subarctic regions. Measurements of dissolved O_2 in the sapwood of birch proved that oxygen deficiency increased from bud break until frondescence, when a deficit of nearly 90% of air saturation marked a maximum of oxygen depletion.

13.11.4. Physics, physiology, and ecology of wintertime xylem cavitation

J. S. Sperry, J. Pittermann;
University of Utah, Salt Lake City, UT, United States.

Cavitation occurs in response to freeze-thaw cycles and water stress, and both contribute to potentially high blockage of xylem transport and winter-related dieback. Several adaptations minimize the problem. Avoidance of cavitation requires narrow xylem conduits and air-tight inter-conduit pitting. This “strategy” functions equally well for conifer tracheids or angiosperm vessels but results in inefficient water conduction under favorable conditions. Alternatively, wide and efficient conduits that cavitate in winter can be refilled or replaced prior to the growth season. This strategy requires any evergreen foliage to be resistant to water loss to avoid severe stress. The refilling occurs by root pressure in many woody angiosperms, and by an unknown mechanism in conifers. Impairment of refilling can lead to dieback. Replacement of non-refilled conduits occurs in ring-porous trees but requires late leafing and a shorter growing season. Although the basic mechanisms of freeze-thaw related cavitation and refilling are known, important gaps remain.

13.11.5. JrSUT1, a putative xylem sucrose transporter, is up-regulated by freezing temperatures over the autumn-winter period in walnut tree (*Juglans regia* L.)

M. Decourteix[1], G. Alves[1], N. Brunel[1], T. Améglio[2], A. Guilliot[1], M. Poirier[2], M. Bonhomme[2], R. Rageau[2], G. Pételt[1], **S. Sakr**[1];
[1]Univesité Blaise Pascal, Aubière, France, [2]INRA, Aubière, France.

Sucrose has long been reported to play multiple roles in the winter biology of temperate woody species. However, no report on the molecular basis of sucrose transport has yet been made. In walnut tree, we showed that active absorption of sucrose from xylem vessel to vessel-associated cells is higher when samplings are done after a freezing period. We tested whether this increased sucrose influx is the result of the sucrose transporter regulation in xylem tissues.

A putative sucrose transporter cDNA (*JrSUT1: Juglans regia* sucrose transporter 1) was cloned from a xylem-derived cDNA library. Over the autumn-winter period, *JrSUT1* transcripts and respective proteins were present in parenchyma cells. They were specifically and highly detected when samplings were preceded by freezing/non-freezing period. The up-regulation of *JrSUT1* level was also found in controlled conditions. Immunolocalization studies showed that JrSUT1 and JrAHA were co-localized to vessel associated cells, which control solute exchanges between parenchyma cells and xylem vessels. These data are discussed with respect to the winter biology of walnut tree.

13.11.6. Seasonal changes in carbon and nitrogen metabolism in *Spartina alterniflora*

R. J. Ireland, L. Adongo;
Mount Allison University, Sackville, NB, Canada.

The intertidal zone of many Eastern North American salt marshes.is often dominated by the halophytic perennial grass, *Spartina alterniflora*. Over winter, this plant stores nutrient reserves in underground rhizomes, which become very metabolically active in spring and fall, when they are exporting organic nitrogen and carbon to the developing shoots. Much of the transported material is in the form of asparagine, most of which is hydrolyzed to aspartate and ammonia by the enzyme, asparaginase in the young shoots. The aspartate has many fates, including transamination to other amino acids. We have isolated and purified five forms of aspartate aminotransferase from *Spartina* leaves, which show distinct seasonal activity profiles and substrate specificities. The ammonia is assimilated by glutamine synthetase, which is present as two forms in *Spartina* leaves, which also show distinct seasonal activity profiles. Antibodies specific to the two forms of GS revealed a complex pattern of changes in cellular distribution of the cytosolic and chloroplastic forms of GS during the spring and summer.

13.11.7. *Arabidopsis* vernalization requirement and response

C. Dean;
John Innes Centre, Norwich, United Kingdom.

Many plant species will not flower until they have experienced a long period of cold temperature, or ‘winter’. This process, known as vernalization, ensures plants overwinter vegetatively and flower in the favourable conditions of spring.

Vernalization epigenetically regulates expression of a floral repressor, *FLC*. Prolonged cold results in reduction in *FLC* RNA levels, which then remain constant at that lower level when plants are moved back to warm temperatures. Identification of mutants defective in vernalization response has defined *VRN* genes required to cause down-regulation of *FLC* and maintain the cellular memory of vernalization.

Vernalization antagonizes the function of FRIGIDA, which up-regulates *FLC*. These combined activities thus prevent flowering until winter has passed. In contrast, vernalization works in parallel to genes such as *FCA* and *FY* to repress *FLC* expression.

The talk will address how these pathways interact to regulate *FLC* expression at different stages in the plant life-cycle and how these have changed in natural Arabidopsis variants adapted to very different growth conditions.

13.12.1. Tannin-containing plants for animal nutrition and health

I. Mueller-Harvey;
University of Reading, Reading, United Kingdom.

Tannins in animal feeds can produce useful benefits: better protein utilisation, growth rates, milk yields, fertility and improved animal health (prevention of bloat, reduction of intestinal parasites, treatment against diarrhea). The classification into condensed or hydrolysable tannins has not proved useful in animal nutrition. Procyanidins and prodelphinidins in *Lotus, Onobrychis* or *Calliandra* sp. and ellagitannins in chestnut are beneficial, but profisetinidins in *Schinopsis* sp., procyanidins in sorghum and complex mixtures of tannins in *Quercus* and *Terminalia* sp. are harmful or even toxic to ruminants. Moreover, slight changes in tannin structures can produce measurable effects. Unfortunately, it is not yet possible to predict which tannins produce what effects. Novel assays will be described that may prove more useful for relating laboratory measurements to animal performance. The inter- and intra species variation of tannins present opportunities for future applications of tanninin-containing plants.

13.12.2. Importance of different phenolic compounds can be judged by inhibition of phenylalanine ammonia lyase, in seedlings of *Betula pubescens*

S. Keski-Saari, M. Falck, R. Julkunen-Tiitto;
University of Joensuu, Joensuu, Finland.

We studied carbon allocation patterns between plant growth and phenolic metabolism in birch seedlings at the beginning of their growth by inhibition of phenylalanine ammonia lyase (PAL), the first committed enzyme of phenolic metabolism. Seeds of Betula pubescens (Ehrh.) were germinated in inhibitor-free agar media and, at cotyledon stage, the seedlings were transferred into hydrophonic culture with 2-aminoindan-2-phosphonic acid (AIP) in the growing medium. Three concentrations (5, 15 and 30 µM) plus control were used. We have an opportunity to judge the importance of different phenolic compounds for the seedlings, since all phenolics were not equally inhibited by AIP. Flavonol glycosides were generally not affected by AIP and even increased in the leaves. In contrast, soluble condensed tannins strongly decreased in all organs, even with 5 µM AIP. However, insoluble condensed tannins were only slightly inhibited. Our results suggest that flavonol glycosides, and bound tannins, have an important role in the development of birch seedlings. In addition, AIP strongly decreased the growth of the seedlings and possible reasons for this will be discussed.

13.12.3. Profiling phenolic acids from hairy root cultures of *Daucus carota* L. for investigating p-hydroxybenzoate biosynthesis

A. Mitra, D. Sircar;
Indian Institute of Technology Kharagpur, Kharagpur, India.

Hairy root cultures of Daucus carota have been used to study the biosynthesis of p-hydroxybenzoic acid (p-HBA). This phenolic compound finds its application in food, medicine and cosmetics. Biosynthesis of p-HBA although demonstrated to proceed via phenylpropanoid pathway, conflict still remains on the chain-cleavage mechanism. In earlier years, attempts had been made to study p-HBA biosynthesis in carrot using elicited cell cultures, but failed to demonstrate the chain-shortening enzyme activity. Metabolite profiling of phenolics by HPLC/ESI-MS from these hairy roots showed a considerable high amount of p-HBA accumulation both in cytosol and in cell wall. Detection of a significant amount of soluble p-HBA in carrot hairy root is interesting, since this may permit us to go forward in discovering the phenylpropanoid chain-shortening enzyme. In fact, our preliminary findings on this enzymatic cleavage suggest that p-HBA biosynthesis is CoA independent and non ƀ-oxidative demonstrating stable p-hydroxybenzaldehyde formation in cell-free extracts. This aldehyde later converted into p-HBA. Work is being continued to confirm this hypothesis.

13.12.4. Hinokinin biosynthesis in *Linum strictum* ssp*. corymbulosum*

Ü. Bayindir[1], T. Umezawa[2], R. Sjöholm[3], W. Alfermann[1], E. Fuss[1];
[1]Institut für Entwicklungs- und Molekularbiologie der Pflanzen, Düsseldorf, Germany, [2]Wood Research Institute, Kyoto, Japan, [3]Department of Organic Chemistry, Åbo, Finland.

Lignans are dimers of phenylpropanoid units. Recently the lignan (-)-hinokinin (HINO) was found in root and callus cultures of *L. strictum* ssp*. corymbulosum* (Mohagheghzadeh et al., in prep.). We established cell suspension and hairy root cultures of this plant in order to elucidate the biosynthetic pathway leading to HINO. Two pathways are under investigation: If matairesinol is a central intermediate, HINO can be formed via haplomyrfolin or pluviatolide, respectively. If the formation of the methylendioxy bridges occurs earlier by using pinoresinol as substrate, sesamin instead of matairesinol could be an intermediate in HINO biosynthesis. We try to clone a cDNA encoding pinoresinol-lariciresinol reductase (PLR) which will be used in antisense experiments to check the responsiveness of PLR in HINO biosynthesis. A grant to Ürün Bayindir from “Turkish Higher Education Council” is gratefully acknowledged.

13.12.5. Molecular cloning and functional expression of benzoate:CoA ligase from *Sorbus aucuparia* cell cultures

H. M. Ramadan, L. Beerhues;
Institut für Pharmazeutische Biologie, Braunschweig, Germany.

Benzoic acids are precursors and signal molecules. In cell cultures of *Sorbus aucuparia* and *Hypericum androsaemum*, benzoic acid is a precursor of biphenyl and xanthone biosyntheses, respectively. Benzoic acid formation in *H. androsaemum* proceeds via cinnamic acid, with the underlying mechanism being CoA-dependent and non-ß-oxidative. Three CoA ligases with different substrate specificities were detected. Cinnamate:CoA ligase channels cinnamic acid from the general phenylpropanoid pathway into the benzoic acid biosynthetic route. 4-Coumarate:CoA ligase is a well-known component of the general phenylpropanoid pathway. Benzoate:CoA ligase provides the starter substrate for benzophenone synthase and biphenyl synthase. Benzoate:CoA ligase from yeast-extract-treated cell cultures of *S. aucuparia* has been cloned, functionally expressed in *E. coli* and purified by affinity chromatography. The enzyme does not accept 4-coumaric acid and cinnamic acid as substrates.

13.12.6. The different possibilities of introducing hydroxyl groups in the flavonoid pathway

H. Halbwirth, K. Schlangen, **K. Stich**;
Technische Biowissenschaften, Vienna, Austria.

Compounds belonging to the widespread group of flavonoids show a number of hydroxl groups within their flavonoid structure. The most common flavonoids show a basic 5,7-hydroxylation pattern in the A-ring and a hydroxyl group in position 4' of ring B, which derive from the precursors in the formation of the C15-skeleton, malonyl-CoA and a suitable hydroxycinnamic acid-CoA ester. Further hydroxyl groups may be introduced in rings A, B and C by hyxdroxylating enzymes. There are two main classes of enzymes responsible for the introduction of hydroxyl groups in the flavonoid pathway, 2-oxoglutarate dependent dioxygenases and cytochrome P450 dependent monooxygenases. An overview is given on well-known enzymes (flavanone 3-hydroxylase, flavonoid 3'-hydroxylase and chalcone 3-hydroxylase) and on novel enzymes which recently could be demonstrated for the first time (flavonol 6-hydroxylase, flavonoid 8-hydroxylase).

13.12.7. Growth promoting nitrogen nutrition affects flavonoid biosynthesis of young apple (*Malus domestica* Borkh.) leaves

T. Strissel[1,2], H. Halbwirth[2], U. Hoyer[1,2], C. Zistler[1,2], K. Stich[2], D. Treutter[1];
[1]Technische Universität München-Weihenstephan, Department für Pflanzenwissenschaften, Fachgebiet Obstbau, Freising, Germany, [2]Technische Universität Wien, Institut für Verfahrenstechnik, Umwelttechnik und Technische Biowissenschaften, Vienna, Austria.

Increasing nitrogen (N) nutrition of apple trees enhances shoot growth but depresses the concentration of flavonoids in young leaves. In the cultivar 'Golden Delicious', which is susceptible to the scab disease, the reduced amount of flavonoids is related to increasing susceptibility after high N nutrition. Several hypotheses exist which try to explain the trade-off between primary and defense-related secondary metabolism by a competition on common substrates, but nothing is known about the regulation at the enzyme level. A set of experiments was performed to elucidate the effect of N nutrition on the activities of key enzymes of the flavonoid biosynthesis and on the accumulation of hydroxycinnamic acids and different flavonoid compounds. The inhibition of flavonoid accumulation by high N nutrition could be confirmed, but the influence of N supply on the flavonoid enzymes was not evident. However, PAL activity seems to be downregulated, thus forming a bottleneck resulting in a generally decreased flavonoid formation. It could furthermore be found that the response of the scab resistant cultivar 'Rewena' to high N nutrition was not as strong as that of the susceptible cultivar 'Golden Delicious'.

13.13.1. Diversity of grasslands under pressure from environmental change

J. Fuhrer, A. Lüscher;
Agroscope FAL Reckenholz, Zurich, Switzerland.

Grasslands play an important role for agriculture and conservation, with their species richness reflecting local management and environmental conditions. In intensively managed, productive systems the influence of management dominates. In more diverse semi-natural systems, environmental drivers are more important, but maintenance of their diversity still requires some management, as either intensification or abandonment reduce diversity. Species diversity of semi-natural grasslands can be altered by changes in atmospheric conditions, including increasing pollution in the form of deposition of reactive nitrogen or ozone (O_3), carbon dioxide (CO_2), and global warming. Spatial and temporal patterns in these drivers are well documented, and data from long-term observations and from manipulative experiments are emerging that demonstrate their potential influence. Results will be presented and discussed in the context of possible changes in management to maintain grassland diversity, and the relationship between observed changes in grasslands and various drivers including management will be explored with data from a case study in the Swiss Alps.

13.13.2. Development of the xerotherm grassland vegetation of the military area Doupov over the past 30 years (western Bohemia).

J. Kolbek, **T. Cerny**;
Institute of Botany of the Czech Academy of Sciences, Pruhonice, Czech Republic.

Military training area Doupov in the western part of the Czech Republic represents a unique landscape, mainly due to the continual absence of inorganic fertilising and preserved water retention of deforested plots. A small portion of this area is subjected to a long-term management practices, featuring by their low intensity. Habitats of subxerotherm grasslands, which now belong to a highly endangered vegetation in cultural mainland, were well developed here. Their diversity and species richness is partly caused by the minerally rich volcanic rocks of the Doupov area. The abandonment of land, where competitive plants (apophytes) become to dominate, is now hazardous for biodiversity. On the other hand, successional trend leads to rich shrub communities, massively covering the most of this area. The overall number of grassland phytocoenoses has declined, floristic composition of vegetation has changed over the past 30 years. Preservation of various unique plant communities, often characterised by the strong development of endangered species, is necessary through continuous disturbance and/or keeping the water regime of stands.

13.13.3. Grasslands in changing landscapes: linking soil seed banks and habitat characteristics

R. Waldhardt, A. Otte;
Justus-Liebig-University Giessen, Division of Landscape Ecology and Landscape Planning, Giessen, Germany.

As shown in previous studies, in changing landscapes with increasing numbers of extensively managed grassland stands, the diversity between the respective vegetation is clearly reflected by the diversity of habitat characteristics including age. Little is known if the soil seed banks of these grasslands and their site characteristics may be linked in an analogous manner.

We therefore investigated the seed banks of 22 grassland stands, and their respective established vegetation and site characteristics. All stands were located in the Lahn-Dill-Highlands (Hesse, Germany). Data were analysed by means of ordination techniques (DCA and partial CCA), Mantel-tests, and ANOVA.

The composition of the established vegetation proved to be the most important variable influencing the composition and structure of the seed banks. However, soil chemistry (pH value and plant available phosphorus) and stand age explained additional proportions of the variance explained in the ordination model.

13.13.4. Niche complementary for nitrogen use - an explanation for the biodiversity and ecosystem functioning relationship in grasslands?

A. Kahmen[1], N. Buchmann[2];
[1]MPI Biogeochemistry, Jena, Germany, [2]ETH Zurich, Zurich, Switzerland.

The relationship between plant diversity and productivity has largely been attributed to niche complementarity, suggesting that an increasing number of species results in a more efficient resource exploitation. We tested this hypothesis with respect to temporal, chemical and spatial N-uptake in three grasslands using 15N labeled NO_3 and NH_4. Specifically, we tested if N-uptake patterns change across communities depending on species composition and diversity or if N-uptake patterns are persistent across different community types. Plant species in the investigated grasslands showed little chemical, spatial and temporal differences with respect to N-uptake. However, depending on quantitative N-uptake and N-use strategy, the different plant species separated into complementary functional groups. Across different grasslands, species composition of a community showed no effect on the plants' N-uptake suggesting that plants within functional groups are consistent in their N-use strategy across different communities. Consequently, the loss of a functional group from an ecosystem cannot be compensated by species from other functional groups.

13.13.5. The process of plant community degradation of two communities-*Leymus chinensis* and *Stipa grandis* grassland, Inner Mongolia, China

H. Tang;
College of Resources Science and Technology, Beijing, China.

Two indicators of plant communitiy degradation are reduction of vegetation cover and decline in land productivity. Intensive human activities,especially overgrazing has been promoting a progressive degradation in grassland. It is necessary work to figure out the process of degradation in order to manage the grassland ecosystem well and efficiently. Three sites were chosen to demonstrate community degradation over the past decades in Xilinguole League,Innner Mongolia. Plant community species composition,aboveground biomass and soil properties were collected at each site. Our results suggested that heavy grazing is one of the major cause of degradation.Plant species number in a site decreased from 55 in 1997 to 38 in 2001 and to 14 in 2004. Plant aboveground biomass declined from 4402.5 kg/hm^2 in 1979 to 708.3 kg/hm^2 in 2004 in one site, from 3409.9kg/hm^2 in 1995 to 1958.6 kg/hm^2 in 2004 in another site. Up to 2005, about 90% of the 4 million km^2 natural grassland in China was degraded at different levels.Our research provided solidate data and new understanding of plant communitie degradation of grassland in north China.

13.13.6. Grassland diversity conservation in the central Apennines (Italy)

P. P. Roggero[1], S. Bagella[2];
[1]Dipartimento di Scienze Ambientali e delle Produzioni Vegetali, Ancona, Italy, [2]Dipartimento di Botanica ed ecologia vegetale, Università degli studi, Sassari, Italy.

The abandon of rural activities in the mountainous areas may increase environmental hazard and reduce biodiversity. The objective of this study was to identify and characterise the current livestock management and the corresponding grassland biodiversity in a pastoral area where traditional livestock activities are still practised. The area includes three pSIC with habitat *6210, which is an important orchid site. Botanical, agronomic and livestock management data were processed with a GIS. Areas with similar grazing value and management were identified and clustered. *Xerobromion* grasslands showed the highest stocking rate, while in some *mesobromion* grasslands it was too low to preserve them from degradation. The uneven spatial distribution of the stocking rates was recognised to be one of the most important factor for grassland degradation and shrub re-establishment. To maintain the current grassland diversity, it would be desirable to exploit the grazing behaviour of different animal species also introducing some devices (e.g. water points) to redistribute the stocking rate according to the carrying capacity of the different areas.

13.13.7. Biodiversity of semi-natural grasslands under human pressure in Central Europe

L. Halada[1], A. Seliškar[2];
[1]Institute of Landscape Ecology SAS Bratislava, Nitra, Slovakia,
[2]Institute of Biology SAZU, Ljubljana, Slovenia.

Despite the semi-natural grasslands belong to the most species-rich ecosystems, their area and habitat quality are decreasing due to changing land use, abandonment, fragmentation and isolation. The decline of plant species richness, changes in composition and disturbance of speciation processes are results. Decrease of grassland area is documented on national, regional and local levels using statistical and remote sensing data from several countries. Changes in community structure of mountain and wet meadows in Slovakia during last 30 years are evaluated on the basis of long-term research data. Using species composition data set in different phases of managed and abandoned grasslands in Slovenia, we quantified and correlated patterns of change in frequency, and species richness. We also made models of possible scenarios particularly for speciation processes of three taxa. Threat status of grassland species and communities is evaluated using analysis of red lists and books for Slovakia, Slovenia, Czech Republic, and Hungary. The main reasons of grassland changes and possibilities for situation improvement are discussed in broader context of Europe.

13.14.1. Ethnobotanical studies of afghan refugees camps in Pakistan

S. S. Gilani, Z. K. Shinwari;
Kohat University of Science and Technology, Kohat, Pakistan.

A survey was conducted in 16 Afghan refugees' camps in NWFP province of Pakistan, to document the local medicinal uses, socio-economic surveys of camps, market surveys of plants and impact of the existence of Afghan refugees on the local flora. The local Afghan refugees used 60 plant species for curing various diseases. Inhabitants of camps consumed fuelwood, annually, 5,099,578.02 Kg in summer, and 6,871,771.8 kg in winter, respectively. They brought fuelwood either from the market (45%) or collected (55%) from the near mountains. Timber smuggling of *Pinus roxburghii* and *Cedrus deodara* from Afghanistan to Pakistan was a common practice. Due to heavy pressure on forests in the surrounding areas of camps, for fuel-wood, dominancy of local flora was decreased. Afghan refugees used 25 fodder species both cultivated and wild. The grazing pressure on the surrounding area was high due to their larger herds of cattle. The study in Refugee camps in Kohat, Hangu and Karak districts of NWFP also estimated that *Nannorhops ritchiana* was harvested, around 2000 tons, annually.

13.14.2. Impact of two recent wars on biodiversity of Afghanistan

Z. K. Shinwari[1], S. I. Ali[2];
[1]Kohat University of Science and Technology, Pakistan, Pakistan,
[2]University of Karachi, Pakistan, Pakistan.

Forests are important natural resources of energy and construction material. Trees like pistachio and almond provide nuts that supplement diet and generate income. Due to lack of communication, many of the earlier remedies for various diseases survived only orally from generation to generation and are practiced in remote areas. Scientific knowledge on biodiversity in the tribal areas of Afghanistan and Pakistan is very scanty. In regions where monsoon has a considerable effect, the tree-line can easily be drawn in different regions. Soviet occupation of Afghanistan and civil wars had repercussions for tribal belt between Afghanistan & Pakistan forcing the people to shift to Pakistan. They indiscriminately harvested the plants and destroyed the natural reserves. Drug/timber smugglers of the area are very influential and offer attractive wages to wood cutters leading to the destruction of biodiversity and the introduction of poppy. Positive sources offer little to the locals. The focus should be to make inventories, reconstruct herbaria, transfer knowledge to Afghanis and build their capacity to record it.

13.14.3. Phytogeography of flowering plants of afghanistan

M. Qaiser;
University of Karachi, Karachi, Pakistan.

Three phytogeographical regions of Afghanistan are recognized. Most of the country belongs to Irano-Turanian region. The bulk of flora (>56.2%) is made up of this element. The southern part belongs to Saharo-Sindian region. The more moist eastern part with summer rainfall is tentatively placed in Sino-Japanese region. This part may be treated as transitional zone between Irano-Turanian and Sino-Japanese region as the climatic data and distribution pattern do not support its inclusion in Sino-Japanese region. Irano-Turanian region is a center of endemism and diversity for families like Labiatae, Compositae and Leguminosae. Genera like *Astragalus, Eremostachys, Cousinia, Dionysia* etc. have center of diversity in Afghanistan and radiating from there are number of species. *Astragalus* has maximum number of endemic species (c. 168 spp.), followed by *Cousinia* (c. 83 spp.). The heavy bombing has created a devastating effect on the natural environment. This may have lead to the extinction of several endemics and also being mutagenic in nature, may also be responsible for creating new taxa. An objective re-evaluation of the endemic taxa therefore seems desirable.

13.14.4. Ecology of alpine plateau pastures at borderlands of Afghanistan

A. A. Dasti, S. M. Wazir;
Institute of Pure and Applied Biology, B.Z.University, Multan, Pakistan.

In species poor alpine pastures located between Pakistan and Afghanistan, we evaluated evidence for plant species associations with physical habitat variables. A total of 42 species were included in the analysis. Data on the composition of plant communities were gathered along a 72Km long transect between 2650 and 3400 m a.s.l. Soil samples were collected to document edaphic conditions of the area. Spearman's Rank Correlation Coefficient was use to detect relationship between environmental factor and species distribution. In Detrended Correspondence Analysis and cluster analysis, based on species presence/absence data, samples (stands) segregated in to five groups. These corresponded closely with the physiographically defined habit types assigned in the field. The vegetation patterns revealed are discussed in relation to geo-morphological factors and problems of plant assemblage in vegetation having widely scattered plants. The results suggested that the distribution and abundances of many species are influenced by local heterogeneity in physical habitat variables. However, there were several species that showed no habitat association.

13.14.5. Invasive Weeds: A major threat to biodiversity in Afghanistan

K. B. Marwat;
NWFP Agricultural University Peshawar, Pakistan, Pakistan.

Afghanistan has a total area of 647,000 sq. km lying between 29 38° N and 62” 72° E with elevation ranging from 258 m to 7485 m without any direct access to sea. With Soviet invasion in 1979 till these days, this area has been under tremendous disturbance; these include natural calamities, like drought etc. and simulated ones, like war and bombing by various forces from within and outside Afghanistan. Drought alone has damaged 30 - 35% Orchards in N-E parts of Afghanistan. These disturbances have resulted in change of agricultural practices and forest management as well as changes in micro-climatic level which in turn has paved way for invasion of alien weeds as well as evolution of new ecotypes of the native weeds, which have become invasive now. Thus during this period of about 25 years, Afhganistan’s natural and Agro-biodiversity was severely affected by invasive weeds, mainly woody and perennial ones. The present paper discusses the threat posed by such weeds, their status as Alien or local invasive and possible management to conserve the biodiversity from the future degradation.

13.14.6. Ethnobotany of Pak-Afghan Tribal Areas

A. Rashid;
University of Peshawar, Peshawar, Pakistan.

Two hundred and seventy-nine species belonging to eighty-one families were recorded during this study from Pak-Afghan Tribal Areas. The inhabitants of this region remained mainly dependent upon plant natural resources due to socio-political and economic reasons. Eighty-five species have been directly utilized for various purposes. The region exhibits a unique Biodiversity with rich medicinal plant wealth. Some of the interesting Reptonia elements are met with in this zone. Biotic interference with indiscriminate exploitation of natural resources, habitat loss, induction of unfriendly species, unstable socio-economic conditions of the inhabitants, huge influx of Afghan refugees in the territory of Pakistan during the last 30 years and recent coalition bombardment have differentially affected the species distribution and the abundance categories. This mass scale destruction of vegetation has caused even drying of the natural springs at places. The entire scenario has resulted in the great loss to the plant natural resources of the region in general and ethno-medicinal wealth in particular.

13.15.1. What do children bring to plants? What do children get from plants?

M. J. Reiss, S. Dale Tunnicliffe;
Institute of Education, University of London, London, United Kingdom.

What sense do children make for themselves when they look at plants? We carried out two studies. One study was carried out in schools where six botanical specimens were shown individually to pupils aged 4, 8, 11 and 14 years. The children were asked a series of questions about each specimen. The results showed that the children used anatomical features in recognising and then naming the specimens and that home was far more important than was school in their recollections of where they learnt the information they told us. In the second study conversations of primary age children (5-11 years) and the adults with them were recorded in a botanical garden as they walked around the exhibits. Again, children talked about easily observable features such as colour, shape and smell and only attended to less obvious features when cued. Older children made more comments focused on plants while pupils in groups without an adult asked fewer questions of each other and commented more about the human use of plants. We interpret our results within a framework that emphasises the importance of building on pre-existing conceptualisations.

13.15.2. enhancing botanical literacy in the public school classroom through the national science foundation teaching fellowship program at the University of Maine

S. Brown[1], M. Doing[2], S. Cromley[3];
[1]George B. Weatherbee School, Hampden, ME, United States, [2]Dr. Lewis S. Libby School, Milford, ME, United States, [3]University of Maine, Orono, ME, United States.

In an ever-changing environment where plants are under constant pressure from development and habitat fragmentation, botanical literacy is critical to plant conservation. The National Science Foundation Teaching Fellowship Program (NSF GK-12) offers students and teachers in the public schools opportunities for scientific enrichment through the expertise of undergraduate and graduate students studying science, math, and engineering. A major goal of this program is to enhance public school education by providing equipment, hands-on activities, field trips, and exceptional role modeling for students. Several University of Maine participants have developed plant-related units for use in K-12 classrooms. These include germination experiments, flower dissections, plant pressing and identification, problems associated with invasive species, plant adaptations, and creating and using dichotomous keys. We provide a summary of unit objectives and various associated activities.

13.15.3. Building botanical literacy in South African schools

M. C. Doidge;
University of Witwatersrand, Johannesburg, South Africa.

Botany forms a relatively unpopular component of the high school biology curriculum amongst both teachers and pupils in South Africa. The emphasis on plant anatomy and physiology and on the life cycles and characteristics of different phyla no longer generates much interest in botany amongst South African students and this is reflected in the decline in enrolment in botany in universities. However, a new outcomes-based curriculum is in the process of being introduced into South African schools. This new curriculum promotes the development of skills, values and attitudes in addition to the construction of knowledge. Thus although the amount of botanical content has been reduced considerably, botanical literacy may in fact be encouraged. This paper describes the changes in the new curriculum with regards to botanical education over the first twelve years of schooling. It then reports on a survey amongst botany tertiary educators on the impact of the new curriculum on general botanical literacy as well as its adequacy in preparing pupils for tertiary education or for jobs in the field of botany.

13.15.4. Trends in botany education in U.S. Colleges and Universities

M. D. Sundberg;
Emporia State University, Emporia, KS, United States.

During the past 30 years several trends in U. S. botanical higher education are clear. On the negative side, the number of botany and/or plant science departments has declined at 0.65 per year and there has been a drastic decline in traditional course offerings, particularly in taxonomy and floristics. This decline is most evident at smaller institutions but even some of the largest universities with traditionally strong botany departments are now experiencing erosion of botanical course diversity. On the positive side, the number of botany graduate students has remained essentially constant and the number of botany faculty (now frequently in biology departments) has increased 0.26/year. Much of this increase focuses on cellular and molecular plant biology, particularly at research universities. However, several examples will be presented where departments maintained or developed new strength through focusing on well-defined missions and/or establishing collaborations with gardens or museums.

13.15.5. Teaching systematic botany at German Universities - Facts, challenges and opportunities.

M. Weigend;
Institut für Biologie - Systematische Botanik und Pflanzengeographie, 14195 Berlin, Germany.

In the past decades systematic botany at German universities has continuously declined, the number of classes, lectures and practical courses has decreased: Courses such as “plant identification” are no longer part of a biologist´s university education and many important fields (e.g., phycology, mycology) are no longer covered in the curricula. At the same time systematic botany is currently more rapidly developing than ever before and new aspects have to be continuously incorporated into fewer and fewer hours of class work. There are two basic approaches towards improving the quality of botanical education at university: 1) Improving and stream-lining the existing courses (e.g., improving teaching aids, internet ressources), co-ordinating teaching with other botany departments (e.g., student exchange) and the teaching of general techniques (e.g., molecular techniques) with other institutes at the same universities. 2) Systematic botany has to improve its image and centre-stage its role in society. This can i.A. be done by outreach programmes and press releases. Systematic botany has to become visible to become respected.

13.15.6. Activites and amabassadors: Creating educational porgrams from existing plant collections

M. D. Cole;
Green Bay Botanical Garden, Green Bay, WI, United States.

Existing plant collections may be in the form of gardens, arboreta, herbaria or University grounds. In many cases, botanists understand their value to their courses and research but are not readily prepared to reach out to other groups, especially with the limited time available to them. Unfortunately the value of Natural History Collections, living or dried, is not well appreciated outside of the user community. Outreach that combines a collection's individual strengths with the interests or needs of target audiences can give a greatly needed. With the right preparation, professors or students train volunteers and others to give tours or programs that they create. The keys to success are 1) simplifying the program development to be quick and easy, 2) picking the ambassador plants to carry your message, 3) choosing activites that play to your target audience and 4) knowing the market realities of your target audience. Case study data and real world experience show support for the "Activities and Ambassadors" approach but also lessons for whatever outreach method is employed.

13.15.7. A research-based model for writing interpretive botanical trail signs

J. H. Wandersee[1], R. M. Clary[2];
[1]Louisiana State University, Baton Rouge, LA, United States,
[2]University of Louisiana at Lafayette, Lafayette, LA, United States.

Outdoor interpretive signage systems can provide reliable, trailside, plant science information every day of the year, without the need for added site personnel to serve as guides or the continuing expense and litter potential of printed trail guides.When we discovered an exemplary outdoor trail signage system at Mississippi State University's Crosby Arboretum, we conducted an in-depth content analysis of all 158 interpretive signs, in order to: (1) uncover what textual and design elements made the Crosby Arboretum signage system's trail signs seem more interesting and readable to us than any we had seen previously worldwide; (2) help plant science instructors choose field trip sites wisely by assessing the *opportunity to learn* from interpretive science signage found along established outdoor trails; and (3) assist those who wish to design a public, interpretive plant science signage system for a nature trail at a school, nature park, arboretum, or botanic garden. Our findings led us to develop our research-based quantitative and qualitative model for writing interpretive botanical trail signs that is currenty being applied at several sites across the US.

14.1.1. Plant food allergens: Structures, characteristics and relationships

P. R. Shewry[1], J. A. Jenkins[2], S. Griffiths-Jones[2], H. Breiteneder[3], E. N. C. Mills[2];
[1]Rothamsted Research, Harpenden, United Kingdom, [2]IFR, Norwich, United Kingdom, [3]Medical University of Vienna, Vienna, Austria.

A wide range of proteins present in plant-derived foods have been reported to result in allergenic symptoms following prior sensitisation via the GI tract or to related proteins present in pollen. Although they occur in a diverse range of foods the vast majority of the proteins that sensitise via ingestion fall into only two superfamilies of plant proteins, called the prolamin superfamily and the cupins. We will compare the structures and evolutionary relationships of both allergenic and non-allergenic members of these superfamilies. We will also speculate on the relationship between their allergenic properties and biological activities and discuss how our knowledge of these relationships can be used to develop risk assessment procedures for novel and GM foods. We will also speculate on the possibility of using GM or other new technologies to reduce the contents or eliminate allergenic proteins from foods.

14.1.2. A structural classification of pollen allergens

C. Radauer, H. Breiteneder;
Center of Physiology and Pathophysiology, Medical University of Vienna, Vienna, Austria.

Atopic individuals can be sensitized by pollen from a great number of conifer species and monocotyledonous as well as dicotyledonous species of flowering plants. Despite the diversity of sensitizing pollen sources, most pollen allergens can be classified into a small number of protein families. The Allergome database contains 129 pollen allergens with complete or nearly complete sequences. 125 of these sequences can be grouped into 24 known protein families. The ten most abundant families contain 80% of all allergens. The most widely distributed pollen allergen families are the profilins and calcium-binding proteins containing EF hand domains. Other nearly ubiquitous families are the Ole e 1 homologues and the polygalacturonases. A large number of grass pollen allergens belongs to the expansin family. Additional allergen families with a limited species distribution include pectate lyases (Cupressaceae and Asteraceae), ribonucleases (Poaceae) PR-10 pathogenesis-related proteins (Fagales), thaumatin-like proteins (Cupressaceae) and flavoproteins (Poaceae). This work was supported by grant SFB-F018-02 from the Austrian Science Fund.

14.1.3. Structure and allergenicity of food allergens from the PR-5 family

W. Keller[1], Y. Dall'Antonia[1], M. Bublin[2], H. Fuchs[2], M. Jankovic[1], T. Pavkov[1], U. Smole[2], H. Breiteneder[2];
[1]Inst. of Chemistry, Graz, Austria, [2]Medical University of Vienna, Vienna, Austria.

Thaumatin-like proteins (TLPs) belonging to the PR-5 family of pathogenesis related proteins have been identified as allergens from plant foods and pollen. We recently succeeded in crystallizing two members of this allergen family: the TLP isolated from ripe cherries, Pru av 2, a 23 kDa protein was crystallized in space group $P2_1$ with unit cell parameters a=44.8Å, b=41.8Å, c=59.6Å, beta=106.8°, and the major kiwi allergen, Act c 2, a 22 kDa protein was crystallized in space group C2 with cell dimensions a=71.6Å, b=48.5Å, c=50.9Å, beta=100.56°. Both crystal forms diffracted to atomic resolution at the synchrotron. The structures were solved by molecular replacement and the model building and refinement is in progress. In this paper the allergen structures will be compared with the known structures of other TLP proteins such as zeamatin, thaumatin, osmotin and PR-5d, and the correlation between structure and cross-reactivity will be discussed. Acknowledgements: This work was supported by the Austrian Science Fonds (FWF) projects F01805 and F01802.

14.1.4. Localisation of *Bet v* 1 and *Bet v* 7 in the anthers of birch, hazel, and rye grass

S. Vinckier[1], P. Cadot[2], M. Grote[3], E. Smets[1];
[1]Institute of Botany and Microbiology, Leuven, Belgium, [2]Gasthuisberg, Leuven, Belgium, [3]Institute für Medizinische Physik und Biophysik, Münster, Germany.

Pollen of birch is one of the main causes of allergic reactions in Europe. In recent studies evidence is supplied that allergenic activity in the micronic aerosol may play an important role in causing allergic reactions. In the anthers of flowering plants tiny (< 4 µm) granules can occur on the locule walls. These granules are called orbicules or Ubisch bodies. The hypothesis of the potential role they may play as vector of allergens is tested by investigating the localisation of the birch allergens *Bet v* 1 and *Bet v* 7 across the birch anther using immunogold electron microscopy. The localisation of cross-reactive homologs of these allergens is studied in the anthers of hazel and rye grass. The results indicate that orbicules and pollen of birch, hazel and rye grass might act as effective vectors for *Bet v* 7. In birch and hazel orbicules only minor labelling occurred for *Bet v* 1. The immunologic consequences of these localisation studies are discussed.

14.1.5. Art v 1, a defensin-like allergen from *Artemisia vulgaris* pollen

G. Gadermaier[1], B. Jahn-Schmid[2], R. Leonard[3], M. Himly[1], F. Altmann[3], C. Ebner[2], F. Ferreira[1];
[1]Department of Molecular Biology, University of Salzburg, Salzburg, Austria, [2]Department of Pathophysiology, Medical University of Vienna, Vienna, Austria, [3]Department of Chemistry, Universitaet für Bodenkultur, Vienna, Austria.

In late summer, pollen grains from Asteraceae weeds are a major source of allergens worldwide. Ninety-five percent of patients allergic to mugwort (Artemisia vulgaris) are sensitized to the major allergen, Art v 1. The N-terminal domain of Art v 1 shows a cysteine stabilized (alpha/beta) motif typical for plant defensins. The C-terminal cysteine-rich region consists of several (Ser/Ala)(Pro)2-4 repeats and is predicted to adopt a left-helical conformation similar to collagen. Proline residues are hydroxylated with a frequency of 78-80% and a new type of plant O-glycans are attached during post-translational modification. Evaluation of the antibody binding properties of natural and recombinant Art v 1 produced in E.coli demonstrated the involvement of the defensin folding and post-translational modifications in the formation of epitopes recognized by IgE antibodies from allergic patients. The T cell response of Art v 1 is characterized by one strong immunodominant epitope and is associated with the expression of HLA-DRB1*01. This work was supported by grant FSP S88 (S8802, S8803, S8808) from the FWF, Austria.

14.1.6. Expression of the latex allergen Hev b 2 in bacteria and tobacco plants

V. Wolf, A. Erler, G. Obermeyer;
Molecular Plant Physiology, Div. Allergy & Immunology, Dept.
Molecular Biology, 5020 Salzburg, Austria.

The use of purified allergens allows a molecule-based diagnosis and therapy of allergies instead of the currently used allergen source-based assays, e.g. skin prick tests with pollen extracts. A low-costs production of high amounts of recombinant allergens can be achieved by molecular farming strategies; an ideal prerequisite for a wide use of recombinant allergens by medical practioners in future. Additional benefits of the plant-based production of allergens are the specific post-translational modifications and the correct protein folding that are unlikely in non-plant expression systems (bacteria, yeast, mammalian cells). The latex allergen, Hev b 2, is a glycosylated ß-1,3 glucanase containing vacuolar targeting sequences (VTS) and so far, no recombinant Hev b 2 is available. The Hev b 2 sequence was cloned into a bacterial expression vector including a Strep-tag but without the VTS and in a plant expression vector including a His-tag and the VTS. Both expression systems were compared in respect to their ability to produce a recombinant Hev b 2 protein that is recognised by IgEs from latex allergy patients.

14.1.7. Characterisation of different allergens in Rosaceous fruits

G. Marzban[1], Y. Ma[1], K. Hoffmann-Sommergruber[2], H. Breiteneder[2], C. Radauer[2], A. Martinelli[3], M. Zaccarini[3], M. Laimer[1];
[1]IAM, Vienna, Austria, [2]Dept. of Pathophysiology, AKH, Vienna, Austria, [3]Consorzio Italiano Vivaisti, Ferrara, Italy.

Regular consumption of fruits and vegetables is generally encouraged in the European Union to enhance health and prevent cancer and cardiovascular diseases. However, certain fruits or vegetables may pose a risk to atopic individuals since up to 70% of birch pollen allergic persons react with proteins homologous to pollen allergens that are expressed in Rosaceous fruits. In the frame of the present work, we focus on the characterisation of different allergens also known as pathogenesis-related proteins, e.g. PR-5, PR-10, PR-14, in fruits, which are consumed in high amounts across Europe, such as apple, pear, peach, apricot, strawberry and raspberry. To this purpose different diagnostic and analytical techniques have been employed, e.g. ELISA, Real Time PCR, ITP (Immuno Tissue Printing) and Western Blot. This methodology has allowed a first insight into localisation and cultivation- and storage method-dependent expression levels of allergens within fruits. Attempts are underway to understand the biological function of these proteins. Financed by contract SAFE, QLK1-CT-2000-01394 and Hochschuljubiläumsstiftung der Stadt Wien, H-998/2004

14.2.1. Seed size and the new fusion between ecology and evolution

M. Westoby;
Macquarie University, Sydney, Australia.

Seed size is a trade-off between maximizing the numbers of offspring produced and maximizing each offspring's chance of survival. The resulting compromise has been struck at seed sizes that vary enormously across species. A larger body of data has accumulated worldwide for seed size than for any other species trait. Therefore seed size research is a testing ground for a new fusion between ecology and evolution, where we seek to explain the spread of a functional trait across the full range of present-day species worldwide, and at the same time we narrate the whole evolutionary history of a trait. The most consistent theme emerging from this scale-shift has been the strong association between evolutionary divergence in size of the vegetative plant at adulthood, and evolutionary divergence in seed size. How can this theme be harmonized with the strong experimental evidence indicating the benefit of larger seed size is improved seedling survival per week under various hazards? New developments in life-history theory are needed.

14.2.2. Evaluation of the tradeoffs between light capture, hydraulics and biomechanics with a 3-dimensional architecture model, Y-plant.

R. W. Pearcy;
University of California, Davis, Davis, CA, United States.

The efficiency of light capture of a crown can be enhanced either by changes in leaf angles or by the repositioning of leaves in space so that self-shading is minimized. Studies with shrub Psychotria species native to a Panamanian tropical forest understory revealed that leaf angles were near optimum for maximizing light capture. However light capture efficiencies were found to be surprisingly low because of significant self-shading. Simulations with the 3-D functional-structural model Y-plant were used to explore the potential constraints on minimizing self-shading. Simulations in which biomass allocation between internodes and leaves was varied revealed that increasing internode length at the expense of leaf area enhanced light capture efficiencies and whole plant carbon gain. However, the biomass costs of maintaining sufficient biomechanical support and hydraulic conductivity are suggested to be constraints on the realized light capture efficiencies of these species.

14.2.3. Hydraulic architecture and transport efficiency

K. A. McCulloh[1], J. S. Sperry[2];
[1]Oregon State University, Corvallis, OR, United States, [2]University of Utah, Salt Lake City, UT, United States.

Plant hydrovascular systems exhibit two pervasive traits: a trunk-to-twig decline in xylem conduit diameter, and in the leaf-specific conductivity of the axis. These traits reduce the frictional resistance per vascular investment. The steeper the trunk-to-twig declines in diameter and conductivity, the fewer and wider are the conduits in trunk vs. twig, and the greater the transport efficiency. Greater efficiency, however, causes top-heavy vasculature and mechanical vulnerability. This consequence limits maximum efficiencies to growth forms like vines where conduits are not mechanically significant. The tendency for trees to follow Da Vinci's area-preserving branching rule may be a compromise between hydraulic efficiency and mechanical stability. Hydraulic efficiency is also limited by maximum conduit diameter. Diameters may be limited by both mechanical considerations and by susceptibility to cavitation, with mechanisms differing between conifer tracheids and angiosperm vessels.

14.2.4. How do palmate and pinnate leaf venation systems differ in function? Divergence in the impacts of damage on hydraulics and gas exchange

L. Sack[1,2], E. M. Dietrich[3], C. M. Streeter[3], D. Sanchez[3,4], N. M. Holbrook[5];
[1]University of Hawai'i, Honolulu, HI, United States, [2]Harvard Forest, Cambridge, MA, United States, [3]Harvard Forest, Petersham, MA, United States, [4]Centro de Ciencias Medioambientales C.S.I.C., Madrid, Spain, [5]Harvard University, Cambridge, MA, United States.

Leaves of dicotyledons vary tremendously in their venation architecture, but little is known of the potential functional consequences. One striking dichotomy is between palmate and pinnate arrangement of major veins. We applied cutting treatments to the veins of leaves on naturally occurring trees of temperate woody angiosperms, for species with pinnately- or palmately-veined leaves. Once the leaves had healed the wounds, we measured performance, relative to control leaves, in leaf hydraulic conductance, in stomatal conductance and in parameters of chlorophyll fluorescence, as an index of photosynthetic function. Pinnately-veined leaves were inherently more sensitive to damage: severing the primary vein dramatically reduced leaf function. By contrast, in palmately-veined leaves, severing the central primary vein reduced function much less strongly, especially further from the cut, with the surrounding primary veins compensating for the loss of water supply capacity. Functional differences among leaves of contrasting vascular design have implications for leaf evolution, ecology and biogeography.

14.2.5. Hydraulics and mechanics of growth form evolution

N. Rowe;
Botany and Plant Architecture Bioinformatics -AMAP, Montpellier, France.

Different plant growth forms possess different combinations of hydraulic and mechanical function. Trees, shrubs, herbs, vines and lianas can show very different functional strategies. Plant size, height and mass are parameters traditionally investigated for surveying trends in plant structural diversity but differences in plant growth form - how the plant is positioned and whether it mechanically supports itself or not - are also important. So, how is growth form diversity best understood? Combinations of functional attributes such as hydraulic and mechanical architectures can play a prominent role in developing appropriate innovations for diverse and extreme ranges of growth forms. It is of extreme interest to know how such complex functional traits appear and become potential innovations for further morphological radiations. The bifacial vascular cambium is an important innovation permitting a wide range of hydraulic and mechanical functioning. One of the most important attributes ensuring long-term survival of lignophytes was the morphological flexibility ensured by cambial development and the potential for varying growth form and body size.

14.2.6. Alternative designs and the evolution of functional diversity in tree seedlings.

C. O. Marks, M. J. Lechowicz;
McGill University, Department of Biology, Montreal, PQ, Canada.

High levels of quantitative variation in functional traits exist among plant species, both within sites and among sites. This trait diversity affects species distributions as well as ecosystem processes. Trait variation among sites often can be explained by species adaption to major environmental differences, but explaining the large variation observed within sites poses more of a challenge. We present the evolution of alternative functional designs of approximately equal fitness in the same environment as an explanation. We use a genetic algorithm and a realistic model of tree seedling growth and survival to demonstrate how the numerous tradeoffs associated with the multifunctional nature of tree seedling designs result in the evolution of many alternative, but functionally equivalent designs. These alternative designs show convergence in terms of growth rate and survival in a given environment while retaining high diversity in individual traits. Changes in environment shift the range of potential values for many traits but do not preclude the evolution of diverse alternative designs.

14.2.7. Climate and land plant architecture - general patterns and individual solutions

V. Mosbrugger, A. Roth-Nebelsick, T. Schneck;
Institute for Geosciences, Tübingen, Germany.

For all land plants, climate is an important environmental parameter influencing not only the distribution and physiology but also the architecture of land plants. In particular it is well known that the distribution of life forms as well as the occurrence of wood anatomical and of leaf morphological characters is largely controlled by climate although the functional relationship between climate and land plant architecture is still poorly understood. Here we test to what extent certain relationships between land plant architecture and climate are controlled by physico-chemical principles and/or by the systematics and evolutionary history of the plants. The result has significant implications for palaeoclimatology since the Recent relationship between features of land plant architecture and climate is frequently used to reconstruct the climate of the geological past.

14.3.1. Structure, function and biosynthesis of arabinogalactan-proteins (AGPs)

A. Bacic[1], K. L. Johnson[2], Y. Qu[1], P. Gleeson[1], U. Nagasandra[3], C. Schultz[3];
[1]University of Melbourne, Parkville, Victoria, Australia, [2]University of Edinburgh, Edinburgh, United Kingdom, [3]University of Adelaide, Glen Osmond, SA, Australia.

Arabinogalactan-proteins (AGPs) belong to the Pro/Hyp-rich family of complex glycoproteins. In *Arabidopsis,* they include classical AGPs, AG-peptides, basic AGPs and fasciclin-like AGPs (FLA) (Johnson et al, Plant Physiol. 133:1911). We are focussing on FLAs because they include putative cell adhesion domains. The identification of a salt overly sensitive (*sos5*) mis-sense mutant in the H2 region of *AtFLA4* (Shi et al, Plant Cell 15: 19) indicates that these domains are important for FLA function. We are now comparing *fla1* and *fla4* (*sos5*) mutants. We are also focussing on the ɓ(1-3) galactosyltransferases thought to be involved in the assembly of the AG chains in AGPs. These Golgi-located enzymes belonging to family GT31 in the CAZY database (http://www.afmb.cnrs-mrs.fr/~pedro/CAZY/db.html). We are studying the expression patterns, sub-cellular locations and enzymatic activity of 5 distinct members of this family. This work is supported by an ARC DP grant (DP0343454).

14.3.2. Lysine-rich arabinogalactan-proteins (AGPs): structure, localization and function

A. M. Showalter, W. Sun, J. Yang, K. McGovern, M. J. Kieliszewski;
Ohio University, Athens, OH, United States.

Lys-rich AGPs comprise a subfamily of hyperglycosylated, hydroxyproline-rich AGPs which decorate plant cell surfaces and include LeAGP-1 in tomato and AtAGP 17, 18 and 19 in Arabidopsis. Overexpression of LeAGP-1 results in tomato plants that: were significantly shorter, were highly branched, produced less fruit, and produced seeds that were significantly smaller than normal seeds. The phenotype of these transgenic plants is similar to that of cytokinin-overproducing plants, and LeAGP-1 mRNA expression is up-regulated by cytokinins. We speculate that LeAGP-1 is an extracellular mediator of cytokinin. In Arabidopsis, a T-DNA knockout mutation in AtAGP19 was obtained. Compared to wt plants, the mutant had: lighter green leaves containing less chlorophyll and anthocyanins, rounder leaves with shorter petioles, shorter and thinner inflorescence stems, slower growth with delayed and reduced flowering, fewer siliques and seeds, and fewer lateral roots. Complementation with the wt AtAGP19 gene restored wt phenotypes. Consequently, AGP19 functions in plant growth and development of multiple plant organs consistent with its RNA expression pattern.

14.3.3. Control of cell elongation by xyloglucan fragment oligosaccharides

C. N. K. Suda[1], T. Takeda[1], Y. Mitsuishi[2], Y. Furuta[3], K. Baba[1], T. Hayashi[1];
[1]Research Institute for Sustainable Humanosphere, Kyoto University, Uji, Japan, [2]National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan, [3]Biological Function Science Course, Graduate School of Kyoto Prefectural University, Kyoto, Japan.

Xyloglucans, which occur in the primary and secondary walls, are composed of 1,4-beta-glucan backbone with 1,6-alpha-xylosyl residues along the backbone. Xyloglucans cross-link adjacent cellulose microfibrils to form tethers in the walls. Xyloglucan endotransglucosylases (XETs) in the walls rejoin a xyloglucan chain to another chain by transglucosylase reaction. In the previous work we have already demonstrated that the integration of whole xyloglucan caused the suppression of cell elongation by the action of wall-bound XET, whereas that of its fragment oligosaccharide (XXXG) accelerated growth. In the present work, we examined the elongation of pea stem segments by the addition of a series of xyloglucan heptasaccharides (XXXG), 1 to 10 units of XXXG (1 to 10 kD). The results showed that the fragment oligosaccharides composed of 1 to 4 units accelerated and those composed of more than 6 units of XXXG suppressed cell elongation.

14.3.4. Di-isodityrosine in extensin analogs crosslinked in vitro

M. J. Kieliszewski[1], M. A. Held[2], L. Tan[2], A. Kamyab[2];
[1]Biochemistry Research Facility, Atnens, OH, United States, [2]Ohio University, Athens, OH, United States.

Extensins are cell wall hydroxyproline-rich glycoproteins that form covalent networks catalyzed by extensin peroxidases. To identify the precise crosslinks involved, we designed a set of extensin analogs encoding tandem repeats of the P3 motif: Ser-(Hyp)4-Ser-Hyp-Ser-(Hyp)4-Tyr-Tyr-Tyr-Lys, , including Tyr to Phe and Lys to

Leu variations. Expression of these P3 analogs in tobacco cells yielded glycoproteins with all Pro residues hydroxylated and subsequently arabinosylated and with galactosylated Ser. This was consistent with earlier analyses of P3 glycopeptides isolated from cell wall digests and the predictions of the Hyp contiguity hypothesis. The tyrosine-rich P3-analogs also contained isodityrosine, formed in vivo. Significantly these isodityrosine-containing analogs were further crosslinked in vitro by an extensin peroxidase to form the tetra-tyrosine intermolecular crosslink amino acid di-isodityrosine. This is the first identification of an intermolecular crosslink amino acid in an extensin module and corroborates earlier suggestions that di-isodityrosine represents one mechanism for crosslinking extensins in muro.

14.3.5. Structure and interaction of HRGPs in *Chlamydomonas reinhardtii*

S. Waffenschmidt[1], U. Goodenough[2], P. J. Ferris[2], J. Lee[2], K. Bollig[1], C. Tschesche[1];
[1]Universität zu Köln, Köln, Germany, [2]Washington University, St. Louis, MO, United States.

Extracellular hydroxyproline-rich glycoproteins (HRGPs) in the unicellular green alga *Chlamydomonas reinhardtii* serve two functions: they are constituents of a non-cellulosic cell wall and mediate sexual interaction of gametes of opposite mating type. The sequenced HRGPs in *Chlamydomonas* all prove to be chimeric, with globular and fibrous (shaft) domains. Shaft domains are in a PP II configuration and their amino-acid sequences fall into families of repeated motifs (e.g. PSn, PPXn, PPSPXn), where a given shaft often carries several discrete repeating subdomains. Both, agglutinins and cell wall proteins interact and form characteristic meshworks. The self-assembly of outer wall proteins *in vitro* was shown to produce the same lattice organization as *in vivo*. In a recent study, we have used isolated outer wall GPs and analyzed their interactions under equilibrium and real time conditions. The data obtained enable us to quantitatively describe the formation of the outer non-covalently crosslinked cell wall.

14.3.6. Mutations affecting pectin formation suppress the *Arabidopsis* cell wall formation mutant lrx1

C. Ringli, A. Diet;
University of Zürich, Zürich, Switzerland.

Extracellular leucine rich repeat-extensin proteins (LRX) are likely to have a regulatory role during cell wall formation. The paralogous Arabidopsis genes *LRX1* and *LRX2* are expressed in root hairs and *lrx1* mutants develop deformed root hairs. This mutant phenotype is enhanced in the *lrx1*/*lrx2* double mutant. Ultrastructural analysis of *lrx1* and *lrx1*/*lrx2* mutants revealed an aberrant cell wall structure. Thus, LRX1 and LRX2 synergistically interact and are important for root hair cell wall formation. A suppressor screen was performed on the *lrx1* mutant and several *rol* (repressor of *lrx1*) mutants were isolated that display wild-type root hairs and thus suppress the *lrx1* phenotype. Two alleles of *rol1* were identified and map-based cloning revealed mutations in a gene that appears to be involved in pectin biosynthesis. We are currently characterizing the cell wall sugar composition and -structure of wild-type, *lrx1*, *rol1-1/lrx1*, and *rol1-2/lrx1* plants. This analysis will possibly allow determining whether the suppressive effect in the *rol1* mutant is specific and thus LRX1 is important for the proper formation of the pectic matrix of root hairs.

14.3.7. Arabinogalactan-proteins and plant cell expansion

P. Knox;
University of Leeds, Leeds, United Kingdom.

Arabinogalactan-proteins (AGPs) are a complex class of plant proteoglycans that occur at plasma membranes and cell walls. AGPs consist of diverse galactan-based heteroglycans that can be associated with a diversity of core proteins. Several lines of evidence indicate that AGPs have fundamental roles in plant biology. The presentation will focus on the possible function of AGPs in plant cell expansion processes. Using a diversity of experimental approaches including Yariv-reagent inhibitors of AGP action, monoclonal antibodies to AGP glycans and genetic dissection, evidence for the involvement of AGPs in the extension of apical cells of protonemata of the model bryophyte Physcomitrella patens will be described. Physcomitrella protonemata extend by a tip-growing mechanism that is sensitive to AGP-binding Yariv reagents. Bioinformatic and biochemical analyses of Physcomitrella AGPs have provided insight into the structure of bryophyte AGPs in relation to those of higher plants.

14.4.1. The evolution of character coding

M. Källersjö;
Swedish Museum of Natural History, Stockholm, Sweden.

All morphological systematists from Linnaeus and Ray and onwards have been faced with the problem of describing observed variation as a recognizable suite of characters and states. While great authorities such as Linnaeus and Hennig undoubtedly encountered this problem, it was only with the introduction of numerical methods in the 1950s, however, that this subject was explicitly discussed, thus giving rise to character coding as a field. Early methods were inadequate, both for expressing information and for use in phylogenetic inference. While more recent methods have solved many of those problems, some confusion has persisted in the literature. Interest in molecular evolution at first led to reduced emphasis on any but trivial coding methods, but more complete use of molecular information, such as indels and other structural rearrangements, gene order and gene expression, seems likely to raise the same kinds of coding problems seen with morphological data.

14.4.2. Character coding for phylogenetic analyses of structural and functional genomic data

V. A. Albert;
Natural History Museum, Oslo, Norway.

Data bearing on the structure and function of genomes is accruing exponentially. However, development of tools to describe heredity-based hierarchical patterns and processes has lagged behind. For structure, reconstruction of organismal phylogeny can be based on 1) gene order among multiple genomes, or 2) gene presence vs. absence. Also possible 3) is optimization of genomic content (genes +/-) onto *a priori* trees to estimate ancestral gene complements at nodes. For 1), the state space provided by enormous numbers of alternative character states (synteny orders) provides a parsimony/likelihood equivalence. For 2) and 3), lengths of strings under comparison (genes) mean that Dollo parsimony coding will also be likelihood equivalent. However, just as with standard phylogenetic analyses, lateral transfer can breach an hierarchical process assumption. Phylogenetic methods are also appropriate for examining functional genomic data if such information has an underlying hereditary basis. Microarray expression profiles from different organisms can be analyzed cladistically with explanatory power unavailable from popular phenetic clustering methods.

14.4.3. Homology and the circumscription of characters

J. V. Freudenstein;
Ohio State University Herbarium, Columbus, OH, United States.

Characters are the fundamental hypotheses on which all phylogenetic analyses are based, meaning that the decision about how observations are translated into characters is of paramount importance in systematics. Some current character definitions are inadequate because they fail to circumscribe the character clearly. Moreover, the distinction between character and character state is accepted by many but rejected by others. Important issues to consider in circumscribing characters are how organismal variation originates and whether units of variation are independent of each other. Here, the position is taken that characters correspond essentially to genetic paralogs and their states to their orthologs and this distinction should be embraced as a paradigm for all data types. This approach provides a non-arbitrary circumscription for characters. Furthermore, there are practical coding implications that follow from the way that characters are viewed and these need to be considered when studies of real organisms are undertaken.

14.4.4. A pluralistic approach as a global solution for phylogenetic analysis of complex data sets

F. Lutzoni, **V. Reeb**, F. Kauff, J. Miadlikowska;
Department of Biology, Duke University, Durham, NC, United States.

Positional homology assessment of nucleotides and amino acids when comparing multiple sequences is tightly linked to phylogenetic inference. Length variation among sequences being considered for phylogenetic analyses represent a special and complex case for which there is no optimal single solution.

Because indels are concentrated in distinct regions of alignments, decoupling the alignment process from the phylogenetic search allows a pluralistic approach where informed decisions can be made for each segments of the alignments containing at least one indel. Solutions for simple to highly complex alignment regions containing indels will be demonstrated using empirical results. Congruence among data partitions, efficiency of phylogenetic methods, availability of characters without indels, and the number of sequences (or taxa) part of the alignment are factors to be considered for finding optimal solutions.

14.4.5. Homoplasy is ignorance: Enlightenment through reciprocal illumination.

D. W. Stevenson;
The New York Botanical Garden, Bronx, NY, United States.

The naming of characters and character states implicitly contains *a priori* homology statements. While morphological characters may be difficult to assess and code *a priori*, they do lend themselves to testing via cladistic analysis and reciprocal illumination, i.e., *a posteriori*. There is no homoplasy in nature only our failure to see the difference. Consider the occurrence of perisperm in *Acorus* and *Hydatella*. What initially appears as homoplasy in a character state because in occurs twice on a cladogram may, in fact, be precisely what the cladogram indicates: two different things. In fact, development has shown this because the former is dermal in origin and the latter is subdermal in origin. Thus, by extension, in DNA (probably an acronym for Don't Need Anatomy) sequence data not all As are the same. An A can be replaced by a T in a sequence and later in time that T can be replaced by an A in exactly the same position. The A's are of course exactly the same but yet not the same A's historically. Of course this does not subject itself to reciprocal illumination in the same way that morphological, phytochemical, anatomical characters do. How ignorant are we?

14.4.6. Character-based phylogenetic Linnaean classification: taxa should be both ranked and monophyletic

D. Potter[1], J. V. Freudenstein[2];
[1]University of California, Davis, CA, United States, [2]Ohio State University Herbarium, Columbus, OH, United States.

The modern approach to classification relies on character-based phylogenetic patterns. Three views have emerged about the relationship between classification and phylogeny reconstruction. The first, exemplified by the PhyloCode, is that ranked classifications should be abandoned in favor of naming clades. The second view is that ranks should be maintained and that this logically requires the acceptance of paraphyletic taxa, which is the result of inappropriate interpretation of cladograms. We support the third view, that ranks should be maintained, but that taxa above the level of species should be circumscribed as putative monophyletic groups, underscoring the fact that cladistic principles and ranked taxonomy are compatible and complementary. Coupling Linnaean taxonomy with the criterion of monophyly facilitates viewing classifications as explicit, testable hypotheses of relationship. Minor changes to the ICBN can address concerns about the proliferation of monotypic taxa that could result from strict application of this idea. Such classifications do not ignore the "modification" in "descent with modification."

14.4.7. Ragged ends and gene duplications: new strategies for old problems

M. Frohlich;
Natural History Museum, London, United Kingdom.

Two topics will be discussed: (1) Regions of poor alignment of amino acid or DNA sequences are typically excluded from phylogenetic analyses, but regions of ragged alignment adjacent to well-aligned blocks may provide especially informative phylogenetic signal. (2) Phylogenetic analyses of duplicated genes are increasingly used to infer organismal phylogeny. The method of Double Data Entry (DDE) can be used to analyze paralogs resulting from a single duplication event. DDE combines information from the two paralogs to infer an organismal phylogeny, as does Uninode coding. DDE avoids a potential artifact arising from the prior calculation of the states at the uninode, which cannot change during the subsequent phylogenetic analysis. DDE is appropriate for parsimony as well as for other methods, such as ML or distance methods. Standard phylogenetic software does not require modification for use with DDE.

14.5.1. Evoluton of cauliflory in Bignoniaceae: systematics, development and ecology

M. L. Zjhra;
Georgia Southern University, Statesboro, GA, United States.
