The role of phylogenetic constraint, preadaptation and/or adaptation in the evolution of cauliflory is explored for this common but poorly understood inflorescence architecture of the tropical rainforest understory. This disassociation of reproductive from vegetative growth has stimulated a range of hypotheses relating to flower/fruit characters, tree architecture, phenology, and visual vs. olfactory attractants. Although much speculation has been generated over cauliflory, little experimental evidence has been produced, and none in a phylogenetic context. Using a comparative phylogenetic approach we examine the evolution of cauliflory within Bignoniaceae. These traits are studied across lineages, as well as compare sister taxa that are not cauliflorous. Species richness is examined as a means to explore the possibility of cauliflory as a key innovation. By comparing these patterns within and across lineages, a better understanding can be achieved of both the phylogenetic, developmental, and ecological constraints on the evolution of the cauliflorous syndrome.

14.5.2. Phylogenetical relationship of the Pithecoctenninae (Bignonieae: Bignoniaceae) subtribe on base of morphological characters

C. Burelo Ramos, F. Lorea Hernández;
Instituto de Ecologia A.C., Xalapa, Mexico.

A phylogenetic hypothesis of subtribe Pithecocteniineae (Bignonieae, Bignoniaceae) is presented, derived from the analysis based on a parsimony model. The ingroup of the surveyed taxon included 33 species (out of 42 in total) of the genera Amphilophium, Distictella, Distictis, Glaziovia, Haplolophium, and Pithecoctenium, while the outgroup considered one species each of Mansoa and Pyrostegia. Forty one characters, comprising features of pubescence, gland types, floral morphology, pollen exine, and seed wing anatomy, were considered in the analysis. The resultant consensus tree of the study (out of 606 equally parsimonious trees) clearly sustain just three distinct monophyletic groups, strongly supported by statistical values of Jacknife and decay index, suggesting the recognition of only three genera: Amphilophium (including Haplolophium, and Glaziovia), Distictis (including Distictella), and Pithecoctenium. Thus a new generic classification within the subtribe is proposed.

14.5.3. Phylogeny and biogeography of the genus *Incarvillea* (Bignoniaceae)

S. Chen[1], K. Guan[1], Q. Cronk[2];
[1]Kunming Institute of Botany, Chinese Academy of Sciences, Kunming, China, [2]UBC Botanical Garden & Centre for Plant Research, Faculty of Agricultural Sciences, University of British Columbia, Vancouver, BC, Canada.

Incarvillea is a herbaceous and temperate member of Bignoniaceae, previously divided into four subgenera, Niedzwedzkia, Amphicome, Incarvillea, and Pteroscleris. Niedzwedzkia and Amphicome have in the past been treated as independent genera, and different relationships have been proposed for the four subgenera. We studied phylogeny of the genus based on the data from cytology, pollen morphology, DNA sequences, and analyzed biogeography of the genus using DIVA (Dispersal-Vicariance Analysis) based on the combined tree resulted by the ITS and trnL-F sequence data analysis. The results indicated that all species studied are very similar in pollen morphology, but differ in karyomorphology. Maximum parsimony analysis using ITS and trnL-F sequences resulted in similar trees and showed that the genus is monophyletic, as the interspecific similarity in karyomorphology and pollen characters implied. Biogeographic history as an explanation for the results is also explored.

14.5.4. Development and Function of Included Phloem in Woody Lianas of the Bignoniaceae

D. R. Dobbins;
Millersville University, Millersville, PA, United States.

Lianas in the subfamily bignonieae exhibit atypical secondary growth by developing included and internal phloem. Development of included phloem first occurs in the "corners" of the stem and is correlated with the phyllotatic pattern and vascularization. Included phloem occurs when segments of cambium become unidirectional and produce secondary phloem but little, if any, secondary xylem. The activity of the unidirectional segments can be reversed by auxin and gibberellin. Multiseriate rays border the phloem furrow and extend the length of the internodes allowing the included phloem to slide by the stationary secondary xylem. Rays also may serve as physiological barriers to growth regulating substances that influence differentiation of cambial derivatives. Selective defoliation experiments suggest these substances are coming from the leaves. In addition, critical experiments have shown that a possible function of included phloem is allowing the liana to twist and bend without separating the vascular connection between stems and roots. When complete girdling occurs, included phloem prevents death by regenerating a new cambium and periderm.

14.5.5. Radiation and risk. Assessing threats to trees endemic to Madagascar.

T. C. Good[1,2], M. Zjhra[3], C. Kremen[2];
[1]DIVERSITAS, Caracas, Venezuela, [2]Princeton University, Princeton, NJ, United States, [3]Georgia Southern University, Statesboro, GA, United States.

Madagascar's flora is among the most species-rich on earth. Of the roughly 12,000 known plant species in Madagascar, however, only 1.6% is found in IUCN's Red List of Threatened Species. We assign preliminary IUCN categories to the species of a comparatively well-known species-rich tribe, Coleeae (family Bignoniaceae), endemic to Madagascar. Since the IUCN Red List Categories and Criteria 3.1 discourages the use of "data deficient" classification of species, we develop a novel method for differentiating between species that are truly range-limited versus poorly-sampled, thereby "rescuing" some of the data-deficient species for status assessment, in a method that can readily be applied to other taxa and regions. Roughly 51% of the species of Coleeae are threatened with extinction, three species are presumed extinct, and an additional 11 have not been seen in decades. Due to their recent discovery, 15 species must remain in the data-deficient category until more sampling has been conducted. If Coleeae is representative of the Malagasy flora, or at least other endemic radiated plant groups, then species loss in Madagascar may be even more extreme than we realize.

14.5.6. Evolution of mammal dispersed fruits: Morphology and Anatomy of fruits in Crescentieae (Bignoniaceae)

S. O. Grose, R. G. Olmstead;
University of Washington, Seattle, WA, United States.

Fruit morphology has had great taxonomic importance in Bignoniaceae and has been used traditionally to distinguish tribes in the family. These tribes are monophyletic, with two exceptions: Tecomeae, now recognized as a paraphyletic group with plesiomorphic fruit morphology, and Crescentieae, traditionally characterized by indehiscent fruits and with members characterized by a disjunct distribution. However, Gentry suggested that indehiscent-fruited Bignoniaceae represented two lines of descent. DNA studies have shown that the historic delimitation of this tribe is incorrect and it has been split into tribes Crescentieae (Neotropics) and Coleeae (Madagascar), with Kigelia (Central Africa) not belonging to either. This study focuses on fruit evolution in Crescentieae. Comparative morphology and anatomy of fruits from four genera, Tabebuia, Crescentia, Amphitecna, and Parmentiera show the structural changes that have taken place in the transition from a typical dehiscent wind-dispersed Bignoniaceae fruit to an indehiscent, fleshy fruit suggested to be mammal dispersed. These changes are interpreted in light of the phylogeny of Bignoniaceae.

14.6.1. Radiations, extinctions, and evolutionary dead ends in the Amaranthaceae/Chenopodiaceae alliance

G. Kadereit;
Institut für Spezielle Botanik und Botanischer Garten, Johannes Gutenberg-Universität, Mainz, Germany.

Molecular data show a rapid formation of five major lineages within the Amaranthaceae/Chenopodiaceae alliance: the species-poor Polycnemoideae (3 gen./16-18 spp.) and Betoideae (6/16), and the species-rich Amaranthaceae s.str. (c. 70/ c. 1000), Chenopodioideae/Corispermoideae (c. 25/c. 570), and Salsoloideae/Suaedoideae/Salicornioideae (66/c. 700). Of the traditional Chenopodiaceae, the strongly disjunct Betoideae are interpreted as relicts of a formerly widely distributed lineage while the C/C lineage and the S/S/S lineage show several phases of extensive diversification. Radiations of these two lineages, however, took place in different geographical regions and/or at different times. Using molecular phylogenies, molecular clock dating, lineage through time plots, comparative net diversification rates, genetic diversity in relation to taxon number, and the geographical distribution of extant taxa, phases of diversification and evolutionary stagnation of the three major chenopod lineages are traced in relation to paleoclimatic changes, colonization of new regions, and possible ecological or physiological key-characters.

14.6.2. Amaranthaceae and Chenopodiaceae - one family or two?

T. Borsch[1], G. Kadereit[2], K. Müller[1], H. Freitag[3], D. Pratt[4], **K. Weising**[3];
[1]Nees-Institute for Biodiversity of Plants, University of Bonn, Germany, [2]Institut für Spezielle Botanik, University of Mainz, Germany, [3]Institute of Biology, University of Kassel, Germany, [4]Dept. of Biology, Stephen F. Austin State University, TX, United States.

Amaranthaceae and Chenopodiaceae form the most species-rich lineage within Caryophyllales. A widely accepted classification recognizes two families although the merger under Amaranthaceae was proposed recently. Single-gene trees based on rbcL, ndhF, and matK/trnK resolve Amaranthaceae s. str. as monophyletic, but are inconclusive to the position of major chenopodiaceous lineages. Thus, Polycnemoideae either appear sister to Amaranthaceae or first branching in the alliance, and morphological characters in support of either topology can be found. Betoideae are either nested among chenopodiaceous lineages, form a basal polytomy, or are first branching in the alliance. To resolve a more robust phylogeny, a multi-gene approach now combines information from plastid rbcL, matK, and ndhF genes, the trnK group II intron, the atpB-rbcL spacer, and the mitochondrial matR gene. In addition to the combined analysis, phylogenetic signals from different data partitions are compared. Alternative taxonomic treatments are discussed that divide the alliance into one, two, three and four families, respectively.

14.6.3. Study of the genetic diversity within the Salicornieae (Chenopodiaceae) of NW France by means of nuclear and chloroplast DNA markers

E. P. Murakeözy[1,2], N. Poupart[2], E. Deslandes[2];
[1]University Szent Istvan, Godollo, Hungary, [2]LEBHAM-IUEM, Plouzané, France.

Phylogenetic relationships in members of the Salicornieae tribe, natively occurring in the NW coasts of France, were assessed by using three molecular markers: nuclear ribosomal internal transcribed spacer (ITS), chloroplast *trn*L-F (*trn*L-F) and chloroplast *matK* sequences. Parsimony analysis of the ITS sequences failed to resolve clearly the phylogenetic relationships at the specific level within the genus *Salicorni*a. In parallel to phylogenetic studies, a population genetic study was carried out by randomly amplified polymorphic DNAs (RAPD). Analysis of molecular variance (AMOVA) of RAPD fingerprints and neighbour-joining analysis of the populations confirms neither the morphology-based classification at the specific level within the genus *Salicornia*. Both sequencing and RAPD studies were able to differentiate diploid and tetraploid species. On the base of our results, the observed morphological differences do not correspond to different species, rather to "morphotypes", as first suggested by Stace (Stace, 1997). In addition, we confirmed the phylogenetic position of the genus *Arthrocnemum*.

14.6.4. Molecular phylogenetic analysis of american *Atriplex* (Chenopodiaceae)

E. H. Zacharias, B. G. Baldwin;
University of California, Berkeley, Berkeley, CA, United States.

A phylogenetic investigation of Atriplex (Chenopodiaceae) is underway to examine evolutionary patterns, historical biogeography, life-form shifts, and ecophysiological change in the North American lineages (ca. 62 species), with an emphasis on Californian diversity (ca. 37 species, including eight endemics). Necessary limits on taxonomic and gene sampling in previous analyses have left relationships within Atriplex incompletely understood. Expanded molecular phylogenetic sampling of North American members of Atripliceae suggest that neither Atriplex, as traditionally recognized, nor the North American taxa are monophyletic groups. American taxa may represent two distinct lineages with different photosynthetic pathways. American Atriplex taxa with the C3 photosynthetic pathway and some other American C3 Atripliceae taxa may constitute a clade. Life-form evolution in North American Atriplex has been dynamic, with multiple, independent shifts between perennial and annual habits. Exploration of additional taxa and gene regions is being pursued.

14.6.5. Phylogeny and C4 evolution in the genus *Suaeda* (Chenopodiaceae) and related taxa

P. Schütze, H. Freitag, K. Weising;
Institute of Biology, University of Kassel, Germany.

The c. 85 taxa of Suaedoideae are important components of halophytic vegetation worldwide and developed different C$_4$-associated leaf types. In this analysis we deepened our earlier study (Schütze et al. 2003) by extending the sampling. We used comparative sequencing of the nuclear ribosomal ITS region and two non-transcribed chloroplast DNA spacers (*atp*B-*rbc*L and *psb*B-*psb*H) to reconstruct phylogenetic relationships and evolution of key characters. The main results are: (1) *Suaeda, Borszczowia* and *Alexandra* together form a monophyletic group while *Bienertia* holds a position intermediate to Salicornioideae. (2) *Suaeda* splits into two major subclades: The first consists of the annual C$_3$ species of sect. *Brezia*, the second contains all other known species. (3) Several taxa of sect. *Brezia* show intraspecific ITS variability which can used for biogeographic studies. (4) The second subclade contains the sections *Schanginia, Borszczowia, Suaeda, Physophora, Schoberia, Salsina* and *Glaucae*. C$_4$ photosynthesis appears to have evolved independently three times in this group, and once in *Bienertia.*

14.6.6. New morphological characters help in classification of Chenopodiaceae

H. Freitag;
Institute of Biology, University of Kassel, Kassel, Germany.

The diversity of traditional classification schemes in Chenopodiaceae, present at all levels, results from both the scarcity of characters and from uncertainties concerning their significance. To overcome these problems, we started a search for new morphological characters and at the same time reassessed traditional characters on the background of molecular trees (rbcL, ITS, *atp*B-*rbc*L, and psbB-psbH). In the contribution some results from Suaedeae, Salsoleae and Camphorosmeae will be presented. New characters were found in particular in leaf and stem anatomy, trichome type, and in cotyledon structure. The anatomical results are supported by molecular data gained from extensive sampling of the respective subfamilies and allow us to suggest refined classifications at the level of tribes, genera and sections. The phylogenetic trees also revealed a tribe-specific distribution of the two subtypes of C$_4$ photosynthesis, which can likewise be used as taxonomic markers in Chenopodiaceae.

14.6.7. New insights in the systematics of *Chenopodieae* s.l. (*Chenopodiaceae*)

S. L. Mosyakin;
M. G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv (Kiev), Ukraine.

Tribe *Chenopodieae* traditionally housed ca. 7 widely recognized genera. However, in many cases their relationships and generic limits remained obscure. Results of recent morphological, phytogeographical and molecular phylogenetic studies considerably changed our views on circumscription of and natural relations within the tribe, which probably require dramatic taxonomic and nomenclatural rearrangements. Some genera traditionally placed in *Atripliceae* appear to be phylogenetically interspersed with *Chenopodieae* s.str. As an example I consider here the case of three clades: *Chenopodium* s.str., *Blitum* (incl. *Monolepis*, *Micromonolepis*, *Scleroblitum* etc.), and *Dysphania* s.l. (incl. glandular-pubescent taxa previously placed in *Chenopodium* or segregated as *Teloxys*, *Roubieva*, etc.). Main trends of morphological evolution and hypothetical dispersal routes of these three lineages are outlined and most promising taxa for molecular phylogenetic studies are identified. Further progress in systematics of the tribe is possible through combination of morphology-based taxonomy, phytogeographical and molecular phylogenetic approaches.

14.7.1. Evolution of fruit epidermal silica bodies in genus *Carex* and tribe Cariceae.

J. R. Starr;
University of Mississippi, University, MS, United States.

Since the 1970s, fruit epidermal silica bodies have become an integral part of systematic studies in *Carex* (ca. 2000 spp.) as a tool for circumscribing species and sections. Early studies suggested that these characters were conserved, though conflicts with traditional classifications have since questioned their value. This study re-evaluates their utility by examining character change on recent phylogenies in *Carex* and the Cariceae. Patterns of silica body variation in genus *Uncinia* parallel the positive and negative conclusions drawn from studies in *Carex*. Silica body groups frequently conflict with traditional classification, large taxa cannot be defined, and the morphologies of distant taxa are often identical. However, silica bodies are generally consistent with the circumscription of small, well-defined clades in both genera. *Carex*-wide analyses demonstrate that silica bodies can sometimes be useful for delimiting sections, and they are often ideal for circumscribing species. Problems with homology assessment and a lack of discrete characters indicate that silica bodies are best used for species circumscriptions.

14.7.2. using morphology to reconstruct fine-scale phylogenetic relationships in *Carex* (Cyperaceae): Lessons learned

R. F. C. Naczi;
Claude E. Phillips Herbarium, Dover, DE, United States.

Two groups are the subject of ongoing studies to determine the suitability of morphology, s.l. (macromorphology, micromorphology, and anatomy) for phylogenetic reconstruction of *Carex* at the levels of species and section. The first group; sections *Careyanae*, *Granulares*, and *Griseae* (subg. *Carex*); consists of ca. 35 North American and Central American species. The second group, section *Deweyanae* (subg. *Vignea*), is comprised of 6 species of North America and Japan. In combination, anatomy, micromorphology, and macromorphology yield informative data in *Carex* sufficient to diagnose sections and provide highly resolved phylogenetic hypotheses, though support is often low. Any one of these data sets alone usually provides low resolution. The trees reveal significant aspects of character evolution, chromosome number change, and evolution of habitat specificity. For example, reddish coloration of shoot bases is phylogenetically informative, though apparently of four independent origins in the first group. Chromosome number and such environmental parameters as soil calcium concentration often are quite labile in closely related species.

14.7.3. Phylogeny, species-richness and ecological specialization in Cyperaceae tribe Cariceae

M. J. Waterway;
McGill University Herbarium, Ste. Anne de Bellevue, PQ, Canada.

Cyperaceae tribe Cariceae is characterized by both species-richness and habitat diversity. Current phylogenetic hypotheses for this tribe and for particular clades within the Core *Carex* group based on DNA sequence comparisons for at least three gene regions will be used to illustrate niche conservatism for ecologically important traits such as flooding tolerance and shade tolerance as well as niche differentiation between closely related species that co-occur within habitats along gradients of soil pH, soil texture, or water depth. The ability to invade wetland habitats appears to be derived within the tribe and to have evolved only a few times, but in concert with different strategies of clonal growth in different clades and varying levels of species-richness. Clades of predominantly wetland species tend to have broad geographic distribution, often with sister-species on different continents, suggesting recent dispersal. In contrast, species within several early diverging clades are predominantly forest specialists with distinct Asian and North American lineages.

14.7.4. The genus Anthracoidea (Basidiomycota, Ustilaginales) - a marker for the evolution of Cariceae?

M. Hendrichs[1], F. Oberwinkler[2];
[1]Bot. Garden University of TÃ¼bingen, TÃ¼bingen, Germany,
[2]Systematic Botany & Mycology University of TÃ¼bingen, TÃ¼bingen, Germany.

The species of the smut genus Anthracoidea are specific parasites on the subfamily Cariceae with great preference on the genus Carex. The infection site is restricted to the ovaries and appears to be exactly synchronized to host's flowering period. The fungal life cycle, the host specifity and the ecology of typical Anthracoidea-species will be presented. For the first time molecular data are available for nearly half of the described species. Phylogenetic trees are inferred with neighbor-joining (NJ), maximum parsimony (MP), and Bayesian Markov chain Monte Carlo (MCMC) methods. The results are discussed with respect to the species concept and the traditional subdivision of the genus Anthracoidea into subgenera and sections. Furthermore, our results support the notion that molecular data from the parasitic smut genus Anthracoidea may help interprete different phylogenetic hypotheses of its host species.

14.7.5. Chromosome evolution in tribe Cariceae (Cyperaceae): Comparative studies at several hierarchical levels with emphasis on *Carex* section *Ovales*

A. L. Hipp[1,2], P. E. Rothrock[3], E. H. Roalson[4];
[1]The Morton Arboretum, Lisle, IL, United States, [2]University of Wisconsin, Madison, WI, United States, [3]Taylor University, Upland, IN, United States, [4]Washington State University, Pullman, WA, United States.

Understanding chromosome number change in sedges (Cyperaceae) is essential to understanding the role of chromosomal evolution in diversification of the family. Phylogenetic reconstructions in tribe Cariceae suggest that chromosomal evolution proceeds neither by stepwise changes nor by a general tendency for chromosome numbers to increase. Phylogenetic data within *Carex* section *Ovales* suggest that chromosome numbers can be phylogenetically patterned at the sectional level, and that there was a significant decrease in chromosome number in the lineage that gave rise to a major clade of eastern North American taxa. There is also weak evidence that sister species are more similar in chromosome number than would be expected if chromosome numbers were randomly distributed. However, chromosome counts appear to be highly labile within species, with no obvious correlations between geography and chromosome number. A model of chromosome change within *Carex* must account for this seeming paradox: an apparently random pattern of chromosome counts within species on one hand, a correlation between phylogeny and chromosome counts on the other.

14.7.6. Relationships, basal taxa, and inflorescence evolution in *Carex* subg. *Vignea* (Cyperaceae) as inferred from non-coding rDNA sequences

B. A. Ford[1], R. F. C. Naczi[2], J. R. Starr[3];
[1]University of Manitoba, Winnipeg, MB, Canada, [2]Delaware State University, Dover, DE, United States, [3]University of Mississippi, University, MS, United States.

Carex subg. Vignea is a distinctive taxon (ca. 300 spp., 28 sections) often characterized by bisexual spikes, distigmatic flowers, and the lack of prophylls. Molecular phylogenetic studies indicate that this subgenus is monophyletic, with the atypical C. gibba, with tristigmatic flowers and prophylls, found at its base. Several clades distinguish the remainder of Vignea; however, these clades do not correspond to easily defined morphological groups. Many traditionally recognized sections are not supported while others, such as sects. Ovales, Stellulatae, and Glareosae, are upheld. Topological tests reject a hypothesis of separate gynaecandrous/androgynous clades. Species of uncertain subgeneric affinity, sometimes linked to subg. Vignea, are variously placed in our analysis. For example, androgynous, unispicate species with distigmatic flowers belong to a clade sister to Vignea, whereas dioecious, unispicate species with two stigmas are nested within the subgenus. Species with highly compound inflorescences, often regarded as representing the primitive condition within Carex, occupy derived positions in the phylogenetic tree.

14.8.1. Flexibility of the coral-algal symbiosis

M. J. H. van Oppen;
Australian Institute of Marine Science, Townsville, Australia.

The relationship between corals and algal endosymbionts of the genus *Symbiodinium* (zooxanthellae) has been a key factor in the success of scleractinian (stony) corals as modern reef-builders. The genus *Symbiodinium* comprises an extraordinarily heterogeneous group of dinoflagellates. So far, eight phylogenetic clades have been identified based on nuclear ribosomal DNA (A-H), and within each clade sub-clades (strains or species) are present. In many cases, the juvenile coral acquires zooxanthellae from the environment, and can associate with a wide range of algal strains. The occurrence of certain *Symbiodinium* types in scleractinian corals is sometimes correlated with the local light and/or temperature environment, even within individual colonies. However, the role of symbiont identity and diversity in terms of fitness of the holobiont (i.e., the host-symbiont partnership) has only been poorly studied. I will discuss the affect of zooxanthella type on holobiont physiology, the flexibility of the host-symbiont association and how this flexibility may be an important mechanism for corals to cope with environmental change.

14.8.2. Coevolutionary patterns and scale: algal selection by lichen fungi.

M. D. Piercey-Normore;
University of Manitoba, Winnipeg, MB, Canada.

Trebouxia is one of the most common genera of green algae that form associations with lichen fungi. Species of Trebouxia are unicellular coccoid green algae that reproduce vegetatively in the lichen while sexual reproduction occurs in the free-living state. It is thought that lichen fungi “select” compatible algal partners to form lichen associations. Low selectivity by the fungus promotes lichenization with a variety of algal genotypes or taxa. High selectivity by the fungus limits lichenization with algal partners and the fungus becomes specific to the alga. With high selectivity, and hence specificity, coevolutionary patterns become apparent between lichen symbionts. Coevolutionary patterns may be detected at various scales of taxonomic breadth and geographic distribution. Effective wind dispersal of algae in vegetative propagules of the lichen would ensure distribution of algal genotypes for sexual reproduction of the alga as well as for selection by the lichen fungus.

14.8.3. Effects of human management on the population biology of the red alga *Gracilaria chilensis*.

S. Faugeron[1], M. Guillemin[2], M. Valero[2], C. Destombe[2], J. A. Correa[1];
[1]P. Universidad Catolica de Chile, Santiago, Chile, [2]CNRS, Roscoff, France.

The Rhodophyte *Gracilaria chilensis* has been used as a resource for the agar industry for decades in Chile. It occurs in two contrasted environmental conditions: (1) in soft-bottom areas protected from waves, characterised by a high biomass of anchored thalli in sand or mud, or (2) on rocky substratum, characterised by a lower biomass of thalli fixed to the substratum by a holdfast. Management practices range from harvesting soft-bottom natural populations to farming of introduced material.

Reproductive phenology, genetic diversity and epidemiology of epiphytes were compared between managed and non-managed populations all along Chile. Both reproductive maturity and genetic diversity are lower in managed than in non-managed populations. Contrarily, epidemiological surveys show a strong epiphytic load in the farms, whereas epiphytes are in very low frequency in natural hard-bottom populations.

The results are discussed in the context of reproductive investment and genetic resources in *G. chilensis*. Overall, the integration of our results indicate that cultural practices have been rambling and point out the need for a strain selection program.

14.8.4. Species versus carotenoid synthesis: what is known about the genus *Dunaliella* from a systematic perspective?

M. A. Gonzalez[1,2], P. I. Gómez[1,2], A. S. Cifuentes[1,2];
[1]Departamento de Botánica, Facultad de Ciencias Naturales y Oceanográficas, Concepción, Chile, [2]Universidad de Concepción, Concepción, Chile.

In spite of 28 morpho-physiological species of *Dunaliella* recognized by Massyuk in her monograph of the genus, the overall phylogenetic perspective of these taxa, including DNA data, is incomplete. This presentation deals with the major progress done by our research group on two approaches in this topic: (1) reappraisal of the biochemical and physiological attributes employed to separate the genus into 4 sections and the underlying DNA data supporting this classification and (2) comparisons among various strains of *D. salina*, based on total amount of carotenoids, Ŭ- and ɓ-carotene proportion, ɓ-carotene isomeric ratio and growth rates under different temperatures, light regimes and salt concentrations. The main results indicate that (1) there is a correlation between the biochemical and physiological attributes with the genetic diversity (nuclear rDNA ITS-1 and ITS-2 spacers sequences) among taxa at the section level, and (2) significant physiological and molecular variability (ITS sequences + DNA fingerprinting analysis-RAPDs) is found among strains in *D. salina*, results that may be indicative of the presence of more than one species among them.

14.9.1. Ovule fates and the evolution of reproductive diversity

L. D. Harder, M. B. Routley, S. A. Richards;
University of Calgary, Calgary, AB, Canada.

Floral and inflorescence traits govern a plant’s reproductive output and the genetic diversity of its offspring through their effects on pollen and ovules fates. The variety of these fates and their interactions create alternate options for the diversification of reproductive morphology and the mating system. These opportunities are illustrated with an exploration of ovule fates, their phenology and interdependence, focusing on two main topics. First, this analysis explores how the low seed:ovule ratio found in outcrossing species could function to absorb embryo death during development, without reducing fertility. Such reproductive compensation exposes the possibility that seed production can be ovule limited, as well as pollen- or resource-limited, which increases the variety of situations in which production of both selfed and outcrossed seeds maximizes maternal fitness. Second, this analysis considers how the evolution of the same mating system can be accommodated by alternate combinations of floral design and display. These examples illustrate the key role played by ovule (and pollen) fates in the reproductive diversification of angiosperms.

14.9.2. Floral design and the evolution of sexual polymorphisms in Narcissus, the daffodil genus

S. C. H. Barrett, K. Hodgins;
University of Toronto, Toronto, ON, Canada.

Narcissus exhibits an unusual diversity of sexual systems, with populations that are monomorphic, dimorphic or trimorphic for style length. Associated with this variation are striking differences among species in floral design and pollination biology. This diversity provides an opportunity to investigate the evolution of sexual polymorphisms, and determine the role that floral morphology plays in promoting transitions among sexual systems. Phylogenetic evidence indicates that stylar monomorphism is ancestral in the genus, with multiple origins of stylar polymorphism, including independent origins of stigma-height dimorphism, distyly and tristyly. *Narcissus triandrus* is particularly useful for investigating the evolution of stylar polymorphisms because populations are either dimorphic or trimorphic for style length and exhibit striking patterns of geographical variation in floral morphology. Here we present new empirical data comparing demographic parameters, floral morphology, mating and fertility in dimorphic and trimorphic populations that yield insight into the selective mechanisms maintaining sexual polymorphisms.

14.9.3. Pollen fates and the evolution of pollen packaging in plants

S. D. Johnson[1], L. D. Harder[2];
[1]University of KwaZulu-Natal, Pietermaritzburg, South Africa,
[2]University of Calgary, Calgary, AB, Canada.

The efficiency of pollen transfer to conspecific stigmas (PTE) largely governs paternal mating success in plants. Compared to species with granular pollen, orchids and asclepiads realize ten- to hundred-fold higher PTE, largely because their aggregated pollinia reduce pollen wastage during transport. Increased PTE should favour packaging, but this benefit is limited by the reduction in potential mating partners for a given number of flowers, and an increased risk of geitonogamous self-pollination, which causes diminishing returns for increased flower production. Many orchids combine pollen packaging with lack of floral rewards, and thereby achieve high levels of cross-pollination. Asclepiads, which are mostly rewarding, appear to experience high levels of self-insertion of pollinia, but also possess self-incompatibility and flowers with multiple stigmatic entrances that increase opportunities for cross-pollination. Gradual torsion of pollinia after withdrawal from the anther also limit self-pollination effectively in both orchids and asclepiads, especially when pollinators spend long periods foraging on one plant.

14.9.4. Towards the quantitative ecology of outcrossing

J. E. Cresswell;
Department of Biological Sciences, University of Exeter, Exeter, United Kingdom.

I focus on patterns of flower-to-flower gene dispersal in animal-pollinated plants, which I term 'paternity shadows'. The paternity shadow provides the basis for an accounting system that enables levels of outcrossing to be calculated. Based on these calculations, I speculate about the factors that influence the form of a paternity shadow and its adaptive ideal. Each plant-pollinator combination produces a different paternity shadow whose implications for outcrossing can be calculated, thereby providing a quantitative foundation for a comparative ecology of outcrossing. Based on paternity shadows, I formulate a model to investigate pollinator-mediated gene dispersal in a plant with two pollinator species. My analysis shows that if the plant is under selection for outcrossing, it is selected to favour visits from one of the pollinators; selection need not stringently favour complete specialization, however. This result provides a new explanation for some of the many incompletely specialized flowers in nature.

14.9.5. Population context of pollination

J. Ågren;
Dept. of Plant Ecology, Evolutionary Biology Centre, Uppsala
University, Uppsala, Sweden.

Plant population characteristics such as size, density, and genetic composition may strongly affect patterns of pollinator visitation, pollen transfer and plant reproductive success. Pollination failure in small, sparse populations can give rise to Allee effects, which may influence population dynamics and mating-system evolution. Frequency-dependent selection caused by interactions with pollinators may contribute to the maintenance of floral polymorphism. In this presentation, I will briefly review recent studies to address the hypotheses that (a) density-dependence of pollination success is stronger in self-incompatible than in self-compatible plants, and (b) density-dependence is negative rather than positive in non-rewarding animal-pollinated plants. I will then widen the perspective, and discuss how variation in the abiotic environment and interactions with herbivores may mould selection on floral characters and effects of population characteristics on plant reproductive success.

14.9.6. Modeling selection on floral characters: conceptual foundations and extensions to pollinator interactions

M. T. Morgan;
Washington State University, Pullman, WA, United States.

Selection drives floral character adaptation. Male and female functions contribute equally to selection in a fundamental and precise sense encapsulated by marginal fitnesses (in optimality models) and selection gradients (in quantitative genetic models). Important features such as hermaphroditism and metamerism emphasize themes of conflict, compromise, and genetic constraint. Coupling plant and pollinator dynamics allows exploration of how floral characters such as reward (e.g., nectar production) or advertisement (e.g., corolla size) evolve. Equally important can be selection for reproductive assurance leading to limited selfing, especially under temporally or spatially variable pollinator service. Such limited selfing influences the structure of genetic variation and the response to selection in ways that are important for floral character adaptation.

14.9.7. Effects of floral characters on flower visits by bumble bees

J. D. Thomson;
University of Toronto, Toronto, ON, Canada.

Within the genus *Penstemon*, hummingbird-adapted species have evolved repeatedly from hymenopteran-adapted ancestors, with independent convergence in flower morphology toward characters exemplifying the “hummingbird syndrome.” In previous work, Castellanos et al. sought to characterize those morphological changes as “pro-bird” or “anti-bee” adaptations by surgically modifying flowers of the bee-adapted *P. strictus* to give them characters more like those of bird-adapted taxa. Castellanos et al. measured pollen removal and receipt, along with short-term choice experiments by bees and birds in flight cage cages. Here, we present improved choice tests using free-foraging animals in the field. Site-faithful bees appear to learn the locations of manipulated plants and respond to two “bird characters” (constriction of corolla tubes and removal of the landing platforms formed by the lower corolla lobes) by making fewer return visits. The data support the interpretation of those characters as “anti-bee” in function.

14.10.1. The structure of plant Photosystem I - It is the biochemistry

N. Nelson;
Tel Aviv University, Tel Aviv, Israel.

We determined the crystal structure of the complete photosystem I (PSI) from a higher plant to 4.4 Å resolution. Its intricate structure shows 12 core subunits, 4 different membranal light-harvesting proteins (LHCI) assembled in a half moon shape on one side of the core, 45 transmembrane helices, 167 chlorophylls, 3 Fe-S clusters and 2 phylloquinones. The determined structure of plant photosystem I (PSI) provides the first relatively high-resolution structural model of a supercomplex containing a reaction center and its peripheral antenna (LHCI). The peripheral antenna of PSI (LHCI) is composed of four gene products (Lhca1-4) that are unique among the chlorophyll a/b binding proteins in their pronounced long-wavelength absorbance and in their assembly into dimers. Some of the structural features responsible for the unique properties of LHCI will be described and the advantages of the particular LHCI dimerization mode over monomeric or trimeric forms will be discussed. The interactions between the peripheral antenna will be discussed.

14.10.2. The light harvesting complex II antenna protein CP29 is involved in regulating photosynthetic state transitions

J. Kargul[1], J. Turkina[2], M. V. Nield[1], S. Benson[1], A. V. Vener[2], J. Barber[1];
[1]Wolfson Laboratories, Department of Biological Sciences, Imperial College, London, United Kingdom, [2]Division of Cell Biology, Linköping University, Linköping, Sweden.

State 1-State 2 transitions in photosynthetic membranes of plants and green algae involve the functional coupling of phosphorylated Light Harvesting Complexes of photosystem II (LHCII) to photosystem I (PSI). We show that exposure of the unicellular alga *Chlamydomonas reinhardtii* to the State 2 conditions leads to phosphorylation of the minor light harvesting protein CP29 of photosystem II (PSII) at four distinct sites localized at the amino acid residues 6, 16, 32 and 102 of its amino terminus. Mass spectrometric analysis of CP29 phosphorylation in the photosynthetic membranes shows that threonine 16 and serine 102 are phosphorylated exclusively in State 2, while phosphorylation of threonines 6 and 32 may also be detected in State 1-exposed cells. The LHCI-PSI supercomplex isolated from the algae in State 2 is found to contain strongly associated CP29 in phosphorylated form. Electron microscopy and single particle analyses indicate that the binding site is close to the PsaH protein suggesting that phospho-CP29 may act as a linker for the association of phospho-LHCII with PSI. In this way CP29 could facilitate the functional coupling of LHCII to PSI in the conditions favoring light absorption by PSII in addition to its well-documented role as a linker between PSII core proteins and LHCII trimers. Redox-dependent multiple phosphorylation of CP29 is suggested as an integral part of the State transition process in which the structural changes of CP29, induced by reversible phosphorylation, may determine LHCII affinity for either of the two photosystems.

14.10.3. Supercomplexes of photosystem I and antenna proteins in green plants and cyanobacteria

E. J. Boekema[1], R. Kouril[1], A. Zygadlo[2], P. Jensen[2];
[1]Biophysical Chemistry, University of Groningen, Groningen, The Netherlands, [2]Agricultural University, Copenhagen, Denmark.

Photosystem I (PSI) and Photosystem II (PSII) can form supercomplexes with various types of antenna proteins. One such protein is Light-harvesting complex II (LHCII). We have characterized the PSI-LHCII complex from Arabidopsis membranes in state 2 by single particle electron microscopy at about 16 Å resolution. PSI binds one trimer at the site of the PsaK subunit. Cyanobacteria express large quantities of the Iron Stress Inducible protein IsiA under iron deficiency. IsiA can assemble into numerous types of single- or double rings surrounding PS I. These supercomplexes are functional in light-harvesting, but empty IsiA rings are effective energy dissipators. Electron microscopy studies on projections of these supercomplexes show that photosystem I trimers bind 18 IsiA copies in a single ring; whereas monomers may bind up to 35 copies in two rings. This shows that IsiA can form a remarkable large variaty of ring-like structures. Work on particles purified from mutants indicates that the PsaF and PsaL subunits facilitate the formation of closed rings around PSI monomers, but are not obligatory components of PSI in the formation of PSI-IsiA supercomplexes.

14.10.4. Molecular mechanisms of light acclimation in plants

O. Kruse, J. H. Mußgnug, R. Borgstädt, L. Wobbe;
University of Bielefeld, Bielefeld, Germany.

One of the great challenges in plant cell biology is to determine the regulatory mechanisms employed by photosynthetic organisms to adapt to environmental changes. To identify components for cellular signalling during light acclimation, we have applied a chlorophyll fluorescence based screen to identify mutants of Chlamydomonas reinhardtii and Arabidopsis thaliana that are impaired in redox-mediated chloroplast state transitions. From this mutant collection we identified three new proteins. All three are involved in inter-organell signalling between chloroplast, nucleus and mitochondrion as a response to a changing light environment. Nab1 was identified as an RNA-binding protein essential for the control of post-transcriptional expression of light harvesting antenna proteins. Moc1 was identified as a mitochondrial factor that regulates the composition of the mitochondrial respiratory chain in the light so that it can act as an effective sink for reductant produced by the chloroplast. Arg2 was identified as a second mitochondrial arginase of Arabidopsis playing an essential role in regulating the arginine metabolism during light stress.

14.10.5. Structure of photosystem II and its implications

J. Barber;
Imperial College, London, United Kingdom.

Photosystem II is a membrane protein complex which catalyses the oxidation of water to molecular oxygen and reducing equivalents. The reaction occurs at a metal centre composed of 4 Mn ions and a Ca ion, is thermodynamically demanding and involves the generation of highly oxidised species. Unavoidable side reactions cause detrimental effects on the protein environment leading to the rapid turnover of the reaction center D1 protein. To understand the mechanisms of water oxidation and D1 turnover structural information is required. Initially the positioning of various protein subunits and their transmembrane helices was elucidated by electron microscopy (1) and more recently a refined structure of the cyanobacterial PSII has been elucidated by X-ray crystallography (2). The implications of these structural studies will be discussed in relationship to the unique facets of PSII function.

14.10.6. Bicarbonate requirement for the water-oxidizing complex of Photosystem II

V. V. Klimov;
Institute of Basic Biological Problems,Russian Academy of Sciences, Pushchino, Russian Federation.

Strong evidence for bicarbonate (BC) requirement within the water-oxidizing complex (WOC) of photosystem II (PSII) is presented. It is suggested that BC is an integral component of the WOC essential for its re-assembly, function and stability. Comparative studies of electrochemical and functional properties of complexes of Mn(II) and Mn(III) with BC and other carboxylate ligands (acetate, formate) show that the unique capability of BC to initiate re-assembly of the tetramanganese cluster of the WOC from Mn(II) and apo-WOC-PSII can be attributed to formation of electroneutral, easily oxidizable Mn-bicarbonate complexes that serve as building blocks for the WOC. It is suggested [Dismukes, Klimov et al., PNAS (2001) 98: 2170] that due to this property BC might have been critical to the evolutionary transition from anoxygenic to oxygenic photosynthesis in the Archean period (>2.2 BYA) (*Supported by the HFSP and the program MCB RAS).*

14.11.1. The hydraulic conductance of plant organs as a major determinant of the water balance of plants

S. Salleo, A. Nardini;
Dipartimento di Biologia, Università di Trieste, Trieste, Italy.

Our understanding of the water balance of plants has enriched with many recent studies mapping the hydraulic parameters in different plant organs. Plants are commonly viewed as water conductors consisting of two opposite poles (the root and the leaf) with high hydraulic resistance (R) and connected by a water pathway with intrinsically low resistance (the stem). This model is, of course, an oversimplification of plant hydraulics. Both the root and leaf include two water pathways i.e. the nonvascular and the vascular compartment. In both organs, the hydraulic conductance (K=1/R) of the nonvascular compartment appears to vary in response to several environmental factors and the K of the vascular compartment can vary greatly due to xylem embolism. A first conclusion is that the hydraulic efficiency of a root or leaf is a close function of the partitioning of R between the vascular and the nonvascular compartment. The stem itself is subject to large impairment due to embolism and may, therefore, contribute tremendously to increase the R of the plant. Recovery from xylem embolism appears to be under metabolic control and is part of the plant water balance regulation.

14.11.2. Distribution of hydraulic conductance within a crown of little-leaf linden (*Tilia cordata*)

A. Sellin;
University of Tartu, Tartu, Estonia.

Responses of leaf conductance (g_L) to photosynthetic photon flux density (Q_P), leaf-to-air vapour pressure difference (VPD), bulk leaf water potential ($ɋ_L$) and total hydraulic conductance (G_T) were examined with respect to leaf position in the crown. The studies were performed on intact and detached branches cut from the upper (UC) and lower crown (LC). The UC leaves demonstrated 2.0-2.2 times higher (P<0.001) daily maxima of g_L than the LC leaves. Mean G_T was 1.9 times higher (P<0.001) for the UC foliage. Distribution of the total resistance: soil to distal branches 41-51%, 25-cm distal branches 10-15%, leaves 39-44%. In LC g_L was constrained both by low light availability and limited water supply. Artificial reduction of hydraulic constraints raised $ɋ_L$ and altered g_L less sensitive to changes in both atmospheric and plant inner factors. Stomatal responses to VPD were significantly modified by leaf water status: high $ɋ_L$ inverted the g_L versus VPD relationship. The improved water supply increased g_L and E in the LC foliage, but not in the UC foliage. The results support the idea that leaves in the lower canopy are hydraulically more constrained than in the upper canopy.

14.11.3. Xylem integrity and transport in developing grape berries

M. Matthews, K. Shackel, B. Bondada;
Univ. of California, Davis, CA, United States.

Water transport to fleshy fruit generally changes from primarily xylemic to phloemic during development, and in grape this transition occurs abruptly. The current hypothesis to explain this transition, particularly in grape (*Vitis vinifera* L.) berries, is that the xylem conduits lose integrity and become non-functional as a result of post-veraison berry growth. We adapted the pressure plate/pressure membrane apparatus that is commonly used to study soil water characteristics, and reevaluated xylem functionality by establishing a hydrostatic (tension) gradient between the pedicel and a cut surface at the stylar end of the berry. The apoplastic tracer dye, basic fuchsin, moved from the pedicel to throughout the peripheral xylem conduits of the berry mesocarp in samples collected both before and after the transition. In addition, isolated tracheids revealed no evidence of physical disruption. We hypothesize that rather than a loss of xylem function, the transition away from xylem transport is a result of the loss of an appropriate driving force (hydrostatic gradient) in the berry apoplast.

14.11.4. Dynamic variations in xylem specific conductivity: mechanisms and consequences for water movement through sapwood

J. C. domec[1], F. C. meinzer[2], B. L. gartner[1], J. housset[3];
[1]OSU, Corvallis, OR, United States, [2]USDA Forest service, Corvallis, OR, United States, [3]INA-PG, Paris, France.

The goal of this study was to determine the magnitude of deviation of trunk sapwood specific conductivity (k_s) from that predicted by Darcy's law when k_s is measured under steady-state vs. non-steady state conditions. In maple and alder, two diffuse porous species with high pit resistance, and in hemlock and Douglas-fir, two conifer species with bordered pits bearing a torus, k_s was 10-30% higher under steady than non-steady state. In these four species, when the pressure gradient increased from 0.01 MPa m^{-1} to 0.15 MPa m^{-1}, k_s increased by 25% and 45% under steady state and non-steady state, respectively. There was no significant difference between k_s measured under steady or non-steady state in white oak, a ring porous species with high k_s and low bordered pit resistance, as well as in western redcedar, a conifer species that has a simple bordered pit structure (membrane lacking torus). We hypothesize that the elasticity of pit membrane is the main cause for flow rate to be disproportional to the pressure gradient. This study showed that the common assumption that water flow in trees occurs in the steady state has led to significant errors.

14.11.5. Light and temperature induced variable leaf symplasmic hydraulic conductances in *Juglans regia* L: are aquaporins involved?

H. Cochard[1], S. Sakr[1], T. Ameglio[1], A. Nardini[2];
[1]INRA, Clermont-Ferrand, France, [2]Università di Trieste, Trieste, Italy.

Leaf hydraulic conductance were measured by perfusion with distilled water. When dark acclimated walnut leaves were exposed to light, a rapid increase in hydraulic conductance was measured. The half time of the response was ca 20 minutes. The light response was strongly temperature dependant, with no response at 5°C and a maximum response at to 35°C. Light response was partly or totally inhibited when leaves were perfused with solutions of DMSO or HgCl2, putative aquaporins inhibitors. In presence of Cycloheximide, a general protein traduction inhibitor, the light response was also inhibited. These results demonstrate that the water pathway in walnut leaves is mostly symplasmic, and that proteins, most likely aquaporins, are involved in the regulation of the hydraulic resistance of this pathway.The funtionnal consequences in terms of water relations and gaz exchanges of these results are discussed.

14.11.6. Net salt circulation and cation exchange in the conducting bundles increase xylem water potential and prevent sodium stress in assimilating leaves of the common reed (*Phragmites australis* TRIN ex Steudel) growing in brackish water

M. Fritz, A. Bellaire, S. Wischer, R. Ehwald;
Humboldt-University, Berlin, Germany.

Salt exudation into the root vessels and desalting of the ascending xylem sap increase the water potential in shoots of reed growing in brackish waters. A non-destructive technique has been developed for field measurement of the water potential in xylem vessels of medial internodes. At night, it was found to be higher by about 0.4 MPa than that of the brackish substrate (- 0.6 to - 0.7 MPa at the investigated stand). Cell sap osmotic pressure in leaves taken from brackish stands was not higher by more than 0.2 MPa than that obtained from fresh water stands. Sap flow velocity was found to be > 20 m/h at sunny days. In the ascending sap, osmotic pressure, [Na^+], and [Cl^-] decreased from basal to medial internodes, whereas K^+ remained constant. Assimilating leaves were stressed by a salty aerosol. They contained K^+ in high concentrations (200-300 mM) but little Na^+ (< 50 mM), even in plants growing at 300 mM NaCl. K^+ leaving the leaf blades with the assimilate flow was recirculated already in the leaf sheath and internodes, where it was exchanged by Na^+. In elder internodes, Na^+ replaced K^+ in vacuoles, thus creating a rise of the vertical sodium gradient during the vegetation period.

14.11.7. Freeze-thaw induced embolism in conifers

S. Mayr[1], H. Cochard[2], T. Ameglio[2], S. B. Kikuta[3];
[1]University Innsbruck, Innsbruck, Austria, [2]INRA, Clermont-Ferrand, France, [3]University of Natural Resources and Applied Life Sciences, Vienna, Austria.

Freeze-thaw events can induce embolism in the water transport system of plants. It was hypothesised that bubbles formed in the freezing xylem sap expand during thawing, when they are big and the sap is under tension. Conifers with small tracheids should be resistant to freeze-thaw induced embolism. We studied the induction of embolism by freeze-thaw events in *Picea abies* and *Pinus cembra* via Cryo-SEM observations, conductivity and ultrasonic measurements. Conifers were vulnerable to freeze-thaw induced embolism, when dehydrated and exposed to repeated temperature cycles. Winter at the alpine timberline with intensive frost drought and many freeze-thaw events therefore caused excessive conductivity losses in twigs. Simulation of these conditions in a temperature chamber also induced embolism in young trees. Cryo-SEM observation revealed clustered air-filled tracheids, whereby cluster sizes increased with the number of temperature cycles. Ultrasonic signals were observed during freezing but not during thawing. We conclude that embolism following freeze-thaw events is not caused by the hypothesised mechanism but probably by air seeding processes.

14.12.1. Bioprospecting of ethno-medicinal plants of Nepal

U. Lindequist[1], R. P. Chaudhary[2], P. K. Jha[2], M. Gewali[3], M. Rajbhandari[3], S. von der Heide[4], R. Mentel[5];
[1]Ernst-Moritz-Arndt-University, Institute of Pharmacy, Greifswald, Germany, [2]Tribhuvan University, Central Department of Botany, Kathmandu, Nepal, [3]Tribhuvan University, RECAST, Kathmandu, Nepal, [4]HIMALASIA, Kathmandu, Nepal, [5]Ernst-Moritz-Arndt-University, Friedrich-Loeffler-Institute of Medical Microbiology, Greifswald, Germany.

Nepal, particularly the Himalayan region, is rich in various plants of medicinal value. The medicinal plants are the backbone of traditional medicine, which is the basis of health care in Nepal for many people. Intelligent bioprospecting of this resource can lead to a long-term scientific, economic and health-promoting benefit to society and country. Important aspects of bioprospecting are acceleration and exploring search for natural products, the use of bioassays relevant to the ethno-medicinal experience as well as to the therapeutic objective and the phytochemical analysis of plants with the aim to identify bioactive components. It is absolutly necessary to accompany bioprospecting by strengthening efforts to conserve the natural resources. The results of an interdisciplinary project between Nepalese and German groups and financed by the Volkswagen foundation demonstrate the high potential of several plants from the Himalayan region for the production of compounds with unique structures and with interesting bioactivities, especially for the treatment of infectious diseases.

14.12.2. Medicinal plants and their management efforts in Nepal

P. K. Jha;
Tribhuvan University, Kathmandu, Nepal.

Nepal is rich in biological resources in general and medicinal plants resources in particular. There are over one thousand plant species of medicinal importance, and around one hundred plant species are used in various drug preparations. Medicinal plants of temperate and alpine regions are of high commercial value, and these resources are either unexplored or over-exploited and illegally traded across the border. It is estimated that every year 20,000 t of the medicinal and aromatic plants (MAPs) are collected from Neapl, however about 90 % of the collection are exported in the raw form mainly to India. Only 10 % of the MAPs collected are processed in the country and exported to third world countries. In the last few years, government and private sectors in Nepal have initiated some efforts to manage medicinal plants. The present paper deals with the status of medicinal plants, management efforts and the analysis of practices related to MAPs.

14.12.3. Politics of biodiversity conservation for rural livelihoods in the Himalayas: An overview of national policies in Nepal

S. R. Khadka;
Social Welfare Council, Kathmandu, Nepal.

This study was carried out reviewing and analysing political arena, policies, legal instruments and practices that are in use for the conservation of biological diversity and promotion of the livelihoods of the ordinary people in Nepal, the country which is situated in the Himalayan region and whose over 80 % total land area is comprised of mountains and hills. This study aimed reviewing policies and practices for biodiversity conservation and livelihoods in Nepal. Despite several efforts, the biodiversity resources sustaining livelihoods of the majority of poverty trodden people are at risk. It is due to lack of appropriate policies and enforcement mechanisms, in addition to several generic causes such as poverty, over exploitation, habitat destruction, invasion by alien species, poor governance, etc. The study recommends overcoming the threats to biodiversity through active participation of the local people. The national policies should entrust ownership, control and management of the resources to the users based on the principles of biodemocracy, human rights and social justice.

14.12.4. Bioprospecting of ethnomedicinal plants of Himalayas: Conservation and sustainable use in Manang, Nepal

R. P. Chaudhary, S. Bhattarai;
Tribhuvan University, Kathmandu, Nepal.

Himalayan medicinal plants are globally unique but threatened due to overexploitation. Research applicable under bioprospecting of ethnomedicinal plants is lacking for Nepal. We are working on bioprospecting of medicinal plants of Manang for conservation and sustainable use with objectives to: (a) document medicinal plants used by the local communities and Tibetan healers "*amchis*", (b) carry out bioassay test to validate the indigenous knowledge, and (c) address issues associated with transfer of indigenous knowledge. Our observations revealed that there has been immense potentiality of bioprospecting of medicinal plants. Antimicrobial testing of 40 valuable medicinal plants by using the disc diffusion method was carried out with three different solvents in different bacteria and fungi to validate the indigenous knowledge. *Amchis* are respected as a social leader contributing in conservation; but the greatest threat of declining their knowledge and profession are lack of apprentices.

14.13.1. Considerations on biodiversity prospecting and utilization for human welfare

K. L. Mehra;
NBPGR & FAO, New Delhi, India.

Agro -biodiversity prospecting has resulted in the selection and improvement of economic plant species for human prosperity over the millennia. Developed countries have continued to benefit from PGR introduced from the gene rich developing countries.When Plant Breeders Rights and IPRs began to be implemented by developed countries, the developing countries started raising ethical issues, demanding equity and benefit sharing using their genetic resources.

Recognizing that unrestricted access to PGR is essential for continued human welfare, the presentation summarizes these historical developments and examines the (i) ethical and equity issues; (ii) elements of CBD, PBRs, TRIPS, FAO International Seed Treaty and national legislations; (iii) FAO Code of Conduct on Plant Germplasm collecting and use; (iv) initiatives of Global Crop Diversity Trust for conservation and utilization of PGR *in prosperity,* and discusses merits /demerits and limitations of alternate mechanisms for benefit sharing, including material transfer agreements, between the providers and users of PGRs.

14.13.2. Issues on Access and Benefit Sharing (ABS) of indigenous knowledge v/s bioresources

P. Pushpangadan;
National Botanical Research Institute, Lucknow, India.

Genetic resources constitute an integral component of biological diversity. The prospects of exploring biodiversity for new medicines, foods, crops, insecticides, pesticides and other commercially valuable genetic and biological products and processes are booming, due to the rapid development in Biotechnology- Herbal Technology and Information Technology. And, this exploring of biodiversity for commercially valuable genetic and biochemical resources is termed as “bioprospecting” which is pursued at three levels viz. chemical prospecting, gene prospecting and bionic prospecting. The paper discusses the recent trends in bioprospecting that necessitate an ever-increasing demand for access to genetic resources and traditional knowledge available in *in situ* and *ex situ* sources. These trends have also triggered conflicting interests and common concerns among all stakeholder states, communities involved in conservation, sustainable utilization, and documentation of genetic resources and traditional knowledge at local, national, regional and global levels.

14.13.3. The Global Crop Diversity Trust: supporting conservation for the welfare of current and future generations

G. C. Hawtin;
Global Crop Diversity Trust, Rome, Italy.

Ex situ collections provide a safety net for restoring agriculture after disasters and provide a reservoir of readily accessible, well-characterized genetic diversity for crop improvement. However, genetic diversity is under threat not only in the field but also in genebanks that are meant to be safe havens. The 1996 Global Plan of Action, calls for a rational global system of *ex situ* collections and several recent initiatives are laying a foundation for this. Significant among them is the recent creation, by FAO and IPGRI, of the Global Crop Diversity Trust - an international public-private fund that, as part of the funding strategy of the International Treaty on PGRFA, aims to raise a non-wasting endowment of US$260 million. Proceeds from the endowment, together with other funding sources, will finance the salvaging and upgrading of the world's key national and international crop germplasm collections and help provide for their maintenance *in perpetuity*, for the ultimate benefit of all humanity. The Trust is currently developing regional and crop conservation strategies to guide the allocation of resources to the most important and needy collections.

14.13.4. Bioprospecting at the community level: An integral component of sustainable ecosystems

C. O. Qualset, A. B. Damania;
University of California, Davis., CA, United States.

The theme of this presentation is to remind us that biodiversity prospecting is a major activity by resource-poor people to meet their sustainable needs. Bioresources may also be exploited by others for business purposes. Bioprospecting can have negative or positive impacts on biodiversity whether applied by local people or by external collectors with commercial or scientific motives. How farmers and local communities manage their genetic resources, we will draw upon a 6-year study of an old, complex agroecosystem of Mexico, called the milpa. An integrated research program, including socio-economics, ethnobotany, gene flow between crops and their progenitors, and farmer management of maize, squash, and bean landraces and quasi-domestic wild species (quelites) showed how the milpa system is evolving to meet the needs of local households and communities. Ideas for sustaining the milpa agroecosystem with appropriate bioprospecting and translocation of biological resources will be offered.

14.13.5. Ethical issues related to agricultural diversity prospecting and use

J. M. M. Engels;
IPGRI, Maccarese (Rome), Italy.

The relationship between human culture and agricultural biodiversity, as opposed to wider biodiversity, is a close one -- humans played a crucial role in the evolution of agricultural genetic resources and these resources, in turn, are crucial to livelihood strategies, particularly of poor peoples. Agricultural biodiversity and related knowledge have been considered a public good. Despite their importance, agricultural diversity is seriously threatened, notwithstanding conservation efforts worldwide.

Ethical considerations regarding prospecting, researching and using agricultural biodiversity and related information are presented. Unrestricted access for breeding purposes is very important but the access conditions should also adequately recognize and reflect contributions local communities and farmers have made to create and nurture these resources. Ethical principles to be followed when involving local people and their genetic resources in research activities or when obtaining access are presented, including self-determination, inalienability and traditional guardianship, prior informed consent and veto, and confidentiality.

14.13.6. Genetics resources as public goods : exchange and benefit sharing under the international treaty on plant genetic resources for food and agriculture

C. M. Correa;
Centro de estudios Interdisciplinarios sobre Derecho Industrial y Economico, Buenos Aires, Argentina.

The International Treaty on Plant Genetic Resources for Food and Agriculture, adopted in 2001 under the auspices of the Food and Agriculture Organization, establishes a Multilateral System (MS) for facilitated access to genetic resources and benefit-sharing for 35 food crops and 29 forage genera. Under the MS, Plant Genetic Resources for Food and Agriculture can be accessed to and exchanged free of charge if they are to be solely used for research, breeding or training purposes. Benefits under the MS are not attributed directly to the country supplying PGRFA on a bilateral basis, but they are shared multilaterally. While the Treaty is compatible with the international rules on intellectual property, it offers a model for research and conservation of global public goods that may counterbalance current trends towards privatization of biological resources and its associated knowledge.

14.13.7. Access and Benefit Sharing of Plant Genetic Resources: Aspects of Equity and Ethics

L. J. G. van der Maesen;
Nationaal Herbarium Nederland & Biosystematics Group, Wageningen University, Wageningen, The Netherlands.

Both fundamental and applied botanists need access to research materials. Uncertainty on how to apply the principles laid down in the Convention on Biological Diversity (CBD), entered into force in 1994, and the International Treaty on Plant Genetic Resources for Food and Agriculture (IT PGRFA), entered into force in 2004, hampers the transfer of biological materials for research, whether pure or applied. A standard Material Transfer Agreement as developed for the Multilateral System of Access and Benefit Sharing of the IT PGRAF would facilitate and probably foster the exchange of materials. In addition, the Bonn Guidelines for Access and Benefit Sharing of the CBD (adopted in 2002) contain many elements that help implementation of the CBD.

It is suggested that responsibilities and rights governing germplasm exchange may depend on the research goals; that rules should be unambiguous, and that material transfer agreements should specify the applicable access and benefit regime. Information exchange, capacity building and transfer of technology next to community development may be major mechanisms of benefit sharing.

Poster Presentations

P0001. Development, transferability and screening of nuclear microsatellites in *Cupressus* ssp.

[1]Istituto per la Protezione delle Piante, Sesto Fiorentino, Italy, [2]Dipartmento di Biotecnologie Agrarie Università di Firenze, Sesto Fiorentino, Italy, [3]Istituto Agrario di San Michele all'Adige, San Michele all'Adige, Italy, [4]Dipartimento di Biotecnologie Agrarie, Firenze, Italy, [5]Dipartmento di Biotecnologie Agrarie, Sesto Fiorentino, Italy, [6]Istituto di Genetica Vegetale, Sesto Fiorentino, Italy.

Cupressus sempervirens L. characterises the landscape in most Mediterranean countries. Since antiquity, cypress has been extensively cultivated far beyond its natural geographic range. Recently, polymorphic microsatellites were developed through the construction of an enriched library, for studying the distribution of diversity, to monitor gene flow, to identify hybrids, and to construct genetic maps. Initially, the level of variation was tested on a total of 24 individuals from four different C. sempervirens populations. High level of allelic diversity was found with a number of alleles ranging from 2 to 13. The new primers were tested in 38 Cupressus species. For some SSRs, the transferability rate was higher than 85%. Interestingly, the transferability success rate decreases from Mediterranean-, to Asian-, to Central- and North-American species. Distribution of diversity was analysed in eleven C. sempervirens populations sampled in Italy, and compared with that of some populations from Turkey. Significant differentiation between the two groups was estimated. Discussion about the possible origin of the Italian populations is reported.

P0002. Determination of ploidy level on the collected natural hybrids of citrus in north of Iran

B. Adouli, M. Golmohammadi;
Iran citrus Research Institute, Ramsar, Islamic Republic of Iran.

It is difficult to observe the chromosomes of citrus in detail due to their small size. Therefore, many cytologists have attempted to improve the techniques for chromosome counts in citrus. In present study Squash technique is used for citrus chromosome counting and distincting the ploidy level of natural hybrids of citrus which established in Kotra citrus collection. In this method, the open-pollinated seeds of 25 natural hybrid ripen fruits are washed and sterilized by 1% solution of Natrium Hypochloride. The seed coats are removed (for faster and better germination) and planted in clean petridishes at 25 ^{c}. After germination, one centimeter of root tips detached and following steps were carried : The plant material used were the 25 natural hybrids of citrus contain : Adeeb, Atabakee, Bakraee, Syavaraz(no. 1,2,3 & 4), She-mahalle, Moallem-kooh, Mino, Hybrids no.1,2,3,4,5,6,7,8,9,10,11,12&13, Limou-golabee-amole(Mina) and Limou-astaraee. Eighteen chromosomes (diploid) were observed in all the natural hybrids used.

P0003. Genetic analysis of apomixis in *Taraxacum* (dandelion; *Asteraceae*)

R. J. Vašut[1,2], K. Vijverberg[3], J. H. de Jong[1], P. J. van Dijk[3];
[1]Department of Plant Sciences, Laboratory of Genetics, Wageningen University, Wageningen, The Netherlands, [2]Department of Botany, Faculty of Science, Palacký University, Olomouc, Czech Republic, [3]Netherlands Institute of Ecology, Centre for Terrestrial Ecology, Heteren, The Netherlands.

Apomixis in the genus *Taraxacum* is represented by meiotic diplospory. It is confined to polyploids, whereas diploids are always sexuals. For apomictic seed formation three steps are essential: diplospory, parthenogenesis and (autonomous) endosperm development. We analysed 194 offspring plants from the *sexual* x *apomict* cross. Segregation of apomixis as a whole suggested three independent dominant genes. *DIP* and *PAR* appeared to be inherited as dominant genes, whereas our data on *END* does not fit to dominant model. Segregation distortion from expected Mendelian ratios was detected for several SSR markers that were linked to apomixis elements (*DIP*, *PAR*). This can be explained (along with an absence of diploid apomicts) by accumulation of deleterious mutations on the apomictic chromosomal segments resulting from repeated hybridisation cycles in long time-scale. First FISH experiments with BACs containing markers linked to diplospory showed higher proportion of repetitive sequences in apomictic genome with clustering in the presumed diplosporic chromosomal segment indicating a high mutational load.

P0004. Nucellar embryo formation time and their further development in five citrus rootstocks

M. Ghasemi;
Iran citrus Research Institute, Ramsar, Islamic Republic of Iran.

In this trial the stages of embryo development and the time of polyembryony were studied via microscopical analysis in five citrus rootstocks (Sour orange, Flying dragon, Citromelo, Citrange and Shell mohalle). The fruits were harvested from expected genotypes at 35, 50, 65, 80, 95, 110 and 125 days after pollination (DAP). Diameter and weigth of fruits were measured and then seeds were extracted and fixed in FAA. After cross section with Parafin method and staining with Safranin- Fast green the number of ovules per seed were determined. The experimental design was RCD with three replications, each replication consisted of ten seeds. Results showed that none of seeds in 35 DAP had any sort of embryo. Embryos at fifty DAP were in globular shape and at later stages the seeds had one or more developed embryos. The first embryo that develop from globular shape to normal and mature embryo is usually zygotic embryo and recognizing that from nucellar embryos might have great impact in breeding of citrus species. In this study the genotype and seed age significantly affected the phenomenon of polyembryony as well as diameter and weigth of fruits

P0005. Using of RAPD markers for identification of nucellar and zygotic progenies in citrus rootstocks breeding program

M. Ghasemi;
Oral, Ramsar, Islamic Republic of Iran.

Because of abundant polyembryony, citrus breeding need very time and costs. For this results, identification of zygotic and nucellar embryo is very difficult. This Trial carried out for identification of zygotic and nucellar progeny in hybridization between some citrus genotypes as sour orange(Citrus aurantium) as male parent and *poncirus trifoliata* as female parent Total DNA was extracted from well grown leaves of parents and progenies. Only seven primers out of 24 primers showed polymorphism after RAPD analysis. Nucellar progenies showed the same RAPD profile as female parent because their origin are from femail parent but zygotic progenies showed bands from both femail and pollen parents. RAPD markers as OPM04-3000, OPM04-5000, OPM11-650, OPM11-850, OPM14-1200, OPM14-1650, OPM14-1800 and OPM18-1650 were able to descreminate between zygotic and nucellar embryos

P0006. Regulation of apoptosis processes in embryogenic calli of wheat and barley

N. K. Bishimbayeva[1], A. K. Amirova[1], A. V. Rusakova[1], E. V. Rakhimova[2], I. R. Rakhimbayev[1];
[1]Institute of Plant Physiology, Genetics and Bioengineering, Almaty, Kazakhstan, [2]Botanical Garden, Almaty, Kazakhstan.

Regulation of apoptosis or programmed cell death (PCD) by the use of phytohormones, organic and stress substances has been developed for wheat and barley embryogenic calli. It was established, that increase of 2,4-D concentration up to 5,0 -7,0 mg/l as well as the 500 mg/l proline addition are accompanied with the intensification of PCD which leading to embryo abortion. 1,0 mg/l BAP and 1000 mg/l casein hydrolyzate reduced PCD level, removed embryo blockation and stimulated their differentiation. Increase the ABA concentration up to 1,0 mg/l lead to the total degradation of embryoids cells by PCD pathway. Presence of moderate concentrations of 0,5% NaCl increased PCD level. At the same time with PCD high concentration of NaCl (1,0%) caused the deeper destructive processes, necrosis. Two types of PCD have been revealed by the use of light and electron microscopies: goings on through the plazmolysis and without plazmolysis (cell wall localization of cytoplasm). The plazmolysis type PCD finding in case of embryo disintegration to death cells and single embryogenic cells. PCD going without plasmolysis of cells takes part in differentiation processes.

P0007. *Fusarium* mycotoxins can inhibit programmed cell death (PCD) in *Arabidopsis thalina*

M. Diamond[1], O. Rocha[2], F. M. Doohan[2], P. F. McCabe[1];
[1]Department of Botany, University College Dublin, Belfield, Dublin 4, Ireland, [2]Department of Environmental Resource Management, University College Dublin, Belfield, Dublin 4, Ireland.

The *Fusarium* genus of fungi can be responsible for commercially devastating crop diseases. Apart from severely reducing yield they also produce damaging mycotoxins that are major food poisoning constituents. Two such groups of mycotoxins are the tricothecenes and the fumonisins. Deoxynivalenol (DON) is the most prevalent tricothecene found in crops for food and feed production. It is known that like other protein synthesis inhibitors (e.g. cycloheximide - CHX); DON induces programmed cell death (PCD) in animal cells. Here we show; using an *Arabidopsis* cell system, not only that DON does not induce PCD; it inhibits the PCD induced by other stimuli. Fumonisin B_1 (FB_1) is the most prevalent subspecies of the mycotoxins produced by *Fusarium verticillioides.* It is known to cause PCD in both plants and animals. Here we show that high levels of FB_1 can induce PCD, whereas low levels partially block the progression of cell death in *Arabidopsis.* Because the modes of action of FB_1 and DON are known, our results reveal aspects of the mechanism of PCD in plants.

P0008. Genomic and proteomic analyses of mitochondria of Arabidopsis cells undergoing cell death

M. Livaja, J. Durner;
Institute of Biochemical Plant Pathology, Neuherberg, Germany.

Harpin is a type III elicitor, secreted by bacteria such as *Pseudomonas syringae.* Previously we reported that the elicited hypersensitive response (HR) is accompanied by inactivation of mitochondria in *Arabidopsis* cells. We observed a loss of mitochondrial membrane potential and of ATP synthesis. Harpin caused a rapid cytochrome c release from mitochondria into cytosol and a strong induction of protecting or scavenging systems such as AOX and small heat shock proteins. Due to the inactivating effect on mitochondrial functions, we surveyed genetic and proteomic programs of mitochondria behind harpin induced apoptosis. Changes in mitochondrial gene expression were monitored within 24 hours after treatment. We found oppositional behaviour in mitochondrial and global gene regulation. Proteome analysis of mitochondrial fractions confirmed an activating effect on mitochondrial enzymes on protein level. A comparison of genomic and proteomic data sets will be presented and discussed.

P0009. H_2O_2 and ceramide induced programmed cell death in Arabidopsis cell cultures requires protein synthesis

K. P. Alden, P. F. McCabe, C. K. Y. Ng;
UCD, Dublin, Ireland.

Programmed Cell Death (PCD) involves a series of events in which the cell directs its own demise. It depends upon the active participation of the dying cell and is gene regulated. PCD is believed to be essential for normal plant development and defence responses. However, very little is known about the regulation of PCD in plants, although *de novo* protein synthesis appears to play an important role in this process. Hydrogen peroxide (H_2O_2) has been established as a key molecule in plant PCD and stress responses. It has been shown to activate numerous signalling cascades resulting in PCD, necrosis and changes in gene expression. Ceramides are bioactive lipids that have been shown to act as second messengers and regulate cellular homeostasis in mammalian cells. Recent research has shown that ceramides can induce cell death in plants. Here, we show the results of inhibiting protein synthesis using cycloheximide and actinomycin D in *Arabidopsis* cell cultures exposed to two different PCD inducing treatments, H_2O_2 and C_2 ceramide.

P0010. DNA Marker for Sex Identification of Papaya (*Carica papaya* L.).

N. Juntawong, S. Chotpattarasumon, M. Nanakorn;
Department of Botany, Kasetsart Univ., Bangkok, Thailand.

Papaya (*Carica papaya* L.) is a dioecious plant which cannot used X/Y chromosome system to indicate sex difference. For this reason, the polymerase chain reaction (PCR) with T12 and W11 primers designed from *Sex1* locus that regulated sex expression in papaya, was performed and showed the amplified products of 838 and 832 bp size, respectively, in male and hermaphrodite, but not in female. The identification accuracy of the reaction for sex-specific DNA was 96.97 % from 66 samples in total for both T12 and W11 primer. Amplified fragments sequence analysis demonstrated no difference between male and hermaphrodite with T12 primer, but with W11 primer there was two different bases at 412 and 474 positions of reverse strand between male and hermaphrodite. According to the base difference, the Papaya Hermaprodite Specific (PHS) primer was designed for hermaphrodite Kheak-dum cultivar. The PCR with W11 and PHS primers showed two different bands of 832 bp for male and 440 bp for hermaphrodite, but no band for female. Under the PCR condition, W11 primer with forward and reverse strand and PHS primer only with reverse strand must be added in one step at the beginning of reaction.

P0011. Cell death induced by hypoxia in the roots

Y. Makita, S. Sato;
Ehime University, Matsuyama, Japan.

We studied an effect of hypoxia on the roots of plants, especially focusing on profiles of cell death. When young seedlings of *Brassica rapa* were placed in hypoxic water, the number of roots ceased their growth increased as the exposure time was prolonged. Evans blue staining suggested that the cell death began at the distal elongation zone (DEZ) of roots and then expanded to the neighboring regions to the DEZ. DNA laddering was faintly detected for plants exposed to hypoxia. This may reflect an occasional finding of cells which exhibited a positive reaction to TUNEL assay. Electron microscopy revealed that organelles such as plastids and mitochondria first began to bloat and then inner cell structures disappeared finally leaving their envelopes. As for nuclei, the nucleolar segregation became prominent in a short time exposure to a hypoxic condition and prolonged exposure rendered chromatin aggregate. On the other hand, meristematic cells first died under a hypoxic condition for *Vicia faba* roots. In particular, clear DNA laddering was detected. Thus, profiles of cell death may vary with species and tissues.

P0012. In vitro propagation of Cupressus semperviren grown in Guilan,IRAN.

G. Asadian, A. Rahnavard;
Poster, tonkabon, Islamic Republic of Iran.

The convntional methods of asexual plant propagation of this species have not been successful so far
Small piece of stemtips of 5-6 years old C.semperviren (0.2-0.5 mm long) with one to three needles fascicles on each, were excised from the plants and after surface sterilization, samples were cultured on a Murashing & Skoog (MS) medium and a Revised MS medium supplemented with different concentration of BAP, Kin and IBA. The cultures were then incubated in a climate chamber at temperatures of 25c (day) and 15c (night) and 12 hours light at 2000-2500 Lux with 75% humidity.
The best stimulation of callus growth occurred on cultures of Rev. MS medium when supplemented
with BAP=0.2 mg/l, Kin=0.1 mg/l and IBA=0.2mg. Callus formation, after several re-culturings became frailable and increased in volume when supplemented with BAP=0.2 mg/l and Kin=0.5mg/l.
Adventitious buds were formed on the callus with green needles, usually found on juvenile stages of
parent plants.

P0013. Ultrastructure of induced callose deposits is related to the nature of the elicitor

M. Weidinger[1], R. Kartusch[2];
[1]Dept. of Cell Imaging and Ultrastructure Research, University of Vienna, Vienna, Austria, [2]Dept. for Ecophysiology and Functional Anatomy of Plants, University of Vienna, Vienna, Austria.

Onion inner epidermal cells form locally separated callose deposits on their cell walls upon stimulation. Potent elicitors are, e. g., heavy metals, fungal toxins, or, as recently discovered, nitric oxide. The depositions induced by copper and by nitric oxide are structurally different. As light or fluorescence microscopy shows, copper- induced callose is very dense with almost no structural details, whereas nitric oxide-induced callose deposits are more loose or spongy aggregates often surrounded by a thick protoplasmic layer rich in organelles. The different structure is also seen by transmission electron microscopy. Copper-induced callose appears more or less homogeneous and translucent and the plasma membrane is clearly separated and smooth, whereas in nitric oxide-induced callose deposits many membraneous whorls as well as cytoplasmic remnants are included, and the boundary between callose and plasma membrane is extremely furrowed. This is an indication that in downstream signalling as well as in callose plaque formation plant cells are able to distinguish chemical stimuli.

P0014. Distribution of Cytokinins in the Fertile Thallus of the Fresh Water *Alga Chara conraria A.Br.*

L. Voytenko, **L. Musatenko**;
Institute of Botany of NAS of Ukraine, Kyiv, Ukraine.

The results of studies and quantitative characteristics of cytokinins in leaf rings from various parts of the fertile thallus of Chara have been described. The subject of studies was the fresh-water *CHARA CONTRARIA*. Leaves of different parts of the alga fertile thallus were found to have different ratios of zeatin Z, ZR, iP and iPA. Of all found cytokinins the highest level of ZR was detected in upper young leaves while levels of Z, iP and iPA were almost similar. In leaves from the thallus middle part levels of ZP, iP and iPA were significantly lower while the content of Z remained the same. Levels of all forms of cytokinins in the lower leaves of the alga were the lowest. It appears that such distribution of cytokinins in leaves from various parts of the Chara thallus is related not only with the cell growth processes (division, elongation) but also depends on the formation and development of generative organs. Morover, in nodes of upper leaves there are located oogonium and antheridium, in middle ones - green oogonium with fertilized eggcell, in lower ones - nature red antheridium.

P0015. Bird-Flower Interactions And Pollination In Some Plant Species Of Eastern Ghats Forests Of Andhra Pradesh, India

J. S. R. Aluri;
Andhra University, Visakhapatnam, India.

The floral characteristics of *Bombax ceiba*, *Firmiana colorata, Erythrina suberosa, E. variegata, E. variegata* var*. orientalis, Bauhinia variegata, Careya arborea, Alangium salviifolium, Gmelina arborea, Spathodea campanulata* (trees), *Butea superba* (woody climber), *Helicteres isora*, *Woodfordia floribunda* (woody shrub), *Leonotis nepetifolia* (annual herb) and *Dendrophthoe falcata* (tree parasite) were examined in relation to their flower visitors for pollination. The study showed that *F. colorata, E. suberosa, E. variegata, E. variegata* var*. orientalis, B. superba, W. floribunda, L. nepetifolia* and *D. falcata* are strictly ornithophilous and pollinated by passerine and non-passerine birds while the other species are partly ornithophilous. The dry season bloomers play a vital role in sustaining birds, bats and bees by providing during dry season. Some birds damage the flowers and squirrels and monkeys consume them while drinking nectar, effecting the reproductive success of some plants. The study suggests that there is an evolutionary relationship between some plant species and passerine birds for the benefit of both partners.

P0016. Characterization of the effect of the Fusarium mycotoxin zearalenone in Arabidopsis thaliana

U. Werner[1], F. Berthiller[2], R. Schuhmacher[2], R. Krska[2], G. Adam[1], M. Hauser[1];
[1]University of Bodenkultur, Vienna, Austria, [2]IFA, Tulln, Austria.

Zearalenone (ZON), also known as F2 toxin, is a nonsteroidal estrogenic mycotoxin produced by plant pathogenic Fusarium species responsible for diseases in cereal crops. ZON is one of the most potent xenoestrogens and therefore of particular interest to human and domestic animal health. Although ZON may serve as potential fungal virulence factor, its effect in plants is not well characterized to date. To identify the molecular mechanism of ZON's action on plant development and defense we used the model plant Arabidopsis. Our results show that ZON inhibits root elongation in a dose dependent manner, antagonizes ethylene's effect on radial cell expansion in CELLULOSE SYNTHASE 3 mutants and interferes with (oxidative) stress responses and cell wall modification/reinforcement. In Arabidopsis ZON is rapidly metabolized into zearalenol, ZON-4-O-glucoside and ZON-4-O-sulfate and later two metabolites are partly secreted. Based on our physiological, genetic and molecular results, we propose a model for the mechanism of ZON's mode of action in plants.
Supported by the Austrian Genome Project (FUSARIUM)

P0017. Physiological effects of ethylene on biochemical parameters of *Crocus satvius* L.

F. S.Nematpour, A. S.Afshar;
azad university of broujerd, Broujerd, Islamic Republic of Iran.

Despite its simple two-carbon structure, the olefin ethylene is a potent modulator of plant growth and development. The plant hormone ethylene is involved in many aspects of the plant life cycle, including seed germination, flowering, flower senescence and fruit ripening . We have investigated the effect of ethylene on corms of saffron (*Crocus sativus* L.). Corms were treated with varying concentrations (0,25,50,100,200 µl/l) of ethylene during various stage of growth and were cultured in greenhouse as well as field conditions. The results revealed that ethylene treatment increased content of reducing sugars in corms, roots and leaves, whereas decreased the content of soluble proteins in corms, roots and leaves during various stages of growth of corms. Electrophoretic profile of proteins in the ethylene treated corms revealed that the number and content of protein bands were different when compared to untreated corms. In this study, use of ethylene concentration @ 100µl/l in the month of July had best effect on flowering. Relationships between ethylene concentration, flowering percentage, protein and sugar levels and stages of growth of plant is discussed.

P0018. Delay in the period G_2 and development of chromosomal aberrations caused to the damage in the DNA induced by 5-aminouracil in higher plant cells

L. B. Marcano[1], A. Del Campo[1], M. Bracho[1], J. Guíñez[1], C. De la Torre[2];
[1]Facultad Experimental de Ciencias., Maracaibo, Venezuela, [2]Centro de Investigaciones Biológicas (CSIC), Madrid, Spain.

Abstract

This work evaluated the qualitative and quantitative cellular changes induced by treatment with 5-aminouracil (5-AU) in plant cells in relation to DNA damage. As biological material, *Allium cepa* L. root tips were used, grown in filtered water, in darkness, with aeration at constant temperature of 25 °C ± 0.5. When the roots were 2-3 cm long, were submerged in 5-AU (5 x 10^{-4} M) solutions. Roots were separated from the bulb and fixed in a mixture of glacial acetic acid - ethanol (3:1 v/v). Afterward, the meristematic tissues were dehydrated in serial alcohol concentrations, stained by the Feulgen technique. Results showed aG2 duration of 4 hours, with a delay of 1.8 hours for the beginning of prophase in comparison with the controls and inducing of aberrant metaphases, anaphases and telophases, indicating that the negative G2 control was weakened during the 5-AU treatment. Settles down the existence of G2 checkpoints in the cell population studied, which when being surpassed, allowed the development of chromosomal aberrations and cellular instability.

P0019. *Arabidopsis EVER SHORTER TELOMERE 1(EST1)* homologue is required for exit from meiosis

S. Akimcheva[1], R. Idol[2], J. Puizina[1], N. Riehs[1], D. Schweizer[1], D. Shippen[2], **K. Riha**[1];
[1]Gregor Mendel Institute, Austrian Academy of Sciences, Vienna, Austria, [2]Department of Biochemistry & Biophysics, Texas A&M University, College Station, TX, United States.

Cell cycle is composed of a chain of events that ensure duplication and equal distribution of genetic material in daughter cells. Chromosome segregation in mitosis requires activation of the anaphase promoting complex, which permits initiation of anaphase via destructing sister chromatid cohesion, and exit from mitosis by degrading mitotic cyclins. We identified and characterized novel *Arabidopsis* gene that is essential for the exit from meiosis. The gene encodes a protein that contains evolutionary conserved EST1 domain. *Arabidopsis* mutants deficient for the protein exhibit severe growth defects and are sterile. Cytological analysis of meiosis in mutant plants revealed that the sterility is caused by a cell cycle arrest at the anaphase II/telophase II transition. Arrested meiocytes contain separated chromatids that are randomly distributed throughout the cell and only very slowly decondense. We propose that mutants fail to exit meiosis likely due to an insufficient degradation of mitotic cyclins. Thus the *Arabidopsis* Est1 protein represents a novel conserved factor that is required for cell cycle progression.

P0020. Visualization and characterization of large-insert T-DNAs in transgenic rice

G. Suzuki[1], A. Nakano[1], M. Yamamoto[2], Y. Mukai[1];
[1]Division of Natural Science, Osaka Kyoiku University, Kashiwara, Japan, [2]Faculty of Health Sciences for Welfare, Kansai University of Welfare Sciences, Kashiwara, Japan.

Introduction of large-DNA fragments into cereals by *Agrobacterium*-mediated transformation is a useful technique for map-based cloning and molecular breeding. However, little is known about the genomic organization and stability of large foreign fragments in plants. In this study, we produced transgenic rice plants by *Agrobacterium*-mediated transformation with large-insert T-DNA containing a 92-kb genomic region of wheat. The structures of the T-DNAs in four independent transgenic lines were visualized by fluorescence in situ hybridization on extended DNA fibers (fiber FISH). By using this cytogenetic technique, we showed that rearrangements of the large-insert T-DNA, such as duplication, deletion and insertion, have occurred in all four lines. Our analysis suggested that the large T-DNAs tend to be rearranged in transgenic rice plants. In addition, significant deletion in the large-insert DNA was also observed in *Agrobacterium*. It is important that the large-insert clones must be carefully constructed to be as short as possible, and the constructs should be checked for rearrangements in *Agrobacterium* before using them for plant transformation.

P0021. Effective Mutagenesis of Arabidopsis by Heavy Ion Beam-Irradiation

Y. Y. Yamamoto, H. Saito, H. Ryuto, N. Fukunishi, S. Yoshida, T. Abe;
RIKEN, Wako, Japan.

Arabidopsis researches frequently include the genetic approach, so efficient, convenient, and safe methods for mutagenesis are required. Currently, the most popular method for in house mutagenesis is application of EMS. Although this method is very effective, its base substitution-type mutations often gives leaky mutants with residual gene functions, leading some difficulty in understanding the corresponding gene functions. Heavy ion beam generated by accelerators gives highest energy transfer rates among known radiation-based mutagenesis methods including X ray, gamma ray, fast neutron, electron and proton irradiation. This feature is thought to give high frequency of the double strand break of genomic DNA and resultant short deletions, resulting frame shift-type mutations. At RIKEN Accelerator Research Facility (RARF, http://www.rarf.riken.go.jp/index-e.html), we have optimized conditions for effective mutagenesis of Arabidopsis regarding to ion species and irradiation dose, and achieved comparable mutation rates to the method with EMS.

P0022. Genome instabilities in Arabidopsis studied by means of molecular cytogenetics

P. Mokros[1], J. Siroky[1], K. Riha[2];
[1]Institute of Biophysics CAS, Brno, Czech Republic, [2]Gregor Mendel Institute of Molecular Plant Biology, Vienna, Austria.

Genome integrity is a vital condition for the cell to maintain genetic information and to transfer it to daughter cells by cellular divisions. We study a number of mutants in *Arabidopsis* that are defective in reparation of DNA breaks, cell cycle progression, and telomere maintenance. Frequent event during the healing of genome damage is fusion of chromosomes via the mechanisms of homologous recombination or non-homologous DNA end joining. To trace the chromosome fusion events we developed a cytological approach employing fluorescent *in situ* hybridization. Using chromosome-specific BAC-derived probes in multicolour *in situ* hybridization experiments particular chromosomes and/or chromosome loci can be accurately assessed within the place of chromosome fusion. Global genome alterations, including aneuploidy, translocations, chromosome deletions and fusions were detected in telomerase-null *Arabidopsis* plants. In *Arabidopsis* deficient in a major repair complex (Mre11), the presence of anaphase bridges and multiple acentric chromosome fragments were detected together with aberrant bivalent formation during meiotic prophase I.

P0023. Which characteristics of the division and of the expansion of maize epidermal leaf cells are intrinsic to the genotype?

C. Fournier[1], B. Muller[2], F. Tardieu[2];
[1]UMR Environnement et Grandes Cultures, Institut National de la Recherche Agronomique (INRA), Thiverval-Grignon, France, [2]Laboratoire d'Ecophysiologie des Plantes sous Stress Environnemenentaux, Institut National de la Recherche Agronomique (INRA), Montpellier, France.

The leaf elongation rate (*LER*) does vary with the position of the leaf on the stem. This study aims to identify if some components of *LER* are independent of the position, thus defining intrinsic characteristics of a genotype. *LER* thermal time course of leaves 4 to 9 was measured for three maize genotypes. The spatial profiles of velocity and of epidermal cell length were measured at 3 leaf positions per genotype. Data were analysed in terms of the spatial organisation of the growth zone, cell-element- specific and cell-group specific characteristics of cell division and cell expansion. The position of the leaf systematically affected the length of the division zone, which accounted for most of differences in length of the growth zone. Leaf position also influenced, but not systematically, *LER* and the relative rate of cell expansion and division. Two position-independent characteristics were found on all genotypes: the length of cells in the basal part of the division zone, and the number of cell-group-specific doubling period of extension after last division. Only the later varied with genotype, and was responsible for the genotypic variability of mature cell length.

P0024. Alfalfa Mob1-like genes are involved in cell proliferation and plant reproduction

S. Citterio[1], E. Albertini[2], R. Aina[1], S. Varotto[3], F. Piraino[1], S. Sgorbati[1], G. Barcaccia[3];
[1]Department of Environmental Science, University of Milano-Bicocca, Milano, Italy, [2]Department of Plant Biology and Agro-environmental Biotechnology, University of Perugia, Perugia, Italy, [3]Department of Environmental Agronomy and Crop Production, University of Padua, Padua, Italy.

Mps-one-binder (Mob) proteins play an important role in yeast cell division. We cloned two *Mob1*-like genes from *Medicago sativa* L. and showed that one gene (*MsMob1-1*) is constitutively expressed while the other (*MsMob1-2*) is expressed only in flower buds during sporogenesis. A polyclonal antibody was raised against MsMob1 proteins and used for immunolocalization in dividing and non-dividing cells. The results show that the Mob1-like proteins are regulated in a cell cycle-dependent manner during cell proliferation. Cytoplasmic localization was faint and diffuse during G_1 and S, and become pronounced and concentrated into punctuate and fibrillar structures in G_2. During cytokinesis, the protein marked the progressive formation of the septum. In situ mRNA localization as well as protein immunolocalization proved that *MsMob1*-like genes are also expressed in degenerating megaspores of normal ovules and in enlarged MMCs and embryo sacs of apomeiotic ovules. Gene products were also found in tapetal cells of anthers undergoing programmed cell death. These results suggest that *MsMob1*-like genes are involved in cell proliferation and in gametogenesis.

P0025. Nocturnal growth rhythm in leaves of Populus deltoides is controlled by cell proliferation.

S. Matsubara[1], V. Hurry[2], N. Druart[3], C. Benedict[2], A. Chavarría-Krauser[1], A. Walter[1], I. Janzik[1], U. Schurr[1];
[1]Institute for Chemistry and Dynamics of the Geosphere: Phytosphere (ICG-III), Jülich, Germany, [2]Umeå Plant Science Centre, Department of Plant Physiology, Umeå University, Umeå, Sweden, [3]Umeå Plant Science Centre, Department of Forest Genetics and Plant Physiology, Swedish University of Agricultural Sciences, Umeå, Sweden.

Expanding leaves show marked diel growth patterns. As a first step toward identifying the genes and processes controlling temporal variations in leaf growth, we compared the transcriptomes of Populus deltoides leaves at times with well-defined growth rates. Rapidly expanding and fully expanded leaves were harvested at times of high and low growth rates during the night as quantified by an online growth-monitoring system based on the image sequence analysis method. In contrast to previously analysed plants with a pronounced base-tip gradient, P. deltoides, which lacks a base-tip gradient across the lamina, showed maximal and minimal growth at dusk and dawn, respectively. Comparison of the transcript profiles highlighted a concerted regulation of ribosomal protein genes during nocturnal temporal growth. Ribosome biosynthesis, a regulatory process in cell cycle, appears to respond to carbon flux from starch breakdown during the night, resulting in growth deceleration at dawn. We discuss the development of distinct spatio-temporal leaf growth patterns in connection with cell division and cell expansion.

P0026. The role of ethylene in the timing of developmental transitions

S. Lumba, Y. Tsuchiya, S. Gazzarrini, P. McCourt;
University of Toronto, Toronto, ON, Canada.

The regulation of the timing of developmental events is crucial for a plant's survival given the environmental conditions. The gene, FUS3, has been identified in Arabidopsis as a key regulator of the transition from the embryonic to vegetative stage of development. A novel role for FUS3 in the timing of post-embryonic events has also been discovered from expression and functional analyses of the loss-of-function fus3 mutant. To investigate the function of FUS3 during these stages, we have used an artificial FUS3 induction system by fusing FU3 to a glucocorticoid receptor. By inducing FUS3 activity during shoot development, we have created a system that retards the transition from juvenile to adult programs. Using a genome wide approach, genes involved in ethylene synthesis and signaling that display a different transcription profile over time, were identified. The leaf profile of an ethylene signaling mutant, ein2, and the use of morphological markers reveal that indeed ein2 plants do not undergo the transition from juvenile to adult. These results posit a novel role for ethylene as a positive regulator of phase transition in the shoot.

P0027. *ENOD40* affects cell size in non legume species

M. Levi[1], F. Guzzo[1], C. F. Guarnerio[1], A. Lillo[1], T. Ruttink[2], T. Bisseling[2], H. Franssen[2];
[1]Scientific and Technological Department, University of Verona, Verona, Italy, [2]Department of Molecular Biology, University of Wageningen, Wageningen, The Netherlands.

ENOD40 gene expression is associated with several developmental processes, but its function is still unknown. In an effort to elucidate the function of this gene, *ENOD40* gene was introduced in the genome of *Arabidopsis thaliana* and tobacco BY-2 cells. This approach allowed us to monitor the effect of over-expression of *ENOD40* both at the organism and cellular level. *Arabidopsis* plants over-expressing *ENOD40* did not show remarkable growth abnormalities, but some tissues revealed significantly smaller cells. *Arabidopsis* protoplasts transiently expressing the gene showed reduced expansion, and the same result was obtained with the administration of the peptide. BY-2 cells steadily over-expressing *ENOD40* were impaired in elongation growth, which is consistent with the observations in *Arabidopsis*.

Thus ENOD40 most likely is involved in a process that regulates cell growth. Analyses of the components involved herein will be discussed.

P0028. On the regulation mechanisms for the direction of division planes upon heterophyllous leaf foramtion in *Ludwigia arcuata* (Onagraceae)

A. Kuwabara, T. Nagata;
The University of Tokyo, Bunkyo-ku, Tokyo, Japan.

A heterophyllous plant of *Ludwigia arcuata* changes the leaf form upon environmental changes. When a shoot of *L. arcuata* was transferred from terrestrial condition to submergence, newly developed leaves became narrow submerged type leaves, while old leaves were still round terrestrial ones. Basal region of young developing leaves fully responded to submergence, resulting in the formation of spoon-shaped leaves. Such changes of leaf shapes were ascribed to change in numbers of epidermal cells in the transverse direction. When we observed the orientation of cell divisions in such developing leaves, directions of cell divisions were classified into two directions: one was parallel to the leaf long axis, while the other was transverse to the leaf long axis. Cell divisions for the transverse direction contributed to the increase of leaf width. Ethylene treatment that induced the formation of narrow leaves decreased the activity of cell divisions in the transverse direction. As these observations suggest the presence of a mechanism that regulates the direction of cell division in leaf development; we propose a novel mechanism for leaf development.

P0029. Isolation of Soybean Seed Coat Peroxidase By Ion Exchange HPLC

A. Rezazadeh;
Shahed Univ., tehran, Islamic Republic of Iran.

Peroxidases(1.11.1.7) are Heme-containing proteins, widly distributed in nature, where play a role in a variety of physiological process such as the structural integrity of cell walls. Peroxidases are also associated with plant defence responces and resistance to pathogens.

Soybean hull peroxidase(SBP), an anionic glycoprotein with isoelectric point 4.1 and M.W. 37 Kda, is found in substantial amounts in soybean hulls, a byproduct of the soybean industry. It exists essentially as single isozyme in hull. It has usually high thermal stability even at low pH.

Commercial preparations such as sigma have low activity and contains several contaminants, so we were interested in developing a method to quickly purify SBP. Fast detection of SBP is also useful in physiological studies.

We purified SBP, by using Anion Exchang High Performance Liquid Chromatography(AEHPLC).

As the quantity of peroxidase is important in plant physiological studies , HPLC provide a more reliable method.

In this work we can achieved purified peroxidase with RZ 2.0.

P0030. Triple Test Cross analysis for genetic components of salinity tolerance in spring wheat

S. A. Sadat Noori[1], A. Sokhansanj[2];
[1]University of Tehran, Abouraihan Campus, Department of Agronomy and Plant Breeding, Tehran, Islamic Republic of Iran, [2]University of Tehran, Faculty of Sciences, Department of Biology, Tehran, Islamic Republic of Iran.

Soil salinity poses considerable problems for agriculture and receives much attention from plant breeders. The identification of genes whose expression enables plants to adapt and/or tolerate salt stress is essential for breeding programs but little is known about the genetic mechanisms of traits in saline conditions.

Data obtained from 75 families produced by crossing 25 F_2 plants derived from a cross between two spring hexaploid wheats, Siete Cerros (salt tolerant) and Axona (salt sensitive) to their parents and their F_1 progenies, was subjected to triple test cross analysis. Genetic components (epistasis, additive & dominance) and their interactions with the environment (control - salinity) were detected for heading date, days to maturity, final plant height, spike length, ear weight, straw weight, number of grains per ear, grain yield per plant, 1000 grain weight, whole plant weight and harvest index. Epistasis was presented only for days to maturity (‘j’ and ‘l’ types) and plant height (‘i’ type) at control and spike length (‘j’ and ‘l’ types) at salinity condition. Additive component (D) was more important than dominance (H) especially in salinity condition. Dominance ratio, $({}^{H}/_{D})^{1/2}$, was less than unity in both environments and heritability (h^2) decreased for all traits at salinity condition.

P0031. Characterisation of calcium-dependent protein kinase (CDPK) isoforms of *Arabidopsis thaliana* in stress responses

J. Kurth[1], M. Boehmer[2], S. Franz[1], T. Romeis[1], **G. Freymark**[3];
[1]Institute for Plant Biochemistry, 14195 Berlin, Germany, [2]Max-Planck Institute for Plant Breeding Research, Cologne, Germany, [3]MPI für Züchtungsforschung, Cologne, Germany.

Plants are constantly exposed to changes in their environment and perceive a variety of biotic and abiotic stresses such as pathogen attack, cold or drought. Among the earliest cellular responses to such stress stimuli are changes in the cytoplasmic calcium concentrations. Calcium-dependent protein kinases (CDPKs) may function as potential sensors that decode the elevation of calcium concentration into enhanced protein kinase activity and subsequent downstream signalling events. *Arabidopsis thaliana* contains 34 CDPK isoforms. Evidence has been provided for CDPKs to participate in environmental stress signalling and CDPK transcript elevation was reported after exposure of *Arabidopsis thaliana* to cold, salt and drought. We have characterized the biological function of selected *Arabidopsis thaliana* CDPKs in specific signalling pathways by combining biochemical and reverse genetic approaches.

P0032. Influence of extracts of some pharmacological active plants to the seeds germinations of weeds invasive plants

N. Sejdiĺ , S. Redžiĺ ;
Faculty of Science, Sarajevo, Bosnia and Herzegovina.

Influence of one plant to another trough their natural metabolites (from different plant organs or different products of dissolution of non-lived plants) is named as allelopathy. In this study were analysing influences of water extracts of pharmacological active plants (Alnus glutinosa, Thymus serpyllum and Tagetes minima) to seeds of weeds of invasive plants (Amaranthus retroflexus, Setaria glauca, Echinochloa crus-galli, Galinsoga parviflora). Comparative investigation of influence of water extracts (in concentration of 0,1 and 0,5%) to seeds germination, of invasive weed plants, showed that all extracts with their pharmacological active compound had effects on seed germination, except to the species Galinsoga parvifora. The pressure of extracts showed the best results for the treated species Amaranthus retroflexus, with decreasing of germination in 50 %. Statistical differences where significant in the number of germinated seeds between non treated and treated plants with different concentration of extracts.

P0033. Metabolic response of the cyanobacterium Anabaena variabilis to iron limitation

A. Kosakowska;
Institute of Oceanology PAS, Sopot, Poland.

Under conditions of iron stress, the many bacteria and some cyanobacteria and algae secrete organic compounds, called siderophores that specifically bind and solubilize Fe.

This contribution deals with the isolation and identification of siderophore-like substances in culture of cyanobacterium, *Anabaena variabilis* under low iron conditions.

The iron-binding ligands were isolated by extraction and liquid column chromatography. The siderophore-like substances were analyzed in the examined samples by the chemical assays: CAS AD and the Arnow test. Biological activity of extracts was determined using specific bioassays with the apply of mutated bacterial strains (*Microbacterium flavescens* JG-9 and *Morganella morganii* SBK-3).

The extracts examined showed strongly positive responses. Detectable levels of hydroxamate and Ŭ-hydroxy / Ŭ-ketohydroxy acids type siderophores were produced by *Anabaena variabilis*.

The study was carried out as part of statutory programme of the Institute of Oceanology in Sopot (No.II.3.1) and was supported by the Polish State Committee of Scientific Research (grant No.3P04F 059 23, 2002-2005).

P0034. Salt and drought induced alterations in proteins and some enzymes activities in seedlings and calli of fenugreek *(Trigonella foenum-graecum* L.)

A. Kyani, V. Niknam;
Science, Tehran, Islamic Republic of Iran.

Fenugreek is an annual legume and important pharmaceutical plant. It is distributed in Africa, Europe, and Asia. Fenugreek grows in non-saline soils, but also it can be grown in relatively saline soils. Besides, it can not tolerate drought stress. In this research we investigated the effects of NaCl (0-200 mM) and drought stress (PEG 4000, PEG 6000 & Mannitol 0-20%) on the germination percentage, content of proline and proteins, and activity of antioxidant enzymes in seedlings and calli. Protein and proline content was determined by the spectrophotometric method. SDS-PAGE system was used for qualitative changes of proteins. According to obtained results seedlings tolerate NaCl up to 100 mM and PEG and mannitol up to 10 %. Proteins and proline content increased under salt and drought stress. Moreover, alterations of some antioxidant enzymes such as peroxidase, catalase and polyphenol oxidase in seedlings and calli were studied under stress using spectrophotometric method and PAGE system.

P0035. Uptake and accumulation of aluminium in root cells of *Arabidopsis thaliana*

P. Illes[1], M. Ovecka[1,2], I. Lichtscheidl[2];
[1]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia,
[2]Institution of Cell Imaging and Ultrastructure Research, University of Vienna, Vienna, Austria.

Aluminium toxicity is an important growth-limiting factor in acid soils; experiments have shown that the root apex is the primary site of aluminium-induced injury in plants. The main symptom of aluminium effect is a decrease of root growth; first physiological responses are observed shortly after aluminium application.

Root growth of *Arabidopsis* plants cultivated for 7 days on aluminium-containing medium (10-300 µM) was inhibited in a concentration-dependent manner. We documented changes in the cytoarchitecture and behaviour of exo-/endocytotic vesicles in root hairs as an immediate response to aluminium. For localisation and uptake of aluminium in root cells we used specific fluorescence dyes: morin for detection of aluminium and FM4-64 for labelling of the plasma membrane. Results showed that aluminium was excluded to the apoplast in elongated and mature cells, whereas it was taken into the cytoplasm of cells in meristematic and transition zones within 1,5 hours. 4 hours after treatment aluminium had further progressed and concentrated into provacuolar compartments and vacuoles.

Supported by: VEGA 2/5085/25; TIPNET (HPRN-CT-2002-00265).

P0036. Phosphatidylcholin-specific phospholipase C may play a role in aluminum toxicity in plants

S. Veselkova[1,2], P. Pejchar[1,2], Z. Novotna[2], O. Valentova[2], J. Martinec[1];
[1]Institute of Experimental Botany, Prague 6, Czech Republic,
[2]Department of Biochemistry and Microbiology, Institute of Chemical Technology Prague, Prague 6, Czech Republic.

Aluminum (Al) is a highly cytotoxic metal for plants, but the molecular base of Al toxicity is still far from being understood. The most important physiological consequence of Al toxicity is changes in root morphology suggesting a role of root cytoskeleton as a target structure. The important role of phospholipid degrading enzymes, phospholipases C (PLC) and D in regulation of cytoskeleton remodelling is now evident. The aim of our work is to study molecular mechanism of aluminum toxicity with special respect to the role of plant phospholipases.

Fluorescently labelled phosphatidylcholine was used to study changes of phospholipid profile after aluminum treatment of tobacco cell culture BY2. Products of phospholipases action were analysed by HP-TLC. The amount of diacylglycerol (product of PC-PLC) decreased within 30 min of Al treatment. Later on, PC-PLC activity *in vitro* was detected in the same experimental material and basic biochemical properties of the PC-PLC were determined.

Presented results suggest a role of the PC-PLC in molecular mechanism of aluminum toxicity.

This work was supported by grants 522/05/0340 (GACR) and 1P05ME825 (MSMT).

P0037. Functional Characterization of a Rice Choline Kinase Gene in Transgenic Plant

J. Lee, Y. Lee, U. Yoon, G. Lee, Y. Kim, S. Suh;
National Institute of Agricultural Biotechnology, Suwon, Republic of Korea.

The rice cDNA clone that encodes osCK1 (*Oryza sativa* choline kinase 1) was isolated by differential screening from cold treated rice cDNA library. While phosphatidylcholine (PC) has known containing a major role in plant stress adaptation, the choline kinase, the first enzyme of CDP-choline pathway for PC biosynthesis, may contain a possible regulatory role in stressed plants. The expression level of osCK1 transcripts specifically increased in cold treatment but not changed in ABA or salt treatments in rice. The osCK1 gene was constitutively over-expressed in rice, and microarray analysis of transgenic plants revealed that over-expression of osCK1 enhanced induction of several genes supposed to be involved in calcium signaling pathways. In Northern blot analysis, genes containing calmodulin binding motif or unknown function were up-regulated in the transgenic rice. These results hypothesize that over-expression of choline kinase may activate the gene expression involving in calcium signaling pathways. The molecular function of osCK1 responding to biotic and abiotic stress in transgenic rice will be further discussed in this presentation.

P0038. Floral Ontogeny of Soybean (*Glycine max* (L.) Merrill) under Drought Stress

P. Nitikul, R. Thavarorith, S. Chadchawan;
Faculty of Science, Chulalongkorn University, Bangkok, Thailand.

The effects of drought stress on floral ontogeny were examined in soybean (*Glycine max* (L.) Merrill) cv. SJ5. The drought treatment was performed by application of 30% of plant-available water to V4-stage soybeans, which consisted of 4 internodes, and floral meristem was initiated at every axillary bud. The drought treatment was ended when the first flower bloomed (R1 stage). The stressed plant showed the significant reduction in height, fresh weight and dry weight when compared to the non-stress controls. Drought stress treatment applied during V4-R1 stage of soybean reduced the number of flowers by 63%. Moreover, it also affected the pollen fertility. The *in vitro* pollen germination test, performed with the pollens from blooming flowers, showed that the stress decreased germination percentage by 82%. However, drought stress had no effect on stigma receptivity. Therefore, at the reproductive stage, the severe effect of drought stress on soybean productivity was caused by both the floral development prohibition and reduction in pollen viability.

P0039. Expression Analysis of GSK-3/SHAGGY-Like Kinases in Arabidopsis thaliana

A. Verhounig[1], C. Jonak[2,1];
[1]Max Perutz Laboratories, University of Vienna, Vienna, Austria,
[2]Gregor Mendel Institute of Molecular Plant Biology, Austrian Academy of Science, Vienna, Austria.

Glycogen Synthase Kinase-3/SHAGGY-like kinases (GSKs) are evolutionary highly conserved, multifunctional non-receptor Serine/Threonine protein kinases.

In Arabidopsis thaliana there are ten different GSKs (ASKs) encoded by a multigene family. The ASKs can be divided into four groups based on their sequence similarity. So far, studies have implicated their involvement in flower development, brassinosteroid signalling, and stress adaptation responses.

To clarify the functions of each ASK in cell signal transduction, we study the temporal and tissue specific expression patterns. Therefore, the distinct ASK promoters were fused to the GUS reporter gene. Expression patterns are analysed under defined growth conditions during plant development, hormone treatment, and in response to biotic/abiotic stresses, including pathogen infection, leaf wounding, hyperosmotic stress, extreme temperature as well as different light conditions.

P0040. Effects of Exogenous Abscisic Acid on Salt Tolerance and Proline Accumulation of Rice (*Oryza sativa* L.)Seedlings

P. Klomsakul, P. Boon-Long, **S. Chadchawan**;
Faculty of Science, Chulalongkorn University, Bangkok, Thailand.

The effects of abscisic acid (ABA) on salt tolerance and proline accumulation were studied in the two similar genetic background rice lines, which have the different salt-tolerant ability. When the two-week old, salt-sensitive seedlings (LPT123) were grown in salt-stress condition by addition of 0.5% NaCl in nutrient solution, it was resulted in shoot fresh weight loss and the stable root growth during four weeks of the stress period. Contrastly, the salt-tolerant rice seedlings (LPT123-TC171) grown in the same condition, showed the maintenance of shoot fresh weight and root dry weight accumulation. The application of 100 µM ABA everyday on leaf blade reduced salt-stress effects in both rice lines by showing the better growth and survival rate. ABA application significantly induced early proline accumulation in both rice lines via the up-regulation of *OsP5CS* gene expression. Our results suggest that the early accumulation of proline, induced by exogenous ABA may be responsible for the increase in salt tolerant ability in rice seedlings.

P0041. Temperature stress tolerance and heat shock granule complexes in Lupinus albus

S. Cherian, R. B. Ferreira;
Instituto de Tecnologia Quimica e Biologica (ITQB), Oeiras, Portugal.

Living organisms respond to high temperatures by repressing the synthesis of most proteins and by inducing the synthesis of a small group of proteins-the heat shock proteins (HSP). One of the physiological functions attributed to the HSP is their involvement in the thermotolerance acquisition. Despite the suggested role of HSP in thermotolerance, the individual function and identity of most HSP remains unknown, particularly in the case of plants. The HSP20 family shows some characteristics that differ from the other HSPs. It has been suggested that the physiological fuinction of HSP20 family is related with the cytosolic formation of heat shock granules (HSG). The abundance of HSG under stress conditions namely, high temperature, amounting to 1% of total cell protein suggests their functional importance in survival at high temperatures. Therefore, the aim of the present study was to analyse those aspects that are known to be directly involved in the acquisition of thermotolerance, namely the HSP20 family and the heat shock granules (HSG) in Lupinus albus.

P0042. Close association of an FtsH protease with photosystem II in higher plants

Y. Nakayama[1], M. Yoshida[1], I. Enami[2], Y. Yamamoto[1];
[1]Graduate School of Natural Science and Technology, Okayama University, Okayama, Japan, [2]Department of Biology, Tokyo University of Science, Japan.

In chloroplasts, there are several protease families, including Clp, DegP and FtsH. Recently an FtsH protease (FtsH2) was suggested to be involved in the degradation of photodamaged D1 protein under light stress. In this study, we carried out Western blot analysis with spinach photosystem II membranes and core complexes prepared by the treatment of the photosystem II membranes by HTG (n-heptyl thioglucoside) using antibodies against the FtsH proteases (DS9 from tobacco and VAR2 from *Arabidopsis*), and showed that the FtsH protease is present in the vicinity of photosystem II. With a chemical cross-linker bis(sulfosuccinimidyl)suberate sodium salt, we showed the FtsH2 and the D1 protein to form a large cross-linked products by the illumination of the photosystem II membranes. These results suggest that the photodamaged D1 protein is recognized as a substrate by the FtsH protease. Our data also suggest the possibility that D1 degradation takes place in the stacked region of thylakoids.

P0043. Degradation of the D1 protein of Photosystem II in *Synechocystis* PCC6803 under heat stress - the role of an FtsH protease

T. Kamata, H. Hiramoto, N. Morita, Y. Yamamoto;
Graduate School of Natural Science and Technology, Okayama University, Okayama, Japan.

With wild type and φFtsH (slr0228) mutant cells of *Synechocystis* PCC6803, cell growth, oxygen-evolution and degradation of the D1 protein of PS II were examined under heat stress. Wild type cells grew normally under heat stress (40°C) conditions, while φFtsH cells were sensitive to the heat stress and showed bleaching of pigments. Oxygen evolving activity of wild type cells showed no decrease upon heat stress (42°C) unless lincomycine was added. Oxygen evolution of the mutant cells suffered from the heat stress in the presence or absence of lincomycin. Western blot analysis with the antibody against the D1 protein showed that the amount of the D1 protein decreased upon heat treatment of the wild type cells. On the other hand, no apparent loss of the D1 protein was observed with the mutant cells under the same stress conditions. These results suggest that the FtsH protease is involved in the degradation of the D1 protein under heat stress conditions.

P0044. Cleavage of the D1 protein of spinach PS II under heat stress: an FtsH protease is responsible for the proteolysis

M. Yoshioka, S. Uchida, N. Morita, Y. Yamamoto;
Graduate School of Natural Science and Technology, Okayama University, Okayama, Japan.

When spinach thylakoids were treated with heat (40°C for 30 min), the reaction center-binding D1 protein of PS II was cleaved and a 23 kDa N-terminal fragment was produced. The proteolysis was specific to the D1 protein and no other proteins around the D1 protein were degraded. The cleavage of the D1 protein was stimulated by the addition of Zn and inhibited by EDTA, indicating participation of a metallo-protease. The protease was solubilized when the thylakoids were treated with 2M KSCN. The protease activity in the supernatant of the KSCN-treated thylakoids was detected by gelatin-activity gel electrophoresis and size of the protease was about 70 kDa. Western blot analysis using antibody against FtsH proteases (anti-DS9 and anti-VAR2) showed that the supernatant contains an FtsH protease. Reconstitution of the FtsH-containing supernatant fraction with the thylakoids was also successfully carried out. Our results strongly suggest that the FtsH protease is responsible for the proteolysis of the D1 protein under heat stress.

P0045. Adaptive responses to high salinity of two subspecies of *Aster tripolium* on different nitrogen sources

B. Sági, J. Csiszár, A. Pécsváradi, Á. Vashegyi, L. Erdei;
Department of Plant Physiology, University of Szeged, Szeged, Hungary.

Soil salinity is an important agricultural problem. One possible way to use affected fields is planting salt tolerant crops such as *Aster tripolium* L..

Aster tripolium is a typical halophyte species with two horizontally isolated subspecies. The ssp. tripolium is a maritime halophyte, while ssp. pannonicus is common on the continental alkaline salty meadows.

Adaptive responses to high salinity of two subspecies of *Aster tripolium* were studied on different pH values and Na^+ concentrations and on different nitrogen sources. One of our interesting result was that young leaves of *Aster tripolium* ssp. tripolium treated with ammonium and relatively low NaCl concentrations became chlorotic, while on high salt concentrations showed the signs of ammonium toxicity. Ion concentrations (Na, Fe, K, Ca and Mg), nitrate reductase (NR) and glutamine synthetase (GS) activity were measured in both leaves and roots.

We conclude that ion concentrations, NR and GS activities have changed differentially in the two subspecies, which can be regarded as adaptive responses to their environmental conditions.

P0046. Comparison of wheat, barley and rye with respect to salt tolerance at the germination stage

K. Thi Ha[1], A. Weidner[1], E. Schumann[2], A. Börner[1];
[1]Institute of Plant Genetics and Crop Plant Research (IPK) Gatersleben, Gatersleben, Germany, [2]Martin-Luther-University Halle-Wittenberg, Halle (Saale), Germany.

Soil salinity is one of the most important environmental factors, which limit the crop production in many parts of the world, particularly in areas with arid and semi-arid climatic conditions. Mismanagement of the valuable resource water enhances the desertification of agricultural arable land by secondary salinisation. Salt tolerant crops could be used to reclaim salt affected soils or for the improvement of the yield.

In 2003 a programme was initiated at the Genebank of Gatersleben for the screening of salt tolerance in cereals. 569 hexaploid and 125 tetraploid wheat and 108 barley accessions of the genebank collection were tested at the germination stage. In addition several rye accessions and inbred lines from the breeding programme of the Martin-Luther-University Halle-Wittenberg were investigated. Germination tests were carried out on filter paper in plastic boxes by using three different concentrations of NaCl solutions (1.5%, 2.0% and 2.5%) and distilled water as control. After ten days in a climatic chamber with a light and dark photoperiod of 12 hours and a constant temperature of 20°C, the lines were scored according to the scheme of Mano et al. (1996).

P0047. Effects of zinc and copper on expression of metallothionein genes, and on polyamine content in *in vitro* micropropagated *Populus alba* L..

C. Franchin[1], T. Fossati[2], E. Pasquini[1], V. Ziosi[1], P. Torrigiani[1], **S. Castiglione**[2], S. Biondi[1];
[1]Università di Bologna Dipartimento di Biologia, Bologna, Italy, [2]Università di Milano Dipartimento di Biologia, Milano, Italy.

In an effort to acquire knowledge of the basic processes underlying metal detoxification and tolerance in poplar, we isolated *Populus nigra* metallothionein (MT) genes on the basis of *P. trichocarpa* cDNA sequences available on DOE JOINT GENOME INSTITUTE databases. Three genes, belonging to class 1, 2 and 3, were cloned and sequenced. Their expression patterns were northern blot analysed in *in vitro* micropropagated shoots of the *P. alba* clone “Villafranca” after exposure for 1, 3, 6 and 15 days to $ZnSO_4$ and $CuCl_2$. Results show that a) Zn (> 1 mM) and Cu (> 0.1 mM) induced leaf chlorosis; b) rooting of shoots was delayed and reduced (Zn >1 mM), or totally inhibited (Cu); c) transcript levels of

MT1, *MT2* and *MT3* genes were enhanced in a dose-dependent manner in the leaves of shoots treated with Zn, whereas Cu did not stimulate expression of MT genes. Since polyamines (PAs) are known to be involved in various abiotic stress responses, free and conjugated leaf PA content was monitored during treatment with Zn or Cu, and was found to correlate positively with metal concentration.

Supported by funds from MIUR (PRIN 2003).

Author 1, 2 and 3 contributed equally to the present work.

P0048. Molecular genetic study on the abiotic stress signal transduction in rice (*Oriza sativa* L.)

S. R. Kim, S. C. Lee, S. H. Kim, S. J. Lee, M. K. Kim, S. I. Ryu, C. S. Choi;
Sogang University, Seoul, Republic of Korea.

Although a part of signal transduction of abiotic stress response has been elucidated in dicot plants, it remains unclear in monocot plants. Using a cold-sensitive rice plant as a model, the stress response mechanism has been studied. First, drought and cold responsive *OsDhn1* and *OsAsr1* were identified from the seed coat ESTs. Both genes were induced by cold stress in the reproductive organ, preferentially in the lower epidermis of the palea and lemma. Second, *OsAsr1* and *OsDhn1* were up-regulated in the transgenic rice expressing *CBF1/DREB1b*, suggesting the possible regulation of those genes by the CBF/DREB stress-signaling pathway. Third, among nine genes retrieved from rice genome database *OsDREB1E, OsDREB1F, OsDREB1G, OsDREB1H,* and *OsDREB1I* were novel. While *OsDREB1E* and *OsDREB1F* were induced by cold, *OsDREB1G* and *OsDREB1H* by drought, *OsDREB1I* was induced by both cold and drought. Fourth, five rice *ICE1* homologues of bHLH type genes were retrieved from the rice genomic database and their characterization is being conducted. Finally, Transactivation assay revealed that *OsDREB1A* and *CBF1*, but not *OsDREB1I*, could induce *OsDhn1* in the rice protoplasts.

P0049. The role of glutathione S-transferases in the drought stress tolerance of different wheat genotypes

J. Csiszár[1], I. Tari[1], Á. Gallé[1], Á. Lendvai[2], P. Miskolczi[2], M. Szécsényi[2], É. Király[1], J. Györgyey[2], L. Erdei[1];
[1]Department of Plant Physiology, University of Szeged, Szeged, Hungary, [2]Institute of Plant Biology, Biological Research Center, Szeged, Hungary.

Investigation of enzymatic antioxidant activities of *Triticum aestivum* varieties with different drought tolerance under osmotic stress revealed the importance of glutathione S-transferases (GSTs). GSTs are ubiquitous enzymes catalysing the addition of reduced glutathione to cytotoxic substrates thus protecting against environmental stress by detoxifying reactive products. The more tolerant wheat lines had higher GST activities in their roots, and enzyme activities increased differentially by 400 mOsm polyethylene glycol (PEG 6000) treatment. Our aim was to identify the water stress-related GST genes in wheat lines and compare the expression pattern of these genes in different wheat varieties under osmotic stress.

Searching for drought tolerance related genes revealed that expression of *GST* genes elevated under water stress (Györgyey et al., unpublished results). Phylogenetic analysis of wheat *GSTs* was performed *in silico* using TIGR database and Clustal softwer. Homology was found between the upregulated sequences and the GST coding TCs in the GenBank database; different *GST* genes from GST classes Phi and Zeta were choosen for further estimation.

P0050. Biochemical expression on salt-tolerant and salt-sensitive lines of rice (*Oryza sativa* L.) responses to salt stress

S. Cha-um[1,2], C. Kirdmanee[1], K. Supaibulwatana[2];
[1]National Center for Genetic Engineering and Biotechnology, Pathumthani, Thailand, [2]Mahidol University, Bangkok, Thailand.

The aim of this investigation is to express on betaine aldehyde dehydrogenase (BADH) for glycinebetaine (Glybet) accumulation in *in-vitro* rice seedlings using salt stress conditions. In both salt-tolerant and salt-sensitive lines, the BADH enzyme progressively increased during the first few hours after NaCl exposure until reach to the maximum point after 72 h and then dropped. It was clearly showed that the seedlings of salt-tolerant line had the highest level of BADH enzyme at 72 h about 2.6 times more than those of salt-sensitive line. Moreover, the highest amount of Glybet was detected in salt-tolerant line that was 1.2 times more than in salt-sensitive line at 96 h. The BADH activities were positively related to Glybet accumulation in salt-tolerant and salt-sensitive lines. It should be noted that the expression of BADH enzyme in salt-tolerant line cultured under salt stress exhibited a significant increase in Glybet biosynthesis and accumulation higher than salt-sensitive line. The accumulation of Glybet immediately following the initial exposure of rice to salt stress may function as a defensive response to salt stress conditions.

P0051. Proline produced due to NaCl pre-exposure is the prime cause behind reduced sensitivity of *Azolla pinnata* plants to UV-B radiation

G. Abraham, A. Masood;
Allahabad Agriculture Institute-Deemed University, Allahabad, India.

Sensitivity of *Azolla pinnata* plants to NaCl (40 and 60 mM) for 8 days and daily UV-B exposure of 3 and 6 h corresponding to 4.32 and 6.48 KJm^{-2} till 8 days was investigated. NaCl and UV-B resulted in visible injury symptoms. At 40 mM NaCl treatment and 3 h UV-B exposure injury symptoms in the form of chlorosis and marginal necrosis was observed with a corresponding increase in peroxidase activity. However, exposure to 60 mM NaCl and 6 h UV-B resulted in chlorosis followed by necrosis and nearly 2.5 fold increase in peroxidase activity. Growth, chlorophyll content and PS II activity decreased due to NaCl but increased proline, H_2O_2 , electrolyte leakage and lipid peroxidation. Similar results were obtained following UV-B exposure. Simultaneous exposure to UV-B and NaCl produced an additive effect. However, pre-exposure to NaCl decreased H_2O_2 generation, lipid peroxidation and electrolyte leakage considerably. These results have been confirmed when plants were exogenously supplied with proline (1-5 mM) and subsequently exposed to UV-B. The role of proline accumulated under salt conditions enhanced resistance of *Azolla* plants to UV-B exposure.

P0052. Characterisation of GSK-3/Shaggy-like Kinases in Arabidopsis thaliana

E. K. Petutschnig[1], W. Rozhon[1], C. Jonak[1,2];
[1]Max Perutz Laboratories, University of Vienna, Vienna, Austria,
[2]Gregor Mendel Institute of Molecular Plant Biology, Austrian Academy of Science, Vienna, Austria.

The ten ASK proteins (Arabidopsis thaliana GSK-3/Shaggy-like Kinases) are homologues of the mammalian GSK-3 (Glycogen Synthase Kinase 3) and the Drosophila melanogaster Shaggy kinases. They can be grouped into four classes, according to their sequence similarity. Plant GSK-3/ Shaggy-like kinases have been shown to be involved in many different signal transduction processes, ranging from flower development and hormone perception to stress responses. To characterise the Arabidopsis members of this kinase family, we have generated transgenic plants overexpressing epitope-tagged versions of the kinases. Furthermore, we have acquired the respective T-DNA insertion lines from SALK, Sail and GABI-Kat and analysed them by PCR and Southern blotting. Phenotypic characterisation of overexpression and knockout plants are in progress. Preliminary transient expression assays in protoplasts revealed highly different protein levels and kinase activities, even between closely related ASKs, indicating involvement in different biological processes.

P0053. Acclimation of poplar trees to heavy metals in polluted habitats: II. Alcoholic fermentation in fine roots of *Populus nigra* and *Populus deltoides*

G. Lorenc-PluciŒska, A. Szadel, B. Kieliszewska-Rokicka, K. Stobrawa, A. Michalak, A. PluciŒski;
Institute of Dendrology Polish Academy of Sciences, Kórnik, Poland.

We studied effects of chronic industrial pollution on the metabolic activity of roots of *Populus nigra* L. and *P. deltoides* Bartr. ex Marsh. The trees had grown for 20-30 years near a copper smelter - at Glogów (51°40'N, 16°05'E, buffer zone A) and at Bogomice (51°41'N, 16°01'E, buffer zone B) - and in a control area at Kórnik (52°15'N, 17°04'E). We assessed the 'vitality' of fine roots, mycorrhizae, carbohydrates, activity of pyruvate decarboxylase, fermentative enzymes: alcohol dehydrogenase and lactate dehydrogenase. Also microbial activity and chemical properties of the soil were analysed. Our results attest to seasonal and interspecific differences in all the parameters. Generally, the microbial activity of the soil and mycorrhizal colonization of fine roots sharply diminished in zone B and disappeared in zone A. In contrast, the 'vitality' of fine roots decreased more strongly in zone B than in zone A. In the area affected by the copper smelter, starch, sucrose, glucose and fructose contents of fine roots and activities of fermentative enzymes increased in *P. nigra* and were reduced or unchanged in *P. deltoides*.

P0054. Etio-chloroplasts to nucleus signalling and Lhc gene expression in Pinus sylvestris cotyledons

N. Rascio, S. De Faveri, M. Di Bella, N. La Rocca;
University of Padova, Department of Biology, Padova, Italy.

It is known that in angiosperms the photodependent expression of Lhc nuclear genes (photo-genes) is also regulated through an inhibitory signal produced by photodamaged chloroplasts as consequence of chlorophyll precursors accumulation. No information is available about gimnosperms where Lhc gene expression is usually not induced but only stimolated by light.

We studied the consequences of an inhibited carotenoid synthesis induced by herbicides on cotyledonal etio-chloroplasts of dark-grown Pinus sylvestris plantlets.The treatment had negative effects (not due to photodamage) on ultrastructural organization, chlorophyll content and molecular composition of thylakoid membranes. An interesting finding was the production by the altered etio-chloroplasts of a signal inhibiting the expression of nuclear Lhc genes, which in this species are constitutively transcripted in darkness. The inhibition was correlated with an increase of soluble chlorophyll precursors. Thus, the plastidic signal which modulates nuclear Lhc gene transcription already exists in gimnosperms and its chemical nature seems to be the same of angiosperms.

P0055. Stress proteins and phytohormones: their role in formation of plant resistance.

I. V. Kosakivska;
M.G. Kholodny Institute of Botany, NAS, Ukraine, Kyiv, Ukraine.

Using the disc-electrophoresis methods, we have studied protein biosynthesis of different plants, including 11 species of *Orchidaceae*, some other tropical and subtropical plants, 9 different fruit plants, and 4 cultivars of *Triticum aestivum* L. under stresses factors such as high and low temperature, clinostating, radioactive irradiation and osmotic shock. Specific and unspecific reactions of plants protein system on stresses were found. *De novo* synthesis of 35 and 45 kD polypeptides were observed in total and mitochondrial proteins fractions after heat-shock and radioactive irradiation. This suggests that mitochondries participate in formation of plant resistance.

Intensive synthesis of ABA revealed as the universal reaction of all studied plants on action of different kinds of stresses. Specific changes in balance of phytohormones were found under different stresses. We observed the correlation between endogenous ABA, IAA and cytokinin level and plant resistance. We also found the interaction between the process of biosynthesis of proteins and phytohormone balance, as well as their direct participation in formation of plant resistance.

P0056. Phytohormonal complex of *Syngonium* under the conditions of hermetically sealed vessel

V. A. Vasjuk, N. P. Vedenicheva, V. N. Generalova, L. I. Musatenko;
M.G. Kholodny Institute of Botany, NAS, Ukraine,, Kyiv, Ukraine.

Plants growing in espesial hermetic vessel are of great interest so as it makes it possible to simulate one of the space flight factors - oxygen deficit, to establish plants with tolerance to such conditions for the following employment at the orbital stations. We didn't determine essential morphological changes in *Syngonium* plants after nine months of staying in hermetically sealed vessel comparing with plants growing in open soil. It is probably the result of these plants high tolerance to hypoxia. To reveal this adaptation mechanism the content of endogenous phytohormones (IAA, ABA, cytokinins and gibberellins) has been investigated in *Syngonium* roots and shoots by HPLC. Studies on the hormonal balans *Syngonium* in this conditions were conducted for the first time. It was determined that all phytohormones level was essential decreased in the experimental plants comparing with the control ones. The obtained results has been analysed as regards the relation of adaptive properties of *Syngonium* plants and hormonal system lability.

P0057. The interaction between WRKY53, a senescence specific transcription factor, and P9, a jasmonic acid inducible protein conferring resistance to bacterial and fungal links senescence to the pathogen responsive pathway

Y. Miao, U. Zentgraf;
Center of Plant Molecular Biology, Tuebingen University, Germany.

Using yeast two hybrid system, we found that WRKY53 interacted with a putative jasmonic acid inducible protein (p9), WRKY53 and p9 colocalized in nucleus. The results of RNA blot showed that p9 was induced in col-0 treated with JA, p9 expression was completely block by jar1-1 but decreased in npr1-1 and col-0 treated with SA. Conversely, WRKY53 expression was suppressed in col-0 and jar1-1 treated with JA, but increased in npr1-1 and col-0 treated with SA. The infection result of bacterial and fungal showed that the 35S:p9 significantly decrease the growth of bacterial and damage degree of fungal in leaf region, but p9 ko-line increase the growth of the bacterial and damage degree of fungal. However, There is no significant difference in 35S:WRKY53 line and WRKY53 ko-line. Moreover, 35S:WRKY53 suppressed the expression of p9 in RNA level and WRKY53 ko-line increased p9 expression. We suggest that WRKY53, as a senescence specific factor, act upstream of NPR1 in a SA-dependent signal pathway, act as an activator of SA-induced genes genes and a repressor of JA-responsive genes, through interacting with p9 integrating senescence signals into pathogen responsive pathway.

P0058. Hormonal complex of two different ecotypes of Sium latifolium L.

N. P. Vedenicheva, V. A. Vasjuk, V. N. Generalova;
M. G. Kholodny Institute of Botany, NAS, Ukraine, Kyiv, Ukraine.

Sium latifolium L. plants can grow in different water conditions: dipping into water (up to 50% of plant body) and on land near the coast. These two plant ecotypes differ only in their sizes - 1.5-2 m and 25 cm correspondently. To understand the physiological mechanisms of such phenotypic plasticity the content of endogenous phytohormones in vegetative and reproductive organs of *S. latifolium* plants, growing in different ecological conditions (in water and on land) was studied during vegetation by HPLC method. It was shown that ABA content was essential higher and cytokinin and IAA level was lower in land plants comparing with water ones. Differences in free and bound phytohormones content were constant during ontogenesis. It is possible that *S. latifolium* plants capacity to form different phenotypes within the same genotype is connected with the ability to maintain the phytohormonal balance in conformity to the environment during long time.

P0059. Intracellular localization of GABA and free amino acids in plants under hypoxic stress and high concentration carbon dioxide

A. N. Ershova[1], E. A. Chernigina[2];
[1]Voronezh State Pedagogical University, Voronezh, Russian Federation, [2]Voronezh State Agricultural University, Voronezh, Russian Federation.

Under hypoxia in plants the exchange processes of free amino acids get disturbed. The effect of hypoxia and CO_2-media (6-24h) on distribution of free amino acids between vacuolar and cytoplasm compartment in leaves of seedlings with different tolerance was studied under usage of DMSO.

It was observed that in all plants under hypoxia the most changes occurred in GABA and alanine (Ala) content. In midtolerant seedlings (corn, soybean) the GABA level increased 3-7 fold and in intolerant (wheat, pea) 1.5-2.5 fold. Accumulation of GABA in intolerant plants occurred in vacuole and in midtolerant plants in vacuole and cytoplasm. The level of Ala increased in 30-150% under hypoxia in intolerant plant cells in cytoplasm, but in midtolerant in vacuolar one. The content of glutamate in all plants under hypoxia didn't change. The level of aspartate in leguminous was decreased on 20-40% in vacuole. Under 24h of hypoxia the increase of vacuolar compartment of GABA and Ala was observed. CO_2-media stimulated more substantial changes in amino acids than hypoxia.

The important role of vacuole in accumulation of stress amino acids GABA and Ala under hypoxic stress was proved.

P0060. Field trial validation of a terminal drought tolerance QTL in pearl millet

S. M. H. Rizvi[1], R. Serraj[2], A. Sharma[3], R. S. Yadav[4], F. R. Bidinger[1], V. Vadez[1], A. G. Bhaskar Raj[1], C. J. Howarth[4], O. P. Yadav[5], C. T. Hash[1];
[1]International Crops Research Institute for Semi Arid Tropics (ICRISAT), Hyderabad, India, [2]International Atomic Energy Agency, Vienna, Austria, [3]Penn State University, Park, PA, United States, [4]Institute for Grassland and Environmental Research, Aberystwyth, United Kingdom, [5]Central Arid Zone Research Institute, Jodhpur, India.

Several putative QTLs were mapped in pearl millet [*Pennisetum glaucum* (L.) R. Br.] for grain and stover yield components *per se* and yield maintenance under terminal drought stress. Marker-assisted selection (MAS) for these QTLs facilitated the development of near isogenic lines (NILs). Nineteen homozygous NILs and their two parents (donor PRLT 2/89-33 and recurrent H 77/833-2) were testcrossed to five closely related male-sterile testers. The resulting 105 hybrids were evaluated for their agronomic performance in replicated field trials during 2003 and 2004 at Patancheru (rainy & post rainy) and in two drought-prone locations at Rajasthan (rainy). Significant effects of genotype (G), environment (E), and G × E interactions were observed on the grain and stover yield components. Across 14 environments, general combining ability effect of introgression lines ICMR 01029 and ICMR 01031 were substantially better than recurrent parent H 77/833-2 for grain yield. Subsequent line-source irrigation experiment confirmed these findings under moisture gradient and validated the effect of a major QTL for grain yield terminal drought tolerance on LG2 of PRLT 2/89-33.

P0061. Mycorrhizal fungi, modalities for reducing the drought stress during acclimatization of vitroplants-biochemical aspects

C. R. Maximilian[1], M. E. Carasan[1], A. Brezeanu[1], A. Rosu[2];
[1]Institute of Biology, Bucharest, Romania, [2]Faculty of Biotehnology,University of agronomical sciences, Bucharest, Romania.

Mycorrhizal fungi established symbiotic association with vascular plant roots. This symbiosis is a bilateral cooperation between partners and supposes structural and ultrastructural changes. Many studies were emphasized that mycorrhizal fungi increase tolerance to extreme conditions, like drought. This tolerance is attributed to changes in the host’s photosynthesis process or in levels of carbohydrates and proteins. The transfer of vitroplants to *ex vitro* is one of the most critical factor in the acclimatization and causes often important damage of the biological material. Therefore, we achieve a study regarding the inducing of drought tolerance by experimental colonization of vitroplants during transfer to *ex vitro*. The mycorrhizal colonization induces the reducing of drought stress and decreasing of oxidative processes. The oxidative processes will be monitored by the level of enzyme activity and electrophoretic spectra of oxidoreductases: superoxide-dismutase, catalases and peroxidases. The variation of antioxidant enzymes activity denotes the amplitude of oxidative processes which undergo in the plant cell during acclimatization.

P0062. Hydraulic conductivity of figleaf gourd (*Cucurbita ficifolia*) roots, a species tolerant to low temperature

G. Chung, S. Lee;
Agricultural Plant Stress Research Center, Chonnam National University, Gwangju, Republic of Korea.

Characteristics of low temperature (LT)-tolerant figleaf gourd (*Cucurbita ficifolia* Bouché, FG) root as an ability to absorb water upon exposure to LT was studied. FG roots were able to maintain positive root pressure at LT (8 ºC) when measured with root pressure probe. While a sudden introduction of LT lowered the hydraulic conductivity of root (Lp_r), pre-conditioning of root with LT for 24 h followed by 5 h exposure to 25 ºC dramatically increased the Lp_r. In this case, hydrostatic and osmotic Lp_r, and cellular hydraulic conductivity (Lp) were increased by a factor of 6.5 and 16.9 and 3.5, respectively. Western blot analysis of the SDS-PAGE confirmed that the aquaporin protein expression in root plasma membrane was marginally increased within 1 d of LT treatment, indicating the increased activity of house-keeping aquaporins that resulted in high Lp_r and Lp. The activity of proton-ATPase and Lp were insensitive to externally applied hydrogen peroxide. These findings suggest that the aquaporin activity may play an important role upon exposure to LT and that the process of root acclimation includes the efficiency of aquaporins to transport water across the membrane.

P0063. Early responses of *Chenopodium rubrum* cells to heat shock

A. Chaidee, W. Pfeiffer;
Abteilung Pflanzenphysiologie, Fachbereich Zellbiologie der Universität, Salzburg, Austria.

Early cellular responses to heat shock were studied in heterotroph cell suspensions from *Chenopodium rubrum* L. The effect of heat shock was quantified using biochemical parameters related to cellular vitality, membrane function and membrane integrity. It was found that extracellular pH and an alkaline phosphatase activity are more sensitive to heat shock than other parameters like reduction of methylthiazoletetrazolium (MTT) and dichloroindophenol (DCPIP), and cellular release of osmotic content, protein and betalain. Reduction of MTT is ascribed to mitochondrial dehydrogenase activity and reduction of DCPIP to plasma membrane electron transport. Both reductase activities were inhibited by heat shock at 45°C and above. Heat shock at lower temperature had no effect on the reduction of MTT and DCPIP. Heat shock at 30-35°C affected only extracellular pH and an alkaline phosphatase. Comparison of these data indicates that extracellular pH and an alkaline phosphatase respond specifically to heat shock. Thus, changes in extracellular pH and alkaline phosphatase described here are suggested to be involved in signalling of abiotic stress.

P0064. Gene expression detection in single trichome cells of plant leaves by direct RT-PCR amplification of mature mRNAs in response to external stimuli

T. Nonomura, Y. Matsuda, H. Toyoda;
Kinki University, Nara, Japan.

A single-cell RT-PCR was conducted to detect gene expression *in situ* in pinpointed trichome cells of tomato leaves. The cytoplasm was removed with the micropipette using a light microscope and directly used for RT-PCR, followed by nested PCR. Two intron-containing genes, glyceraldehydes 3-phosphate dehydrogenase gene and plasma membrane H^+-ATPas gene were constantly expressed in this tissues and therefore used as the indicator, because of easy detection of shorter-size PCR-products produced by splicing. In addition, the sucking of nucleus-free cellular contents was effective to prevent contamination of genomic DNA led to miss-amplification of corresponding genomic DNA sequences of the intron-less genes in the process of RT-PCR and subsequent nested PCR. Thus, the present technique could be applicable to single trichome cells of tomato leaves for directly detecting their gene expression in response to chemical and physical stimulation.

P0065. The effect of salinity and temperature on germination, growth, development and production of active substances in *Silybum marianum*

H. Kooshapur;
School of Pharmacy, Ahwaz, Islamic Republic of Iran.

Two types of *S. marianum* (German type and Ahwaz wild type) were studied in the field and laboratory. The laboratory experiments were carried out to determine the effect of seven levels of salinity (0.01, 1, 3, 6, 9, 12 and 15 dS/m) and three levels of temperature (15, 25 and 35 ºC) on germination characteristics. The field experiments were carried out to determine salt tolerance of six salinity levels (1, 3, 6, 9, 12 and 15 dS/m) on emergence, growth, development and production of active substances. The results indicated that, salinity affected germination and survival of seedlings at the mentioned temperatures. The optimum temperature for germination of both types was 15 ºC. Growth of seedlings was reduced significantly by salinity above 9 dS/m. Other growth parameters were significantly reduced compared to the control plants. Salinity levels had less effecte on vegetative growth of Ahwaz wild type. The wild type produced higher silymarin levels in all salinity treatments compared to the German type. The results also indicated that, during the growth, *S. marianum* could survive up to 15 dS/m salinity and produce seeds rich in active substances.

P0066. *flubber (flb)*, a new root hair mutant in *Arabidopsis thaliana*

A. M. Doran, M. W. Steer;
University College Dublin, Dublin, Ireland.

Understanding the genetic programme behind the development of a specific cell of an organism will allow us to ultimately manipulate and change the way in which an organism is formed. This project is concerned with understanding the genetic programme that controls root hair formation and development. We carried out a screen and identified a new true breeding mutant in *Arabidopsis thaliana* called *flubber.* The *flubber* (*flb*) mutant had abnormally short root hairs which showed branching along their length. *flb* plants also had smaller rosette diameters, shorter inflorescence stems, smaller siliques, increased numbers of trichomes and a reduced number of stomata. It is thought that the cell elongation process is affected in *flb* plants. A defect in polarity would account for the branching that is evident along the root hair. Crossing this mutant with other known root hair mutants established that the *FLB* gene acts during the main elongation phase of the root hair development. Mapping of the *FLB* gene is underway and subsequent characterisation of gene products will allow the exact function of *FLB* to be determined.

P0067. Comparative and phylogenetic analyses of the microtubule-associated protein 65 (MAP65) family in plants

J. A. Torres Acosta, V. Wagner, M. T. Hauser;
BOKU, Institute of Applied Genetics and Cell Biology, Vienna, Austria.

Recently, we have shown that the Arabidopsis PLE/MAP65-3 protein binds to microtubules (MTs) and is important for the proper organization of the phragmoplast. Mutated ple alleles fail to execute cytokinesis in a root specific manner. In addition it has been shown that related proteins from yeast, fruitfly, C. elegans and human - ASE1, FEO, SPD-1 and PRC1, respectively - have similar functions. PLE/MAP65-3 belongs to a gene family of nine members in Arabidopsis. Detailed analyses of the gene and protein structure of all the Arabidopsis MAP65s will be presented. Phylogenetic analyses including related proteins of other plants and kingdoms revealed a structuring of the MAP65 family into five subclasses.

Transcript profiles of the nine Arabidopsis MAP65 genes were analyzed by real-time RT-PCR at different developmental stages and in diverse plant organs and compared with whole genome microarray data. To functionally characterize the MAP65 family we started a reversed genetic approach and the phenotypes of the identified knock-outs alleles of six members and their double mutants will be presented.

Supported by the Austrian Science Fund (FWF P16410-B12)

P0068. Characterization of HYADE, an Arabidopsis gene involved in cytokinesis

V. Winter[1], S. Müller[2], M. Hauser[1];
[1]Institute of Applied Genetics and Cell Biology, Vienna, Austria, [2]Department of Cell and Developmental Biology, UCSD – University of California San Diego, San Diego, CA, United States.

Cytokinesis is the final step during cell division. Plant cells, in contrast to animal cells, divide their cytoplasm by constructing a new wall between daughter nuclei. This partition is achieved by phragmoplast guided transport of secretory vesicles carrying cell wall and membrane components towards the plane of cell division. Upon fusion of these vesicles a cell plate is formed which grows centrifugally towards the site at the plasma membrane, that was previously occupied by the preprophase band (PPB).

We have isolated an Arabidopsis mutant, hyade, that exhibits root specific cytokinesis defects such as irregularly expanded cells, partially formed transverse cell walls and multiple nuclei. During cell division, these multinucleated cells divide synchronously and influence the position of microtubule arrays including PPB, the mitotic spindle and the phragmoplast. Here we present the cloning and molecular characterization of the HYADE gene and present evidence for the involvement of the endosomal sorting complexes required for transport (ESCRT) during cytokinesis.

P0069. Dynamics of cytokinin composition in the leaves of winter wheat under high temperature

Y. A. Sadovnychenko[1], L. A. Krasilnikova[2];
[1]National University of Pharmacy, Kharkiv, Ukraine, [2]V.N. Karazin Kharkiv National University, Kharkiv, Ukraine.

Cytokinins is one of the most mobile classes of plant growth regulators under stress conditions, although they have unique role in plant metabolism and control processes of protein synthesis and cell division. There are some assumptions about the fast decrease after stress beginning and their later decrease. Thus in our research we has been investigated the dynamics of cytokinins (zeatin and zeatin riboside) in the leaves of two cultivars of winter wheat under high temperature stress.

It has been shown that under optimal temperature conditions (22-24°C) cytokinin content something varied, but under high temperature (38-40°C) these oscillations have been more sufficient: zeatin content rised in the first 30 minutes of exposition under high temperature and later something restored. Zeatin riboside dynamics had another character - it was increased after the start of stress and decreased in the second half of hour. Probably the pool of zeatin riboside is the reserve for zeatin in leaves but this reserve is not enough for the compensation of concentration of physiological active forma of cytokinins.

P0070. Structures parameters and contents abscisic acid in Persicaria amphibia (L.). Delarbre in different ecological conditions of growth

I. Gumenyuk, V. Generalova, L. Musatenko;
Institute of Botany named after M.G. Holodniy, Kyiv, Ukraine.

In modern science there are few investigations in hormonal control of growth and development of plants which can grow for a long time in natural adverse conditions. That is why we have studied adaptive reactions of Persicaria amphibia (L) Delarbre by the example of comparative analysis structures parameter of aquatic and ground forms of a plant adapted to various moisture conditions and changes of the contents of an abscisin acid (ABA) at vegetative and reproductive organs. We took sprout height, quantity of intermodes and leaves on a sprout, size of inflorescence and leaves, mass of wet and dry sprouts as data of our studying.

We discovered that in conditions of temperate moisture deficit there was higher percentage of ABA implants, smaller leaves and sprouts, lower data of wet and dry sprout mass. We consider all these factors to be adaptive reactions to the change of moisture conditions.

In our further study we plan to investigate peculiarities of Persicaria amphibia (L) Delarbre phytohormone complex during ontogenesis in different ecological conditions.

P0071. Role for aldehyde oxidases in the biosynthesis of indole-3-acetic acid and abscisic acid in *Zea mays*

Y. Cho[1], V. Kriechbaumer[2], Y. Lee[1], E. Glawischnig[2], A. Gierl[2], W. Park[1];
[1]Department of Molecular Biology/ Institute of Nanosensor and Biotechnology, Seoul, Republic of Korea, [2]Lehrstuhl fuer Genetik, Technische Universitaet Muenchen, Muenchen, Germany.

Aldehyde oxidase (EC 1.2.3.1) activities in the protein extracts from several tissues of maize (*Zea mays*) were detected by native PAGE and activity staining. The aldehyde oxidase signals were observed as triple bands, following general patterns that have been reported in many other plants, in maize kernels and young seedlings with slightly different tissue specificities. Among the many tissues, we concentrated on the aldehyde oxidase activities in the tip of primary roots where the aldehyde oxidase activities were clear. Efforts not only to measure the activities, but also to examine the gene expression were made. The major role for the enzyme has been known in abscisic acid biosynthesis in *Arabidopsis.* However, in maize the function of the enzymes is not yet definitely verified. Therefore, we discuss the possible correlations between the aldehyde oxidase activities and indole-3-acetic acid/abscisic acid biosynthesis in maize.

P0072. Phytohormones are involved in the pollen-pistil interactions during progamic phase of fertilisation in petunia

L. V. Kovaleva, E. V. Zakharova, G. V. Timofeeva, A. A. Dobrovolskaya, V. Y. Rakitin;
Institute of Plant Physiology RAS, Moscow, Russian Federation.

The data obtained provide evidence for the involvement of ethylene (and ACC and two key enzymes in ethylene biosynthetic pathway, ACC synthase and ACC oxidase) together with other phytohormones (IAA, ABA, GA and cytokinins) in pollen-pistil interactions, controling uninterrupted pollen tube growth after self-compatible pollination or its inhibition after self-incompatible pollination. Endogenous levels of the above hormones in pistils, and their parts (stigmas, styles and ovaries) and growing *in vitro* pollen tubes were determined by HPLC. Ethylene production by pistil tissues was estimated by GC. The ethylene/ABA status of the stigma may be proposed to control the processes of adhesion, hydration, and germination of pollen grains, whereas the auxin/cytokinin status of the style may be involved in the control of pollen tube growth. Sharp differences in the ABA levels in stigma and cytokinin levels in style most likely reflect different abilities of pollen tubes to grow following compatible and incompatible pollination. These data suggest that ethylene, ABA and cytokinins appear to be implicated in RNAse -based gametophytic self-incompatibility.

P0073. Characterizing cytokinin oxidase (CKX) throughout the development of R50, a pea mutant accumulating cytokinins

M. A. Held[1], **F. C. Guinel**[2];
[1]University of Waterloo, Waterloo, ON, Canada, [2]Wilfrid Laurier University, Waterloo, ON, Canada.

Cytokinins (CK) are an adenine-based family of hormones, the content of which is regulated by cytokinin oxidase (CKX). The pea mutant R50 (*sym-16*) displays several traits indicative of increased CK content. This accumulation was recently confirmed by LC-MS-MS and may be a result of either reduced activity or expression of CKX. Biochemical activity was detected through development of R50 and wildtype (WT) by a colorimetric assay (Liberos-Minotta and Tipton, 1995). Activity in mature, dry and imbibed seeds of R50 was low but comparable to that of the WT. In contrast, a significant decrease in CKX activity was noted in the roots and shoots of R50 seedlings and mature plants, which mirrored the previously obtained CK profile. Using two recently published ESTs (Vaseva-Gemisheva *et al.*, 2003), we have begun to analyze the *Pisum sativum* CKX (PsCKX) gene family. Protein alignment and Southern blotting indicate that the PsCKX gene family is similar to those of *Arabidopsis* and maize in that it is a multi-gene family containing a conserved FAD-binding domain. The CKX expression profile throughout development is now being pursued to complement the biochemical data.

P0074. Cytokinins in tobacco chloroplasts

I. Machackova[1], L. Polanská[1,2], J. Malbeck[1], A. Travnickova[1], R. Vankova[1];
[1]Institute of Experimental Botany, Praha 6, Czech Republic, [2]Dept. Plant Physiology, Faculty of Science, Charles University, Praha, Czech Republic.

Cytokinins (CKs) are plant hormones, which have a very close relationship to chloroplasts. We have reported the occurrence of a whole spectrum of cytokinins and cytokinin oxidase in tobacco and wheat chloroplasts (Benková et al.: Plant Physiol. 121, 245-251, 1999). Further we analysed CK levels by LC-MS in chloroplasts of transgenic plants with an altered CK metabolism (carrying an isopentenyltransferase P*ssu-ipt*, a zeatin-*O*-glucosyltransferase *ZOG1,* a cytokinin oxidase *AtCKX3* or a β-glucosidase *Zm-p60.1* gene). The presence of the CK overproducing transgenes results in whole leaves in elevated levels of CK glucosides. But this increase was not found in isolated chloroplasts, which indicates that CK glucosides are accumulated outside chloroplasts, probably in vacuoles. The overexpression of CK catabolic *AtCKX3* gene decreased the CK content in chloroplasts. Chloroplasts isolated from plants overexpressing gene *Zm-p60.1* quickly cleaved added ZOG and thus affected the equilibrium between free and conjugated CKs.

Acknowledgement: Supported by the grants LN00A081 and GACR 206/03/0369.

P0075. Growth Regulatory Activity of Parthenin as a Function of Time and Concentration

S. Kaur[1], R. K. Kohli[1], D. R. Batish[1], H. P. Singh[1], D. B. Saxena[2];
[1]Panjab University, Chandigarh, Chandigarh, India, [2]Indian Agricultural Research Institute, New Delhi, India.

Parthenin, a sesquiterpene lactone, is a natural constituent of *Parthenium hysterophorus*. Since sesquiterpene lactones, in general, possess growth regulatory activity, a study was planned to explore this property in parthenin. Effect of parthenin (25 to 500 µM) was assessed on the morphogenetic response of mung bean hypocotyls cuttings as a function of time period exposure (up to 96-h). Number of roots per hypocotyl cutting of mungbean increased significantly compared to control when treated with lower concentrations of parthenin (25 and 50 µM) for lesser time. Even the length of roots was more compared to control. However, at higher concentration of parthenin (100 µM or more) number of roots per hypocotyl cutting either decreased or remained same depending upon the time of exposure and parthenin concentration. At 500 µM parthenin, a severe toxicity (the cuttings turned brown and were completely wilted) on the hypocotyls cuttings was observed even if exposed for a short time of 1h. Based on the study, it is concluded that parthenin exerts a growth regulatory response that is not only dependent upon concentration but also on time of exposure.

P0076. Quantification of endogenous ABA levels in normal and water-stressed *Nicotiana tabacum* L. leaves

V. Hradecká, A. PƱnļ ík, O. Novák, L. Havlíļ ek, M. Strnad;
Laboratory of Growth Regulators, Palacký University, Institute of Experimental botany ASCR, Olomouc, Czech Republic.

Immunoassay for abscisic acid (ABA) has been confirmed as the most sensitive and selective detection method for ABA. We have raised polyclonal antibodies (pAbs) specific against C1-immobilised (+)-*ct*-ABA conjugated to bovine serum albumin according to Weiler (1980). The pAbs isolated from rabbit serum by ammonium sulfate precipitation were characterised by ELISA and the affinity purified antibodies (ABA-1, ABA-2) were used for development of immunoaffinity chromatography. The polyclonal antibodies reacted preferentially with the (+)-*ct*- ABAmethylester and relatively well with (+/-)-*ct*-ABA glucosylester,(+/-)-*ct*-ABAmethyl ester. (+/-)-*ct*-ABA alcohol, (+/-)-*ct*-ABA aldehyd, (+/-)-*ct*-ABA, (+)-*ct*-ABA were also strongly reactive. Cross-reactivity with other coumpounds was negligible. The LC-ESI-MS and HPLC-ELISA have been used for comparative estimation of endogenous levels in immunoaffinity purified extracts of normal and water-stressed *Nicotiana tabacum* L. leaves.

P0077. Characterization of a plant chromatin-remodelling complex involved in auxin and cytokinin signalling

J. C. Moulinier Anzola, A. E. Muellner, T. Sieberer, C. Luschnig;
IAGZ, Vienna, Austria.

Growth and development are extensively studied phenomena in multicelullar organisms, and depend on the coordinated interplay between cell cycle progression, cell cycle exit and the onset of differentiation programs. In plants, the phytohormones auxin and cytokinin play central roles in the regulation of cell division and differentiation. Recent work in our laboratory demonstrated that the impact of both growth regulators on cellular identity, involves components of a chromatin-remodeling complex. Specifically, PROPORZ1 (PRZ1), a putative transcriptional adaptor protein, was shown to affect spatial and temporal expression of cell cycle regulators in response to variations of phytohormone concentrations. Progress in the characterization of the regulatory impact of PRZ1 on cell cycle regulator transcription and in the identification of additional components of the PROPORZ chromatin-remodelling complex will be presented.

P0078. Auxin plays a key role as intercellular signal in embryo development of European larch (Larix decidua Mill.)

J. Thiel[1], A. Müller[2], K. Zoglauer[1];
[1]Humboldt-University, Institute of Biology, Botany, 10115 Berlin, Germany, [2]Ruhr-University Bochum, Institute of Plant Physiology, 44801 Bochum, Germany.

Somatic embryogenesis provides the opportunity to study embryo development from early to mature stages in the absence of maternal factors. Auxin transport inhibitors or -antagonists added to the culture medium caused alterations of the embryo phenotype correlating with investigations of excised zygotic and somatic embryos of angiosperm species. Similar morphological effects have been provoked by conjugating free IAA (35S::IAAL). The GH3 promoter has been shown to be auxin-inducible in L. decidua embryos and was used to visualize auxin distribution. An expression of the GH3::GUS gene was first detected in the late globular stage in the columnella cells and precursors. Exogenous auxin induced a heterogenous expression pattern which changed during embryo development. GC-MS analysis of IAA levels showed a strong increase of IAA concentration during the transition stage from globular to bilateral symmetry which decreased later to the basal level of the earlier stages. The results indicate that specific patterns of auxin distribution combined with an increase of IAA levels during the transition stage might be a prerequisite for establishing the embryo axis.

P0079. The effect of kinetin on the level of polyamines bound to thylakoidal membranes and activity of thylakoidal transglutaminase during the chloroplast differentation in cucumber cotyledons

J. Legocka[1], E. Sobieszczuk-Nowicka[1], A. Di Sandro[2], D. Serafini-Fracassini[2];
[1]Adam Mickiewicz University, Faculty of Biology, Department of Plant Physiology, Poznan, Poland, [2]Dipartimento di Biologia e.s, Università degli Studi di Bologna, Bologna, Italy.

In the early phases of chloroplast differentiation under light-condition, the content of putrescine (PU) and spermidine (SD) bound to plastid membranes was enhanced by kinetin treatment; conversely, the content of spermine (SM) was not affected. At 6h kinetin enhanced by 60% the SD level in comparison to the control. At 24h of light exposure, which represents the completion of the differentiated structure of cytokinin-induced chloroplasts in cucumber cotyledons, the PAs binding to plastid membranes decreased.

It was verified that the binding was at least in part due to a transglutaminase (TGase) conjugation. Spermidine was conjugated to thylakoidal membranes with higher efficiency than PU. The kinetin pre-treatment enhanced the SD conjugation in the early phases of thylakoid differentiation. The net decrease of TGase activity at 24h of experiment was correlated with the decrease in the content of PAs bound to the thylakoids.

The novelty of the present research is the finding that PAs, at least in part are covalently linked by a TGase activity stimulated by cytokinins during the early phases of chloroplast photodevelopment.

P0080. Effect of culture media and phytohormons on organogenesis and proliferation of the shoots in Codiaeum aucobifolium

G. Barzin, M. Ghorbanli;
Azad Islamic University, Tehran, Islamic Republic of Iran.

The ongoing way of multiplication in Codiaeum aucobifolium is cutting of the leafy stems, which is not completely successful and it could increase the number of infected plants. Therefore, we used plant tissue culture for proliferation. First, the explants of leaves and internodes were cultured on 2, 4-D (1mg/lit) supplemented media including: MS, An, and MC. The An medium was the best in regard to the production of big and fresh calli. Then, callogenesis was studied only in An by adding different concentrations of BAP (0, 0.5, 1, 2, and 4 mg/lit) with various dilutions of one of the auxins including: IAA, 2, 4-D or NAA. Callus induction was greatest in IAA (4mg/lit) + BAP (1mg/lit), NAA (2mg/lit) + BAP (1mg/lit) and 2, 4-D (1mg/lit) alone. To evaluate the organogenesis, the greenest cultured Calli were transported to the media supplemented by various concentrations of different cytokinins (2ip, BAP, Kin, and coconut milk) and above auxins. The most excellent organogenesis was seen in coconut milk (20%) + 2, 4-D (1mg/lit). The best combinations for elongation and proliferation of shoots were 2ip (1mg/lit) + IAA (0.5mg/lit) and IAA (2mg/lit) + BAP (1mg/lit) respectively.

P0081. Inflence of Photoperiod and Gibberellic acid(GA$_3$) on the growth and flowering of cowpea[*Vigna unguiculata*(L)WALP]

F. B. Mukhtar;
Department of Biological Sciences, Bayero University, Kano, Kano, Nigeria.

The effects of different levels of photoperiod P;h) and 50ppm gibberellic acid (GA$_3$) were studied on the vegetative growth, phenology and yield of a selected, unimproved but popular cowpea variety - Kanannado. The different photoperiods used were 10, <12.5, >12.5 and 14h. Greater growth was observed in the long day lengths (P > 12.5 and P = 14h) except for hypocotyl length and stem circumference. Flowering and pod maturity were enhanced under short photoperiods (P= 10 and P< 12.5h) while Yield was higher in the long photoperiods (P>12.5 and P=14h). The GA$_3$ treatment stimulated an increase in the growth of the cowpea, enhanced its flowering and pod maturity by 1- 5days and increased yield under all the photoperiods. This study indicates that as efforts are being made towards maximizing yield of this crop in the dry season (with irrigation) ,efforts should be made on increasing its vegetative growth. Foliar application of GA$_3$ appears promising and more work should be carried out to determine the optimum concentration of the hormone as well as explore the possibility of using other hormones and/or combined hormones.

P0082. Diversity in salicylic acid effects on growth criteria and different indole acetic acid forms among faba bean and maize

R. A. El-Mergawi, M. S. A. AbdelWahed;
National Research Center, Cairo, Egypt.

All SA doses (1-5 mM) tended to induce increases on faba bean growth criteria. After 30 days from treatment, there was a progressive increase in the fresh and dry weights of stem, leaves and whole plant as well as number and fresh weight of kernels by increasing SA level. Aapplication 3-5mM resulted in a remarkable reduction in maize growth . Free, ester, amide, bound and total IAA were determined by using HPLC. Free IAA in leaves of faba bean and maize plants reached about 31 and 14% of the total IAA, respectively. Spraying faba bean plants with SA tended to cause increases in free IAA and decreases in ester IAA, after 3 days from treatment. Values of free and ester IAA reached 113% and 44% of control by using SA at 4mM, respectively. As for maize, all SA doses caused decreases in free IAA and increases in ester IAA. SA did not induce a great consistent effect on amide-IAA and total IAA, while, changes in ester form were in opposite manner to changes in free IAA, in most cases, meaning that SA interfere with IAA-conjugation.

P0083. 6-Benzylaminopurines - an interesting cytokinin alternative for plant biotechnology and agriculture

K. Dolezal[1], L. Spichal[1], E. Hauserová[1], I. Popa[1], D. Tarkowská[1], D. Hradecká[2], M. Strnad[1];
[1]Laboratory of Growth Regulators, Olomouc, Czech Republic,
[2]Department of Crop Production,Czech University of Agriculture, Prague, Czech Republic.

Our search for naturally occurring aromatic cytokinins in plants using LC-MS methods led recently to the discovery of several new plant hormone substances - methoxybenzylaminopurines (Tarkowská et al., 2003). Subsequently, a group of their synthetic analogues has been prepared and characterized. Various aspects of their biological activity (cytokinin effect studied on molecular (receptor) level and *in-vitro* as well as in field experiments, anti-cancer properties etc.) have been investigated. To study these interesting compounds in more details, rapid and highly efficient method for their isolation from complex biological matrices, based on immunoaffinity chromatography, has also been developed.

Studied compounds are proposed to be new endogenously occurring members of the aromatic cytokinin subgroup, which might have specific physiological functions. Mechanism(s) of their anti-tumor ativity will be further studied using newly depeloped analytical methods.

We thank AS CR (IBS4055304) and GA CR (203/04/1168) for financial support.

P0084. The role of ABA and NO in the drought stress acclimatisation mechanisms of wheat genotypes

I. Tari, J. Csiszár, Á. Gallé, B. Bartha, F. Horváth, A. Pécsváradi, Á. Szepesi, D. Zeller, L. Erdei;
Department of Plant Physiology, University of Szeged, PO Box 654, Szeged, Hungary.

The biosynthesis of the plant stress hormone abscisic acid (ABA) is regulated not only by osmotic stress but also by the level of ABA itself. Two water stress tolerant wheat varieties (*Triticum aestivum* cv. Kobomugi and GK Öthalom) were exposed to 400 mOsm polyethylene glycol (PEG) and the changes in water potential, stomatal conductance, ABA level and aldehyde oxidase activity (AO, a key enzyme of ABA biosynthesis) was estimated. Water potential values decreased substantially in the leaves of GK Öthalom, and remained constant in cv. Kobomugi. We found a higher increase in ABA concentrations and AO activities in cv. Kobomugi than in cv. GK Öthalom plants. ABA induces stomatal closure by activating several different signal transduction pathways. Stomatal conductivity measurements suggested that guard cells responded sooner to osmotic stress in Kobomugi than in Öthalom. The level and the distribution of NO during the osmotic stress, determined by DAF-2 DA fluorescent probe staining showed different patterns in the two genotypes. Our results show that the two wheat lines possess different drought stress acclimatisation strategies.

P0085. Effect of ethylene on the seed germination of halophytes

M. A. Khan;
University of Karachi, Karachi, Pakistan.

Seeds of halophytes usually fail to germinate under unfavorable conditions, such as too high salinity but remain viable and germinate upon the removal of environmental constraints. In contrast many seeds are unable to germinate, or do so with difficulty, when placed under favorable conditions, and they are considered as dormant seeds. This dormancy could be due to inactive embryo, impermeable seed coat or imbalance in hormone concentration etc. Ethephon -an ethylene releasing compound- stimulates germination of dormant and non-dormant seeds, although in some case they inhibit or do not affect germination. Ethylene removes primary dormancy, secondary dormancy and light induced dormancy. Salinity, high temperature, and stress caused by osmoticum could be reduced by ethylene. Ethylene shows a differential affect in reducing the stress caused by salinity during germination of halophytes. Germination inhibition caused by salinity could be partially or completely alleviated by ethylene while in other ethylene may not have any effect or a negative effect on seed germination. Variation in halophyte seed germination response to ethylene will be discussed.

P0086. The flowering of *Dendrobium* isolated shoots: the effects of thidiazuron on the endogenous levels of cytokinins and IAA

W. M. Ferreira[1], G. B. Kerbauy[2], J. E. Kraus[3], R. Pescador[4], R. M. Suzuki[5];
[1]Federal University of Tocantins, Porto Nacional, Tocantins, Brazil, [2]University of São Paulo, São Paulo, Brazil, [3]University of São Paulo, São Paulo, Brazil, [4]Regional University of Blumenau, Blumenau, Santa Catarina, Brazil, [5]Botanical Institute of São Paulo, São Paulo, Brazil.

Flowering is a unique event in the developmental cycle of a plant. Different internal as well as environmental factors are known to participate in the various steps that lead to flower formation. This study reports the effects of TDZ on the endogenous levels of Z, [9R]Z, iP and [9R]iP as well as some structural changes in the apical meristem of *D.* Second Love shoots during flower induction and initial development *in vitro*. The obtained results revealed that the addition of 1.8 µM TDZ to the culture medium had a profound effect on the endogenous cytokinins and IAA levels of the explants, when compared to those grown on TDZ-free medium. A significant increase in total cytokinins (especially [9R]iP and [9R]Z) and IAA on the 5th day of culture on TDZ-enriched medium was associated with flower induction, and a second increase in the level of these hormones after 25 days of culture was related to flower development. The histological changes detected in the shoot apical meristem of explants grown in the presence of 1.8 µM TDZ during 30 days of culture are also described. Based on our findings, both auxin and cytokinins were involved with the floral transition of *D*. Second Love *in vitro*.

P0087. Quantification of free and total salicylic acid in plants by solid-phase extraction and isocratic high-performance anion-exchange chromatography

W. Rozhon[1], E. Petutschnig[1], M. Wrzaczek[1], C. Jonak[1,2];
[1]Max F. Perutz Laboratories, University of Vienna, 1030 Vienna, Austria, [2]Gregor Mendel Institute of Molecular Plant Biology, Austrian Academy of Science, 1030 Vienna, Austria.

Salicylic acid (SA) is an important plant hormone with a key role during plant resistance responses. The resistance mechanisms involving SA signalling include hypersensitive response, systemic acquired resistance, pathogen-related (PR) gene expression, oxidative burst, and programmed cell death. Furthermore, SA seems to induce resistance to viruses by inhibition of viral replication and systemic movement.

Despite its central role in plant defence the levels of SA remain often uncharacterised due to requirement of special equipment and the time consuming nature of current protocols for SA quantification. Here we describe a simple, novel method for reliable quantification of SA with a standard HPLC equipment that can be easily applied to different plant species by many laboratories. The techniques presented here combine several advantages including highly selective sample preparation, a novel, improved internal standard, a reduced analysis time and increased sensitivity. Thus, sample size can be scaled down compared to current HPLC methods - an invaluable benefit for applications with limited plant material.

P0088. Structures parameters and contents abscisic acid in Persicaria amphibia (L). Delarbre in different ecological conditions of growth

I. Gumenyuk, V. Generalova, L. Musatenko;
Institute of Botany named after M.G. Holodniy National Academy of Sciences of Ukraine, Kyiv, Ukraine.

In modern science there are few investigations in hormonal control of growth and development of plants which can grow for a long time in natural adverse conditions. That is why we have studied adaptive reactions of Persicaria amphibia (L) Delarbre by the example of comparative analysis structures parameter of aquatic and ground forms of a plant adapted to various moisture conditions and changes of the contents of an abscisin acid (ABA) at vegetative and reproductive organs. We took sprout height, quantity of intermodes and leaves on a sprout, size of inflorescence and leaves, mass of wet and dry sprouts as data of our studying.

We discovered that in conditions of temperate moisture deficit there was higher percentage of ABA implants, smaller leaves and sprouts, lower data of wet and dry sprout mass. We consider all these factors to be adaptive reactions to the change of moisture conditions.

In our further study we plan to investigate peculiarities of Persicaria amphibia (L) Delarbre phytohormone complex during ontogenesis in different ecological conditions.

P0089. Glycoproteins from sugarcane cv. Ja 60-5 regulate cell polarity of *Ustilago scitaminea* teliospores as a defence mechanism.

A. M. Millanes, C. Vicente, M. E. Legaz;
Complutense University, Madrid, Spain.

Saccharum officinarum, cv. Ja 60-5 is a variety of sugarcane with a moderate susceptibility to smut disease caused by *Ustilago scitaminea* . Sugarcane produces glycoproteins that accumulate in the parenchymatous cells of stalks and that have been described as factors of resistance to smut. Glycoproteins obtained from a resistant cultivar of sugarcane show inhibitory effect on processes related to viability and development of the pathogen such as teliospore polarization and germination and growth of the micellium. In this work we have studied the effect of glycoproteins obtained from a susceptible cultivar, on smut fungus. Smut teliospore aggregation is observed when glycoproteins of both healthy and inoculated plants are used. However, although the amount of glycoprotein is higher in inoculated plants, these glycoproteins show an ability to bind to the teliospore cell wall receptor and to inhibit cell polarization and germination lower than those obtained from healthy plants. So, smut development seems to be able to change the pattern of glycoprotein action, leading to a higher level of susceptibility in this variety of sugarcane.

P0090. Physiological response to inoculation of Cryptococcus laurentii in harvested peach fruit

X. Zheng, T. Yu;
Institute of Biosysterm Engineering and Food science, Hangzhou, China.

We examined the effect *Cryptococcus Laurentii* and/or challenge by *Penicillium expansum* induced of harvested peach fruit on changes in the ethylene productions, the activities of superoxide dismutase (SOD), catalase (CAT), peroxidases (POD), phenylalanine ammonialyase (PAL), the polyphenol oxidase (PPO), and the contents of malondialdehyde (MDA). The results showed that *C. laurentii*-treated significantly reduced the decay and inhibited the ethylene production, and the activities of SOD, CAT and PAL, enhanced the activities of POD and PPO, and MDA contents compared with wound control fruits. Compared with infected by *P. expansum only*, pre-inoculated with *C. laurentii* and challenged by *P. expansum* inhibited the activities of PPO and POD and slightly inhibited the ethylene production (day 3), maintained relatively higher lever of SOD activity, and induced a rapid and great increase in PAL activity in wound inoculated fruits. At the increasing distances (at +45-and +90mm), the higher activities of SOD, PAL, and PPO, and the MDA contents were observed compared to that at +2mm from *C. laurentii*-inoculated site.

P0091. Avaliation of pathogenesis isolated from *lasiodiplodia theobromae* in carica fruit (*carica papaya*) and activity agaisnt actinomycetes in the control of lasiodiplodiose

R. M. Silva[1], N. T. Oliveira[2], A. Chiappeta[2], K. Sena[2];
[1]UFRPE, Recife, Brazil, [2]UFPE, Recife, Brazil.

Pathogenesis of *L. theobromae* was evaluated to the papaya, and the activity, *in vitro* and *in vivo*, of actinomycetes against *L. theobromae*. The pathogenesis of *L. theobromae* was tested with seven isolated of different hosts. Of the seven isolated tested, two (URM-3184 and URM-2704) were the more pathogenics. Of the 40 tested actinomycetes, 17 went assets.The best times of fermentation was 72, in medium ISP-2. The result of the test of unit of Waksman showed that the active substance is contained predominantly in the cell mass. The ethanol in pH 7, as the best solvent extractor of the same. Three experiments i*n vivo* were accomplished; for each experiment three treatments were accomplished (preventive, curative and simultaneous), with three repetitions each. Isolated URM-2704 was more sensitive than URM-3184, to the antagonistic effect of the actinomiceto DAUFPE-11470. The experiment 2, presented total protection until, for isolated URM-2704 in the preventive treatment.

P0092. Sources of the free radical nitric oxide during Arabidopsis thaliana-Pseudomonas syringae interaction

I. Salgado[1], L. V. Modolo[2], O. Augusto[3], J. R. Magalhaes[4];
[1]Universidade Estadual de Campinas, Campinas,SP, Brazil,
[2]Universidade Estadual de Campinas, Campinas, Brazil, [3]Universidade de São Paulo, São Paulo,SP, Brazil, [4]Empresa Brasileira de Pesquisa Agropecuária, Juiz de Fora, MG, Brazil.

Despite the many processes controlled or induced by nitric oxide (NO) in plants, the molecular mechanisms responsible for the synthesis of this radical remain controversial and a NO synthase (NOS)-like enzyme and nitrate reductase (NR) are claimed as potential sources. Here, we used wild-type and double mutant plants deficient in the NR enzyme to investigate NO production in *A. thaliana* in response to *P. syringae* pv. *maculicola* (Psm). Production of citrulline from arginine following the inoculation of Psm was increased in *A. thaliana* leaves from wild-type and NR-deficient plants. EPR experiments showed a much higher NO production, in both genotypes, that was dependent on nitrite rather than on arginine or nitrate. Electron transport by the mitochondrial respiratory chain was essential for this NR-independent NO production. *In situ* NO production was substantially increased in wild-type plants but not in mutant, following a challenge with Psm, as measured with the fluorescent indicator DAF-2DA. Concluding, NOS, NR and a mitochondrial-dependent nitrite-reducing activity are involved in producing NO for *A. thaliana* defense against *P. syringae*.

P0093. First Report of Pathogenicity of Binucleate Rhizoctonia spp. Causing Corm and Stem Rot of Gladiolus

M. J. Soleimani;
Bu-Ali Sina University, Hamadan, Islamic Republic of Iran.

Fungi with Rhizoctonia-like mycelia were isolated from root and stem of Gladiolus (Gladiolus hybrida L.) grown in commercial glasshouse in Mahallat, Iran, during the summer and fall of 2003. On the basis of hyphal characteristics and nuclear number, twenty-three isolates of *Rhizoctonia* spp. were obtained from infected corms and stems. Of the 23 isolate, 9 had binucleate and 14 had multinucleate vegetative hyphal cells. Representative isolates of binucleate *Rhizoctonia* spp. were characterized for anastomosis, optimum temperature in vitro, and virulence on gladiolus. Isolates of binucleate *Rhizoctonia* failed to anastomose with tester isolates of anastomosis groups (AG)-A through -S (not including AG-J and AG-M). Growth rate of binucleate *Rhizoctonia* spp. was more rapid than *R. solani*. Five isolates from each group caused severe corm rot and mortality of plant during rooting. This is the first detailed report of corm and stem rot disease of gladiolus caused by binucleate *Rhizoctonia.* Further field studies are needed on the ecology of *Rhizoctonia* spp. to formulate steps for controlling the disease.

P0094. Analysis of salicylic acid - inducible protein-DNA interaction using chromatin immunoprecipitation in tobacco leaves

T. Butterbrodt, C. Thurow, C. Gatz;
Albrecht-von-Haller-Institute for Plant Sciences, Goettingen, Germany.

The as-1 element, originally found in the Cauliflower Mosaic virus, is inducible by salicylic acid, auxin and also by pathogen attack. Several as-1 like elements were found in plant promoters of pathogen defense genes like the “early” response gene Nt103 (a glutathione-S-transferase) or the “late” response gene PR1a encoding pathogenesis related protein 1a.

Binding studies with tobacco nuclear extracts using EMSA revealed recognition of the as-1 element by TGA factors TGA2.1 and TGA2.2, members of the bZIP transcription factor family.

To investigate the in vivo interaction between TGA factors and as-1 like promoter elements we have developed a chromatin immunoprecipitation assay (ChIP) for tobacco leaves. Establishment of the technique was validated using the tetracyclin (Tc) - inducible expression system in tobacco plants allowing successful analysis of two different conditions (+ / - Tc).

ChIP experiments with transgenic tobacco plants carrying the reporter construct as-1:GUS showed a constitutive binding of TGA2.2 to the native as-1 element and inducible binding to the as-1 like element of the PR1a promoter by SA treatment.

P0095. Assessment of root-organ cultures to study the mycorrhizal phenotype of pea nodulation mutants.

F. C. Guinel, L. D. Martin, E. Peebles, R. Mehta;
Wilfred Laurier University, Waterloo, ON, Canada.

Our lab is interested in studying the mycorrhizal (myc) phenotype of a number of pea nodulation mutants using root-organ cultures. To assess this technique, we used the mutant E107 known to accumulate Fe in its shoots, exhibit a low nodulation phenotype, and display a low myc phenotype when associated with *Glomus aggregatum* in the soil. Roots were used either as a root-organ culture or as a chimera (roots transformed / shoots non transformed). Whereas the primary root was cut before *Agrobacterium rhizogenes* was applied for the former, it was pricked with a needle for the latter. Once transformed, roots were transferred to Phytagel® medium, and hyphal plugs with *Glomus intraradices* spores were placed next to them. Spore germination and infection were followed with light microscopy. Interestingly, E107 forms numerous mycorrhizae in root-organ cultures. However, the limits of the cultures will be ascertained only when the chimera’s roots are examined. Indeed, the myc$^+$ phenotype of E107 root-organ cultures could be explained either by the excision of the shoot (removing either the accumulated Fe or a potential shoot inhibitor), or by a more competitive fungus.

P0096. Molecular and biochemical studies to elucidate fireblight (*Erwinia amylovora*) resistance in apple (*Malus* spp.)

R. Milcevicova[1], M. Berenyi[1], T. Fischer[2], V. Hanke[3], H. Halbwirth[4], K. Stich[4], E. Wilhelm[1];
[1]ARC Seibersdorf Research GmbH, Biogenetics and Natural Resources, Biotechnology, A- 2444Seibersdorf,, Seibersdorf, Austria,
[2]Technical University, Munich, Germany, [3]BAZ, Fruit Tree Breeding, Dresden, Pillnitz, Germany, [4]Technical University, Vienna, Austria.

Erwinia amylovora, the causal agent of the necrotic disease fireblight infects most members of the Pomoideae such as pear and apple. Differentially expressed genes (isolated via cDNA-SSH) of fireblight resistant and susceptible apple are screened to characterize genes involved in pathogenesis and resistance to fireblight. In addition isoflavonoids are important phytoalexins and have been shown to play a role in disease resistance. The gene expression patterns of phenylalanin ammonialyase (PAL), chalcon synthetase (CHS), dihydroflavonol reductase (DFR), flavanone 3-hydroxylase (FHT) of moderate resistant cv. Rebella and Reka were compared with the susceptible cv. Idared and with the resistant species *Malus robusta*. The temporal and spatial expression patterns of PAL, CHS, FHT, and DFR were investigated via in situ hybridisation, in situ PCR and real time PCR. The results show increased transcription of CHS and PAL in *M. robusta* corresponding also with high enzyme activities.

P0097. The composition and function of xylem sap proteins (XSP) during weeping period of the grape *Vitis vinifera* L.

I. A. Dascaliuc[1], V. G. Artenie[2];
[1]M. G. Kholodny Institute of Botany, National Academy of Science, Kyiv, Ukraine, [2]Al. I. Cuza University, Iasi, Romania.

At the beginning of plants vegetation, xylem sap contains organic compounds that might be involved in root-to-shoot communication. To clarify the physiological functions of proteins in xylem sap, we studied the composition and biochemical activity of XSP of *V. vinifera* during its weeping period. SDS-PAGE showed at least 40 visible protein bands in a molecular mass range from 10 to 100 kD, whereas 2DE revealed more than 200 XSP. The spectrums of XSP from different *V. vinifera* varieties during tree years of analysis were qualitatively constant and quantitatively different. This suggests that XSP are not the products of degradation. Most of XSP are likely to be involved in redox regulation and to defense against biotic and abiotic stimuli. In support of this assumption are results of enzyme assays, which showed that XSP of *V. vinifera* have well delineated protease, Ŭ- amylase, and peroxidase activities. We also found that the part of XSP are lectins, which specifically bind D-glucose and D-galactose. It is known that lectins are implicated in cell recognition and their being in xylem sap is the strong argument supporting the signaling functions of XSP.

P0098. Gene expression of IAA-amidohydrolases from Brassica rapa during clubroot disease

A. Schuller, J. Ludwig-Müller;
Institut für Botanik, Dresden, Germany.

Clubroot disease is caused by the obligate biotroph organism Plasmodiophora brassicae, who infects roots of all members of the Brassicaceae. The infected root show abnormal cell enlargement and cell proliferation, correlated with an increase in IAA. One source of free IAA is the release from conjugates with amino acids, catalyzed by IAA-amidohydrolases. We isolated cDNA fragments with homology to IAR3, ILL2, ILL6, ILL3 and ILR1 out of different tissues from Brassica rapa and full length cDNAs from the following amidohydrolases like genes: IAR3, were we found 2 different clones varying in the 5'-region of the genes, ILL2 and ILL6 which is placed in a separate group in the dendrogram of the IAA-amidohydrolases. Expression studies of the corresponding genes in infected and uninfected roots using Real Time RT-PCR revealed a differentially and very stage specific regulation. Heterologous expression studies in E. coli revealed first results for the in-vitro enzyme activity.

P0099. Pathogenesis-Related protein -1 Transcript Expression in Response to Salicylic acid in Potato

L. Faravardeh[1,2], A. Rabbani[1];
[1]Institute of Biochemistry and Biophysics,University of Tehran, Tehran, Islamic Republic of Iran, [2]Agricultural Biotechnology Research Institute of Iran, Karaj, Islamic Republic of Iran.

Pathogenesis-Related proteins (PR) are defense proteins that express during pathogen attack. The effect of Salicylic Acid (SA), an important signal molecule in plant defense, was investigated on PR-1 transcript expression in potato. Potato leaves were treated with 1mM, 2.5mM and 5mM of SA. There was a little PR-1 transcript expression in the controls from 3 to 48 hours and PR-1 transcripts accumulated after 6 hours of treatments only at 2.5mM of SA and after 12 hours at 1mM of SA. Similar levels of PR transcripts accumulation were observed at 1 mM and 5 mM of Salicylic Acid from 24 to 48 hours. Electrophoresis of extracted DNA from the controls and treated ones showed no fragmentation after 24 hours, but some similar smears were appeared in the treated leaves in comparison to the controls. It seems that basal expression of PR-1 may contribute to make potato leaves resistance to DNA fragmentation after 48 hours in the controls. The data indicate that 2.5 mM of Salicylic Acid is critical concentration in inducing PR-1 expression in potato leaves. Therefore, PR-1 might be a signaling protein that makes cells more resistance to some stresses in Salicylic Acid - dependent pathway.

P0100. Tobacco bZIP transcription factor TGA2.2 and related factor TGA2.1 have distinct roles in plant defense responses and plant development

C. Thurow, S. Krawczyk, T. Butterbrodt, C. Gatz;
Albrecht-von-Haller-Institut fuer Pflanzenwissenschaften, 37073 Goettingen, Germany.

Salicylic acid (SA) plays a crucial role as signaling molecule in plant defense reactions. TGA transcription factors bind to *activating sequence-1 (as-1)*- like elements, SA-responsive *cis* elements found in promoters of "immediate early" and "late" SA-inducible genes. Our earlier work has shown that the main component of tobacco *as-1*-binding complex ASF-1 is TGA2.2. TGA2.1, which differs from TGA2.2 by being able to activate transcription in yeast, constitutes a smaller fraction of the complex. Both TGA factors interact with NPR1, a protein essential for SA-inducibility of "late" genes. By using dsRNAi mediated gene silencing we demonstrate that reduced amounts of TGA2.2 lead to less ASF-1 activity and to decreased inducibility of "immediate early" and "late" genes. In contrast, reducing the amount of TGA2.1 had no effect on the expression of the analysed genes. TGA2.1 dsRNAi plants developed sepal like stamens indicating a regulatory role in defining organ identity in tobacco flowers.

P0101. Endopolygalacturonase from a saprophytic fungus releases elicitors of phytoalexin response from plant pectin

M. Marques[1], M. S. Buckeridge[2], M. R. Braga[2], **S. M. C. Dietrich**[2];
[1]Universidade Federal do Mato Grosso do Sul, Mato Grosso do Sul - MS, Brazil, [2]Instituto de Botânica, São Paulo - SP, Brazil.

We investigated the capacity of a saprophytic fungus, *Mucor ramosissimus*, to synthesise endopolygalacturonases (EndoPGs) capable of degrading cell wall pectins from *Palicourea marcgravii*, a tropical forest native Rubiaceae where the spores of the fungus have been found. The capacity of products of hydrolysis of pectin by this enzyme to elicit defence response in soybean and in other Rubiaceae species was also analysed. The fungus is capable of releasing pectinases to the culture medium when pectin is supplied as carbon source. The enzyme, purified by ion exchange chromatography and preparative isoelectric focusing presents pI 9.8 and optimal activity at pH 5.0 at 30 °C. The products of hydrolysis of different pectic substrates by the action of this endoPG elicit in different extents the phytoalexin production in soybean cotyledons and in the leaves of *P. marcgravii*. These results suggest that, besides the role in recycling organic matter, saprophytic fungi can also play an important role in the induction of defensive mechanisms in plants growing under natural environmental conditions by enhancing their unspecific resistance against pathogens.

P0102. Use of 3TAC (Trichodermas)in the clean tobacco growing.

M. S. Reyes;
AVance Biotechnologies, Chile, Conchali, Santiago, Chile.

3TAC, is a biotechnological product, based on live trichodermas in all of its development stages, with its water soluble metabolites, powder, 100% organic made in Chile by Avance.
Tobacco growing problems: it is developedin a water environment, what favours the growth of fusarium, phytium, and a fungus complex that causes damping off. To do this cultivation it is necessary to apply chemical fungicides. The restrictions to the traceability and the need of having cleaner cultivations, made easer to use the 3 TAC on 3000 trays during season 2003-2004. Result: 3 applications of 3 TAC to the cultivation (peat, pre forst cut and second cut) replace 9 applications of chemical fungicides. There was a total control of pathogens, a greater % of germination and of spelling strenght.The release of auxine pulses from 3 TAC to the plants allowed a fast cicatrization after the pruning and a null development of pathogens, in comparison to little plants treated with traditional chemicals .

P0103. Influence of catenarin on cell cycle of wheat and triticale root tissue

W. WakuliŒski[1], E. śliwiŒska[2], P. Kachlicki[3], B. Ğotocka[4];
[1]Department of Plant Pathology, Warsaw Agricultural University, Warsaw, Poland, [2]Department of Genetics and Plant Breeding, Agricultural University, Bydgoszcz, Poland, [3]Institute of Plant Genetics, Polish Academy of Sciences, PoznaŒ, Poland, [4]Department of Botany, Warsaw Agricultural University, Warsaw, Poland.

Catenarin (1,3,5,8-tetrahydroxy-6-methyl-anthraquinone) was found as major compound among anthraqinone derivatives produced by Pyrenophora tritici-repentis (Died.) Drechsler. Ability to biosynthesis of this metabolite is strain depended, and varied from traces up to 400 ppm. P.tritici-repentis is world - wide distributed polyphagous fungus recognized on numerous Poaceae and responsible for tan spot of wheat and triticale. It is mostly a leaf pathogen but it is also seed transmitted and can infect cereal roots. In performed studies influence of catenarin on cell cycle of wheat and triticale root tissues was tested. After 48 hours of treatment the metabolite at 5 and 50 ppm arrested cell division. In case of the both mentioned cereals, cell accumulation at the G2 phase was observed . Root tip squashes showed fewer mitotic index in treated than in catenarin untreated plants. No effect was observed after 24 h exposure time.

P0104. Effect of non-nodulating soybean seed lectin on nodulation of soybean plants by Bradyrhizobium japonicum

N. Melnykova, S. Omelchuk, P. Mamenko, L. Mykhalkiv;
Institute of Plant Physiology and Genetics of NASU, Kyiv, Ukraine.

As a result of germination the non-nodulating soybean seeds released haemagglutinating protein (lectin) in environment. The non-nodulating soybean seeds lectin was extracted and purified. Pretreatment of Bradyrhizobium japonicum 634b with either 10^6 or 10^7 the lectin molecules per bacterium resulted in enhancement of nodule formation at 11 days after inoculation. This effect is also seen after preincubation of the nodule bacteria with nodulating soybean seed lectin. But pretreatment with nodulating soybean seed lectin increased nodule number during 30 days after inoculation. The persentage of nodulated plants within first days of plant growth increased to 82% when they were inoculated with treated nodule bacteria. Interestingly, non-nodulating soybean seed haemagglutinin promoted mainly formation of nodules on primary roots at 16 days after inoculation. These findings suggest that the non-nodulating soybean seed lectin can be kind of the substance, which is able to modulate legume-Rhizobium symbiosis formation.

P0105. Comparison of the migration of gfp labeled Erwinia amylovora on blossoms of apple cultivars of different susceptibility to fire blight

E. Mihalik[1], T. Bubán[2];
[1]University of Szeged, Szeged, Hungary, [2]Research and Extension Center for Fruit Growing, Újfehértó, Hungary.

Detached flowers of susceptible and tolerant apple cultivars were inoculated with gfp labeled Erwinia amylovora. Migration of the bacteria and progression of the infection has been detected. The traits of the hypanthium surface are of prominent importance in the progression of the infection. The wrinkled surface, the convex shape of the outer epidermal cell walls with thin cuticle and the sunken stomata helped to preserve a water film for a longer period providing medium for the motility of the bacteria in the susceptible cultivar. Large bacterium aggregations emerge gradually in the intercellular spaces of the glandular tissue, in the adjacent parenchyma of the hypanthium wall, in the wall of the ovary and in the pedicel. In the blossoms of the tolerant cultivar bacteria were restricted to small water droplets on the flat and waxy surface of the hypanthium and only a few were able to enter the tissues. Low level of bacterium aggregation and migration was found in the intercellulars of the subepidermal tissues of the hypanthium. In the tissues of the ovary wall and pedicel bacteria were not detected.

P0106. Effects of OTC-treatment on subcellular glutathione contents and symptom development during ZYMV-infection

B. Zechmann, G. Zellnig, A. Urbanek, M. Müller;
Institute of Plant Sciences, Graz, Austria.

Styrian oil pumpkin seedlings (*Cucurbita pepo* L. subsp. *pepo* var. *styriaca* GREB.) were treated with 1mM OTC (L-2-oxothiazolidine-4-carboxylic acid) to artificially increase cellular glutathione contents. Biochemical and immunocytological investigations revealed that two days after OTC-treatment glutathione contents were increased in all investigated organs (roots, cotyledons and the first leaves) of up to 2.5-fold in peroxisomes of cotyledons. Seedlings were infected with Zucchini Yellow Mosaic Virus (ZYMV) 10 days after OTC-treatment and symptom severity was evaluated three weeks later. 70% of ZYMV-infected plants treated with 1mM OTC prior to infection showed no signs of symptoms although virus particles were detected in leaves and roots with negative staining. Only 30% of the plants showed signs of ZYMV-infection like yellowing, minor stunting and first signs of mosaic patterns. No effects of OTC-pretreatment on glutathione contents were observed at that time within these plants.

This project was supported by the "Fonds zur Förderung der wissenschaftlichen Forschung (FWF)", Project nr.: P16273-B06.

P0107. Leaf beta-1,3 glucanase and chitinase activities as defense mechanisms of sugarcane plants against pathogens

R. Santiago, A. M. Millanes, M. E. Legaz, C. Vicente;
Complutense University, Madrid, Spain.

Leaf scal produced by *Xanthomonas albilineans*, and smut, caused by *Ustilago scitaminea* are the two major diseases of sugarcane plants. Plants develop several enzyme activities as a defense mechanism against pathogen. Some hydrolases, proteases and enzyme related to phenolics acid metabolism are included in these defense mechanism.
We are used five different cultivars of *Saccharum oficinarum* with different sensitivity against both pathogens. Using leaves of these plants, ɓ-1,3-glucanase, and chitinase were assayed in healthy and experimentally infected plants. Enzyme activities were measured using intact discs of leaves permeabilized with 4% *iso*-propanol. Laminarin was used as a substrate for glucanase whereas commercial chitin was the substrate of chitinase. L 55-5 produces the highest ɓ-1,3-glucanase activity after infection with *X. albilineans*, whereas My 55-14 contains the lowest level of this enzyme. Ba 42-231 shows the highest levels of chitinase activity after smut infection whereas My 55-14 newly develops the lowest enzyme activity.

P0108. Biological properties and nucleotide sequence of a begomovirus from *Malvastrum coromandelianum* (L.) Garcke

P. Lotrakul[1], S. Kanmarangkool[1], W. Srithongchai[2];
[1]Chulalongkorn University, Bangkok, Thailand, [2]Ministry of Agriculture and Cooperation, Bangkok, Thailand.

A yellow-veined *Malvastrum coromandelianum* (Malvaceae) was collected in Thailand. Transmission tests showed that the symptom could be transmitted to healthy plants by grafting and by whitefly (*Bemisia tabaci*) in persistent manner. Southern blot hybridization using begomovirus DNAs as probes gave positive results in DNA extracted from infected plants, indicating that this putative virus was a bipartite begomovirus. Insect transmission tests showed that individual whitefly could transmit the virus to 30% of tested plants. Once the insects acquired the virus, they could transmit as long as 12 days or more. Host range study on 21 plant species showed that the virus could not multiply in 18 species tested. In *Nicotiana benthamiana* and tomato infected with the virus, leaf curl symptom was detected. Although infected tobacco did not show visible symptom, Southern blot hybridization indicated the presence of the virus. Nucleotide sequence comparison of the common region showed that the virus was slightly similar to *Cotton leaf curl Rajasthan virus* (79.63% identity). Phylogenetic analyses revealed that the virus was closely related to the Old World viruses.

P0109. Effect of sugarcane glycoproteins on the production and activity of UDPG-dehydrogenase from *Xanthomonas albilineans*.

M. Blanch, Y. Blanco, M. E. Legaz, C. Vicente;
Complutense University, Madrid, Spain.

X. albilineans produces a xanthan like polysaccharide consisted of a basal tetramer composed by two molecules of fructose, one mannose rest and a final glucuronic acid. *Xanthomonas* produce an active UDPG dehydrogenase which is seen as a virulence factor. Sugarcane plants are able to produce glycoproteins as a response to parasitic invasions. They are grouped in two classes as a function of their molecular mass. HMMG (high molecular mass) and MMMG (mid molecular mass). The addition of HMMG or MMMG from 22 month-old stalks of Ba 42231 cv, highly sensitive to leaf scald, did not inhibit the initial loss of enzyme activity but strongly enhanced this activity from 15h (for HMMG) or 21h (for MMMG) to 24h culture. The enzyme was completely inhibited when HMMG and MMMG isolated from 22 months-old stalks of My 5514, highly resistant to leaf scald, were added to the culture media. This enhancement of UDPG-DH activity effected by HMMG and MMMG from Ba could be due to an activation of a pre-existent enzyme by sugarcane glycoproteins or to an activation of the enzyme synthesis. To study this effect we included in the culture media the inhibitors 8-azaguanine, chloramphenicol and piperine.

P0110. Lysozyme-like bacteriocin production from *Gluconacetobacter diazotrophicus* against *Xanthomonas albilineans* (scald leaf pathogen) in stalks of sugarcane

Y. Blanco, M. Blanch, M. E. Legaz, C. Vicente;
Complutense University, Madrid, Spain.

Leaf scald is a major disease of sugarcane which occurs in most sugarcane-producing countries and continues spreading. *Xanthomonas albilineans* is the pathogen. Gum exudates, which occluded bundle vessels, were observed in the ultrastructure of sugarcane scalded leaves. The gum was identified as a xanthan-like polysaccharide.
Gluconacetobacter diazotrophicus is a sugarcane endophyte which produces a lysozyme-like bacteriocin in liquid medium that inhibits growth of *X. albilineans*.
7 months-stalks of *Saccharum officinarum* were inoculated with the endophyte, or with the pathogen or with both bacteria and maintained for 11 days at 30º C. Extraction of xanthan was carried out from juice of these stalks, filtered through Sephadex G-10 and G-50 columns and carbohydrates were monitored. Main fractions of carbohydrates were hydrolyzed with 6 N HCl at 80º C overnight, dried and ground with cold 80% (v/v) ethanol. After evaporation to dryness, xanthan precipitates were analyzed by capillary electrophoresis.
The aim of this work is production of bacteriocin from *G. diazotrophicus* in sugarcane to establish a possible mechanism of biological control of scald leaf.

P0111. Localisation of *Xanthomonas albilineans* within inoculated leaves of sugarcane

C. Vicente[1], Y. Blanco[1], M. Blanch[1], M. E. Legaz[1], E. K. James[2];
[1]Complutense University, Madrid, Spain, [2]University of Dundee, Dundee, United Kingdom.

Leaf scald, caused by *Xanthomonas albilineans*, is a major disease affecting sugarcane and has been found in 57 countries. The initial characteristic symptom of disease is a white-yellowish streak on the leaf along the main veins. The streaks may later become more enlarged and affected leaf becomes wilted and necrotic. The white-yellowish streaks developed large bulliform cells and a gum exudates which occluded phloem and bundle vessels. The gum was purified from juice obtained from scalded stalks and was identified as a xanthan-like polysaccharide.
To localise *X. albilineans* in sugarcane leaves, 10-months leaves of *Saccharum officinarum* were inoculated with 0,6 mg dry weight of X. *albilineans* with a needle in the main vein and maintained in green house conditions. Small pieces (1 mm x 1 mm) of sugarcane leaves were taken at 1, 2, 5 and 7 days and to 2 cm above and below from the point of inoculation and infiltrated in LR White resin. Semithin sections were used for inmunogold labelling (IGL) or stained with metilen blue for conventional light microscope. Ultrathin sections for transmission electron microscope were used for IGL.

P0112. Activation of actinorhizal nodulin gene promotors in legume nodules of *Medicago truncatula*

J. Liang[1], M. M. C. Gouveia[2], S. Svistoonoff[3], L. Laplaze[3], F. Auguy[3], P. Fevereiro[1], D. Bogusz[3], C. Franche[3], K. Pawlowski[4], A. Ribeiro[5];
[1]Instituto de Tecnologia Química e Biológica, Oeiras, Portugal, [2]Universidade da Madeira, Funchal, Portugal, [3]IRD, Montpellier, France, [4]Göttingen University, Göttingen, Germany, [5]DCN/IICT, Oeiras, Portugal.

Two groups of plants, legumes and actinorhizal plants, are able to enter root-nodule symbioses with nitrogen-fixing bacteria, rhizobia and *Frankia*, respectively. In spite of the differences between actinorhizal and legume symbioses, the two systems share common aspects, especially regarding the infection process and nodule functioning. Our main goal is to compare the two symbioses at the molecular level. This way, we expect to identify some of the common aspects determining the capacity to develop nitrogen-fixing root nodule symbioses and/or to provide insight about the different strategies used by plants to achieve symbiotic nitrogen fixation. Here we report on the study of two actinorhizal nodulin gene promotors, one from *Casuarina glauca* and one from *Datisca glomerata*, in the legume *Medicago truncatula*. The results indicate that at least part of the transcriptional environment in plant cells infected by endosymbiotic bacteria is conserved between legumes and actinorhizal plants.

P0113. Influence of lectin on the efficiency of symbiotic system soybean - Bradyrhizobium japonicum under different mineral nitrogen supply

D. M. Sytnikov, S. Y. Kots, S. M. Malichenko;
Institute of Plant Physiology and Genetics of National Academy of Sciences of Ukraine, Kiev, Ukraine.

The influence of preliminary incubation of nodule bacteria *Bradyrhizobium japonicum* (active strain 634b and non-active strain 604k) with homologous soybean lectin on the infectivity, nitrogen fixing activity of root nodules and development of soybean plant (*Glycine max (L) Merr.*) under different mineral nitrogen supply were studied. It is shown that preliminary incubation of nodule bacteria with lectin increases the nitrogen fixing activity of soybean nodules that were formed by the active strain 634b. And on the contrary, there has been revealed the tendency of inhibiting the activity of nodules that were formed by non-active strain 604k under the conditions of different supply with mineral nitrogen. As a result of our research it has been established that the influence of preincubation of nodule bacteria with lectin on the efficiency of symbiotic system depended on the strain activity and was limited by volume of mineral nitrogen in substrate.

P0114. Rhizobial isolates effectiveness on cowpea

J. C. Mayz, F. Campos, N. Valladares;
Universidad de Oriente, Núcleo de Monagas, Maturín, Venezuela.

In order to identify rhizobial strains with higher biological N_2 fixation capability in cowpea 15 strains isolated from non-inoculated cowpea plants grown in the savannah soils of Monagas State, Venezuela, were evaluated. A completely randomized design with four replicates was used. Two control treatments were included, one non-inoculated and N-fertilized and the other non-inoculated and non-fertilized. The plants were cultivated in plastic pots with 4 kg of sterilized fine granite and the strains in yeast extract and mannitol broth during 5 and 10 days. two mL of rhizobial suspension (individually) were applied at sowing time and six days later. The plants were watered and harvested 45 days after planting. Nodule number and dry weight, shoot nitrogen concentration and content, shoot and root dry matter, and total dry weight were evaluated. Rhizobia inoculation was significant for all parameters evaluated. The highest shoot nitrogen content and total dry biomass identified the strains JV91, JV94, and JV101 as effective. Shoot nitrogen content correlated significantly with shoot dry weight (r = 0.85), total dry weight (r = 0.90), and nodule biomass (r = 0.72).

P0115. The leaf pathogen Cymadothea trifolii locally degrades pectins, but not cellulose or xyloglucan in clover cell walls.

U. K. Simon[1], R. Bauer[1], D. Rioux[2], M. Simard[2], F. Oberwinkler[1];
[1]Lehrstuhl Spezielle Botanik und Mykologie, Universität Tübingen, Tübingen, Germany, [2]Natural Resources Canada, Canadian Forest Service, Quebec, PQ, Canada.

The biotrophic pathogen Cymadothea trifolii proliferates intercellularly within leaves of Trifolium species. The fungus produces a unique structure, which we have termed interaction apparatus (IA), in its own hyphae. Opposite the IA, the plasmalemma of the host cell invaginates to form a bubble. The two structures are linked by a 300 nm wide tube leading through the walls of plant and fungus without disrupting them. A wide array of antibodies against different plant cell wall components and a fungal polygalacturonase were applied to high-pressure frozen, freeze-substituted and Epon, HM20 or LR White embedded leaves of heavily infected Trifolium repens plants. Samples were studied with the electron microscope. Our results show that within the tube pectins are degraded, while cellulose and xyloglucan are left intact. Furthermore, a polygalacturonase was detected in functioning but not in old IAs. The degradation of the pectin matrix probably results in an increase of pore diameter in the plant wall at the point of interaction.

P0116. Artificial bacterial symbiosis as a tool for extending biological nitrogen fixation to asymbiotic plants.

P. Koranyi, I. Gyurjan, E. Preininger;
Eotvos Lorand University of Sciences, Budapest, Hungary.

Artificial symbiotic associations were established between aerobic nitrogen fixing *Azotobacter* species and different plants from unicellular green algae to perennial crops with the methods of cell and tissue culture and regeneration. The description and further utilization of such systems required the incorporation of molecular markers (first GUS and later wild-type and mutant forms of GFP) into symbiont candidate bacteria to detect and monitor them inside and outside their host cells and tissues. The performance of different transformation methods was compared using different plasmids. The techniques adapted for the preparation of transformation competent bacterial cells and electroporation provided significantly more viable transformants than the formerly used procedures. Chromosomal integration of transforming plasmids and a stable expression of marker genes were also observed. The new strains grew on carbohydrate and nitrogen free media having normal morphological and growth characteristics. Bacterial nitrogenase retained its activity in inoculated or regenerated plant material. This work was supported by OTKA T-034875 grant.

P0117. Are grapevine moving particles from *Vitis rupestris* responsible for the resistance to powdery mildew (*Uncinula necator*)?

Z. J. Chen[1], G. C. Costa[1], A. V. Coelho[1], A. L. Martins[2], R. B. Ferreira[1,2];
[1]Instituto de Tecnologia Quimica e Biologica, Universidade Nova de Lisboa, Oeiras, Portugal, [2]Instituto Superior de Agronomia, Universidade Tecnica de Lisboa, Lisbon, Portugal.

Both the American grapes (*Vitis* spp.) and the European one (*V. vinifera*) are important for the viticulture. The American grapes are usually resistant to powdery mildew, whereas the European is more susceptible. Grapevine moving particles (GMPs) were first observed around 20 years ago. The number of GMPs per cell was found to be directly correlated with the plant resistance to *Uncinula necator.* The cellular number of GMPs in the American grape was 15 to 30 times higher than in the European. There is a clear increment in the number of GMPs during an infection process. GMPs exhibit random movement *in vitro* and *in planta*. The movement of isolated GMPs was reduced in an ATP-depleting system. Purified GMPs are round to ellipsoid, with a size ranging from 100 to 400 nm, and contained xylanase, carboxymethyl cellulase, chitinase activities and other proteins. A serine/threonine-specific protein kinase was also identified, an enzyme possibly required for GMP movement. GMPs strongly inhibited powdery mildew spore germination, appressorium formation and penetration. These results suggest that GMPs are at least in part involved in the grapevine defence system.

P0118. Histopathological changes in plant tissues due to fungal infection

S. M. M. Shama;
Faculty of Agriculture(Saba Basha)-University of Alexandria, Alexandria, Egypt.

The interaction between a host and pathogen has been divided into three consecutive phase which although interdependent are physically separated by the host surface, namely, growth of the pathogen prior to penetration, penetration, and growth within the host. The growth of the pathogen within the host and the histological changes in plant tissues had been studied in different hosts with special references to cowpea and cucumber plants.*Rhizoctonia,Phoma,Macrophomina* & downy mildew fungi caused important diseases to the tested plants and different histopathological and ultrastructure changes were observed and photomicrography using bright field and scanning electron microscope. The most important changes recorded were changes in plant cell color and size, increased of cambial activity, location of strange particles within tissues, deposition of callose in xylem tissues, death of cells, increase in the number of vacuoles, distortion of cells, tissues collapsed, and many other changes. Most of the previous mentioned changes were photographed and examined in different plant organs & seeds.

P0119. Effects of PGPR on the Growth of Maize (Zea Mays L.)

M. G. Stefan[1], O. Ailiesei[1], E. Ungureanu[2], S. Dunca[1], C. Maniu[3], M. Zamfirache[4];
[1]Microbiology Department, Faculty of Biology, University Alexandru Ioan Cuza Iasi, Iasi, Romania, [2]Biochemistry Department, Faculty of Biology, University Alexandru Ioan Cuza Iasi, Iasi, Romania, [3]Biostatistical Department, Faculty of Biology, University Alexandru Ioan Cuza Iasi, Iasi, Romania, [4]Department of Plant Physiology, Faculty of Biology, University Alexandru Ioan Cuza Iasi, Iasi, Romania.

In the framework of the soil increased pollution with chemical fertilizers, the maintaining and growing of the crops impose finding alternative solutions based on biofertilizers usage. One group of microorganisms which are beneficial to crops is bacteria that colonize roots or rhizosphere soil of crop plants which are referred to as plant growth promoting rhizobacteria (PGPR).

Several PGPR strains influences (isolated from *Zea mays* rhizosphere) were studied on the maize plants development in field conditions (a bio-preparation with a concentration of 16.4 x 10^7 CFU/ml was used).

The results indicate a stimulation of growing and development processes (the catalase activity recorded in the test was double compared to the control; the content of photosynthetic pigments was higher in the leaves of the test plants; biometrical parameters and the harvest were significantly higher on the test). The PGPR beneficial influence was recorded before flowering when majority metabolical processes intensity is highest, probably, because of stimulation radicular nutrients exchange mediated by rhizobacteria.

P0119a. Direct RT-PCR amplification of mature mRNAs in cytoplasm micropipetted from barley coleoptile epidermal cell - A model system for analyzing gene expression in host cells attacked by powdery mildew

Y. Matsuda, T. Nonomura, H. Toyoda;
Kinki University, Nara, Japan.

Two-step PCRs (RT-PCR and nested PCR) were used to detect gene expression in powdery mildew pathogen-infected cells of detached inner epidermis of barley coleoptile. Cellular contents of the infected cells were microscopically suctioned with a micropipette and subjected to the PCRs. Two genes involved in the glycolytic pathway and stimulus-induced endochitinase gene were targeted, and their expression was determined by detecting cDNAs derived from spliced transcripts. Two gycolysis-related genes were constantly expressed in the tissue irrespective of pathogen inoculation. Contrarily, the chitinase gene expression was induced in non-infected inner epidermis after the detachment. After inoculation, this expression was selectively suppressed in pathogen-invaded cells, in spite of continuous expression in non-invaded cells of the same epidermis. Thus, the present method enabled us to directly analyze transcripts in individual cells at the infection site and indicate the capability of the pathogen to regulate host gene expression.

P0120. Epigenetic transposon regulation in Arabidopsis neopolyploids

A. Madlung[1,2], T. Kagochi[1], S. Bradshaw[1], C. Rempel[1], L. Jurevic[1], B. P. Dilkes[2], L. Comai[2];
[1]University of Puget Sound, Tacoma, WA, United States, [2]University of Washington, Seattle, WA, United States.

Polyploids are common and arise frequently by genome duplication (autopolyploids) or interspecific hybridization (allopolyploids). In spite of their frequency in nature, early generations of human-made allopolyploids often display sterility, inviability, phenotypic instability, gene silencing, gene activation, and epigenetic changes. We have previously shown that several transposons, including the novel CACTA-like transposon *Sunfish,* are transcriptionally and, less frequently, transpositionally activated in neopolyploid offspring of synthetic crosses of *Arabidopsis thaliana* and *A. arenosa.* Transposons may thus play an important role in the evolution of novel traits in neopolyploids. We have assessed *Sunfish* activity in diploid chromatin mutants of *A. thaliana* and in several accessions of the natural allopolyploid *A. suecica*. Our data correlate *Sunfish* activity both with the loss of epigenetic control in *A. thaliana* and with polyploidization in the natural allopolyploid *A. suecica.*

P0121. Expression of ribosomal RNA genes in two Tragopogon allotetraploids of recent and recurrent origin

R. Matyasek[1], A. Kovarik[1], D. Soltis[2], A. R. Leitch[3], J. C. Pires[4], K. Y. Lim[3], J. Tate[2], J. Fulnecek[1], P. Soltis[5];
[1]Institute of Biophysics of the Academy of Sciences, Brno, Czech Republic, [2]Department of Botany, University of Florida, Gainesville, FL, United States, [3]School of Biological Sciences, Queen Mary, University of London, London, United Kingdom, [4]Department of Agronomy, University of Wisconsin, Madison, FL, United States, [5]Florida Museum of Natural History, University of Florida, Gainesville, FL, United States.

Nucleolar dominance is an epigenetic phenomenon where one parental set of ribosomal RNA (rRNA) genes is silenced in interspecific hybrids. We investigated silencing of parental rRNA genes in multiple populations of Tragopogon mirus (T. porrifolius x

T. dubius) and T. miscellus (T. pratensis x T. dubius), allotetraploids formed within the last century. Natural variations in rRNA gene silencing were found among individual populations. In most populations, rRNA transcripts of T. dubius origin outnumbered those of the partner genome. Since rDNA units of T. dubius-type are partially lost through homogenization, it is likely that genetic events leading to reduction of one parental type units did not prevent their expression and dominance. In one population of T. mirus the general trend of silencing was reversed and T. porrifolius units were predominantly expressed showing that bidirectional rRNA silencing within a single species can occur. In this population silencing was unstable and expression patterns varied even among progeny of a single plant. Leaf and flower expression patterns were similar suggesting that silencing is not influenced by development.

P0122. Expression profiling and polyploidization in *Gossypium*

R. A. Rapp[1], J. A. Udall[1], A. B. Arpat[2], T. A. Wilkins[2], J. F. Wendel[1];
[1]Iowa State University, Ames, IA, United States, [2]University of California Davis, Davis, CA, United States.

The reunification of two divergent genomes via hybridization and subsequent doubling (allopolyploidy) requires instantaneous coordination of the two suddenly co-resident genomes. Although allopolyploidy may be accompanied by some level of genome rearrangement, little is known about regulatory interactions and gene expression changes. Previous work in *Gossypium* has shown that many genes experience expression alteration on a tissue-specific basis. Using synthetically derived cotton (*Gossypium spp.*) allopolyploids, we explored the effect of polyplodization on patterns of gene expression for approximately 12,000 loci using 70mer oligonucleotide technology. Using controlled growth conditions in a replicated block design, we examined expression alteration in two independent synthetic polyploidy events, including one involving diploids representing the genome donors of the economically important *G. hirsutum* and *G. barbadense*. Here we present the analysis of these experiments and the evolutionary implications for recently formed polyploids.

P0123. The effects of colchicines and the induction of polyploidy in *sorghum bicolor* (Keller, IS4546 and R10 cultivars).

B. Delnavaz Hashemloian, a. ataei azimi;
azad islamic university, Saveh, Islamic Republic of Iran.

This investigation was set out to determine the most suitable treatment for inducing polyploidy in Sweet sorghum using colchicines. Three methods of colchicines application for three cultivars are used, namely (1) to seed, (2) to apical meristem of seedlings and (3) to seedlings. In these methods colchicines concentration was 0-0.5% for 4-72 hours. The percent of mortality for three cultivar (Keller, IS4546 and R10) was 89.7 to 98.9%. The normal chromosome number in three cultivars was 2n=2x=20. In 0.75% to 12.2% pollen mother cells (pmc) of these cultivars were induced by colchicines, chromosome number was double or 2n=4x=40 (in Is4546= 12.2% and in Keller= 0.75%). In cytogenetically studies beside autotetraploid, lagging and no disjunction was observed too. The lagging phenomenon for these cultivars was high (15-28%). Also aberration such as fusion of two or more pmc's with 30, 40 and 52 bivalent chromosomes (5, 7 and 2%) was observed.

P0124. Meiotic elaboration of the of homoeologous pairing suppressing genes on genomes B and C of Brassica

H. Ahmad[1], S. Hasnain[2];
[1]Department of Botany, Government Jahanzeb Post Graduate College, Saidu Sharif, Swat, Pakistan, [2]Department of Botany, University of the Punjab, Lahore, Pakistan.

Meiotic analyses of 8 digenomic triploids, 4 each having genomic combination of AAC and AAB, synthesized through hybridizing *Brassica rapa*, *B. juncea* and *B. napus*; showed gross meiotic anomalies in the form of univalents and multivalents. The rate of chromosomal associations, orientation of multivalents and combination types was different from genotype to genotype. The hybrids showed differences in the frequencies of associating chromosomes at the individual levels but the percentage of paired and unpaired chromosomes remained nearly equal in both types of the digenomic triploids. The ratio of paired and unpaired chromosomes was c 27 and 26 percent in the having genomic constitution ABA and ACA, respectively. The average ratio of the pairing and non pairing chromosomes remained 70 to 30 percent, respectively. The high frequency and nearly equal amount of IIs in both the digenomic triploids revealed the absence of gene on genomes B or C, which could be held responsible for a role of suppressing homoeologous pairing in Brassica.

P0125. Differential expression analysis of aberrant and normal phenotypes in *Brassica oleracea*

A. Salmon, M. Manzanares-Dauleux, M. Renard, H. Bellis, V. Chable;
UMR 118 INRA-Agrocampus APBV - Amélioration des Plantes et Biotechnologies Végétales, B.P. 35327, 35653 Le Rheu Cedex, France.

Phenotypic aberrations affecting leaves morphology and vigor during the vegetative development of plants have been described in all the observed varieties of *Brassica oleracea* var. *botrytis*. In field conditions, 3 to 20% of plants can show these aberrations, the percentage varying according to both plant genotype and environment. The phenomenon can be reversible, suggesting the involvement of epigenetic mechanisms.

In this study, we investigate the expression polymorphism between “normal” and “aberrant” individuals by using two complementary approaches: cDNA-AFLP and candidate genes. Candidate genes were chosen given their roles in transcription regulation, epigenetic controls or in leaf morphology.

Differential expression was analyzed at 6 kinetic points corresponding to different developmental stages in the F1 hybrid Nominoé. Forty bands were differentially expressed in either normal or aberrant plants, at different kinetic points, notably when the aberrant phenotype appeared. Thirty of them have been sequenced. Results will be discussed in regard of epigenetic mechanisms described in *Arabidopsis thaliana*.

P0126. Patterns of homeologous recombination in Brassica napus haploids

S. Nicolas, F. Eber, M. O. Lucas, J. C. Letanneur, G. Le Mignon, A. M. Chèvre, E. Jenczewski;
UMR INRA-Agrocampus Amélioration des Plantes et Biotechnologies Végétale, Rennes, France.

Interspecific hybridization and polyploidy are major forces driving the evolution of plants. Structural rearrangements, sequence divergence and gene(s) are known to modify the rate of homeologous recombination and thus the rate of gene flow between related species/genomes. Here, we present the analysis of homeologous recombination in Brassica napus haploids (AC, n=19). B. napus (AACC, 2n=38) is an allotetraploid whose progenitors are B. oleracea (CC, 2n=18) and B. rapa (AA, 2n=20). We have analyzed the progenies of high and low pairing haploids and used the non transmission of alleles from the haploid parents as an evidence for homeologous recombination. We show that the gene PrBn has a major effect on the level of homeologous recombination; we provide evidence that the amount of homeologous recombination depends on the level of synteny between the A and C recombining chromosomes. These results will be discussed with regards to the emergence of allopolyploids.

P0127. Secondary Thickening by MRI in Stem of Eucalyptus grandis

V. Sarafis[1], H. vanAs[2], C. Windt[2], E. Gerkema[2], A. deJager[2], F. Vergeldt[2], E. Darley[3];
[1]CHAPS,UWS. CSSIP &School of Lfe Sciences U of Qld, Penrith south&St Lucia, Australia, [2]University of Wageningen, Wageningen, The Netherlands, [3]CHAPS,UWS., Penrith south, Australia.

MRI of Hydrogen nucleil atlow field strength was used in imaging of a plant of Eucalyptus grandis to study secondary thickening of its stem as it was taking place.Low field strength was chosen so as to minimise artefacts at air water interfaces. The plant grew with supplementary illumination and regular watering and an occasional commercial minerals solution was given to prevent mineral deficinecy.

The plant was vigorous and added several branches during the experimental period .

Two months during which secondary growth was visualised show the method's power

The same plant was killed after the experiment and its structure imaged by a Leica stereozoom optical microscopy.

We identify the same tissues in both imaging systems . However the pith shows stratification by MRI into an outer and inner zone.MRI of studies of secondary thickening permit dynamic studies of this process in living plants without the destrucutive methods of classical plant anatomy.

P0128. Spatial and temporal relation between cytokinin localisation and ectopic expression of a class1 knotted like gene in peach leaves affected by the curl disease caused by thaprina deformans

L. Bruno[1], A. Chiappetta[1], A. Bruno[1], D. Giannino[2], G. Testone[2], D. Mariotti[2], A. M. Innocenti[1], M. B. Bitonti[1];
[1]University of Calabria, Cosenza, Italy, [2]Istituto di Biologia e Biotecnologia Agraria, Monterotondo Scalo (RM), Italy.

In plants, the class1 knotted-like transcription factors (KNOX) are crucial in determining the identity and fate of meristem cells. The down regulation KNOX1 genes is necessary for leaf primordia inititiation, while their overexpression leads to alterations of plant architecture and organ morphology

A KNOX1 gene of peach (KNOPE1) was isolated and attributed to class 1 based on its specific expression in the SAM and on its aminoacidic identity. KNOPE1 transcript was localised in leaves affected by the curl disease, caused by Taphrina deformans, a fungus able to produce auxin and cytokinin-like compounds. The disease is characterised by hypertrophic and hyperplastic development of leaf accompanied by a misbalance and/or misallocation of phyhormones. In situ analysis was performed on leaves at distinct phases of the disease, revealed that KNOPE1 message was abundant and misplaced as compared to healthy leaves, and zeatin (Z) highly accumulated in curly tissues. Moreover, in sectors of histological disorder, the localization (Z) overlapped that of KNOPE1 transcript suggesting a spatial and a temporal relationship between gene regulation and (Z) accumulation

P0129. Improvements of shoot meristem identity and somatic embryo development of white spruce (Picea glauca) through modulations of glutathione metabolism.

M. F. Belmonte, **C. Stasolla**;
Dept. Plant Science, University of Manitoba, Winnipeg, MB, Canada.

Optimizing propagation of tree species through somatic embryogenesis remains one of the main objectives in sustaining superior quality genotypes for re-forestation strategies. In white spruce, improvements of embryo development were observed following experimental alterations of the endogenous glutathione redox state. An increase in embryo number and quality can be obtained through initial applications of reduced glutathione (GSH), which promote cell proliferation and the formation of immature embryos, followed by applications of the oxidized form (GSSG), which induce proper embryonic development. Structural and ultrastructural studies reveal marked differences between the meristematic cells of the control embryos and those of the treated counterparts. In addition, RNA in-situ localization studies of a shoot apical meristem marker gene, HBK1 (Sundas Larsson et al. 1998, P.N.A.S. 9: 1118) indicate that changes in glutathione metabolism during embryo development improve shoot apical meristem stability, and ultimately regeneration of viable plants.

P0130. Function Analysis of the Millet (*Stetaria italica*) Gene *PF40* Involved in Plant Apical Dominance

Q. Zhao, Y. H. Liu, X. Y. Feng, J. J. Yu, G. M. Ao;
State Key Laboratory of Agrobiotechnology, China Agricultural University, Beijing, China.

The aerial architecture of flowering plants is determined to a large extent by shoot growth and shoot branching arising from the initiation and growth of axillary meristems. But the underlying regulatory mechanisms have not been unraveled. *PF40* gene isolated from the cDNA library of millet immature seeds encodes a 30KDa protein with 35%-75% sequence identity to the ZIPs gene family. Software analysis showed *PF40* protein had eight trans-membrane regions. Southern blot indicated that *PF40* gene was ubiquitous distributed in cereal crop genome. Northern blot showed *PF40* gene was expressed in all tissue of millet but predominant in very young tissue such as hypocotyl and bud and the expression level can be regulated by 6-BA and GA.Transgenic plants showed that overexpression of *PF40* gene can reduced the apical dominance of both millet and tobacco by effecting the growth of lateral shoots developing in the basipetal pattern early after floral transition. The ratio of auxin/cytokinin was more than 5 fold in the *PF40* gained function plant than that in wild type. Furthermore the *PF40* gene effected differentiation of the vascular bundles in transgenic plants.

P0131. Characterization of novel systemic non-coding small RNA molecules isolated from pumpkin phloem sap

S. Zhang, F. Kragler;
Vienna BioCenter, Vienna, Austria.

Plant growth and tissue differentiation is coordinated via exchange of local and long distance signals. Regulatory signals in form of micro RNAs, which inhibit the translation of mRNA can move cell-to-cell and throughout the plant using the long distance phloem pathway. These mobile micro RNAs are suggested to control pattern formation and cell fate. It was shown that non-cell-autonomous micro RNA and mRNA present in the phloem sap are transported by RNA-binding proteins via plasmodesmata to gain access to the phloem translocation pathway. Interestingly, in the phloem sap of pumpkin we could detect additional RNA molecules not resembling mRNA or micro RNA with unknown function. These novel non-coding RNA molecules change in size and number during tissue maturation and by environmental impacts. We started to isolate and characterize these RNA molecules to gain insights into their potential function. Currently we are establishing cDNA libraries representing these systemic small RNA molecules with the aim to predict potential target genes and to study their putative function(s) in systemic signaling.

P0132. Highly frequent RNA editing in rbcL gene of Takakiophyta

T. Arikawa[1], M. Higuchi[2];
[1]Keio Univ., Yokohama, Japan, [2]Dept. Bot., Naitonal Science Museum, Tsukuba, Japan.

The genus Takakia is sometimes treated as independent division. We analyzed the partial nucleotide sequence of the chloroplast gene rbcL (ca. 1260 bp) form T. lepidozioides from Japan, Taiwan, and Malaysia, and T. ceratophylla from China. There was no difference between each sequences of T. lepidozioides. There were twenty one differences between the sequence of two species. Thirteen differences of them were correspond to non-synonymous substitutions, in which twelve were between T and C. Many C to U substitutions were especially found as the result of RNA editing, which had been reported in the chloroplast genomes of some plants. We analyzed the cDNA sequence of rbcL gene from T. lepidozioides from Taiwan with RT-PCR. There were thirty two differences between the genomic and cDNA sequences. We confirmd that the RNA editing were frequently occured in the rbcL gene of Takakia.Twenty four sites of thirty two were considered as editing sites common to both species. T. ceratophylla seems to have additional eight editing sites independently.

P0133. Efficiency of RNA isolation from potato protoplasts

M. Maior[1], B. Jørgensen[2], B. Borkhardt[2], P. Ulvskov[2];
[1]Babes-Bolyai University, Faculty of Biology, Cluj-Napoca, Romania,
[2]Danish Institute of Agricultural Sciences, Biotechnology Department, Frederiksberg C, Denmark.

Resynthesis of cell wall after protoplasts isolation is far of beeing known closely. Potato protoplasts were used as source for RNA. Potato cultivars were tested for protoplast isolation efficiency and were chosen for the RNA experiment. The RNA probes were meant to be a part of a microarray experiment, which should give an idea about the cell wall regeneration in the first days after the isolation of protoplasts. To get a general idea about the regeneration process the protoplasts were stained with different reagents (Calcofluor White, Yariv reagent, Aniline Blue) and with some antibodies for plant cell walls were used. For the extraction of RNA we made several tests for a method that uses lithium chloride and we also tested for extraction a kit (RNeasy Plant Mini Kit). The RNA which was isolated using the kit was qualitatively superior to the one using the LiCl. After comparing the results from the staining experiments were chosen 5 time points to make the experiment. First time point at 5 hours from isolation and then at 12h, 24h, 36h, 48h.For each time point an amount of more than 29 µg of total RNA was obtained-which was considered suficient for a microarray experiment.

P0134. A NAP (nucleosome assembly protein)-like polypeptide binds specifically chloroplast intron RNAs of *Chlamydomonas reinhardtii*

S. Glanz, A. Bunse, C. Balczun, C. Schwarz, U. Kück;
Lehrstuhl für Allgemeine und Molekulare Botanik, Bochum, Germany.

In *Chlamydomonas reinhardtii* the chloroplast *psaA* gene is fragmented into three independently transcribed exons which are flanked by consensus sequences of group II introns. To generate a mature *psaA* mRNA two *trans*-splicing steps are necessary involving a small chloroplast-encoded RNA (*tscA*). In recent years, the *C. reinhardtii* system has been used to identify components which are part of a postulated chloroplast spliceosome that is involved in the *trans*-splicing process.

In our effort to isolate further factors binding specifically intron RNAs, we used the yeast three-hybrid system to identify chloroplast RNA binding proteins. By using the *tscA* RNA as bait, we identify a clone encoding a 40 kD prey protein with similarity to nuclear localized nucleosome assembly proteins (NAP). In contrast to nuclear NAPs, the derived polypeptide carries a 44 aa chloroplast signal. Therefore the corresponding gene was designated *Nap-like*. The organellar localization of NAPL was shown with an antibody which detected specifically a recombinant NAPL-Tag fusion protein. Thus, NAPL is most probably part of a chloroplast spliceosome.

P0135. DYW domain proteins and RNA editing: a phylogenetic correlation

V. SALONE[1], B. Hoffmann[1], B. Szurek[1], I. Small[1], V. Knoop[2], C. Lurin[1];
[1]Unité de Recherche en Génomique Végétale (URGV), 91057 Evry Cedex, France, [2]IZMB-Institute of Cellular and Molecular Botany, Bonn, Germany.

PPR (pentatricopeptide repeat) proteins form a huge family (about 450 members in Arabidopsis) defined by repetitions of characteristic motifs. Genetic and functional data support that these proteins are implicated as specificity adaptors in post-transcriptional processes in plant organelles, including RNA editing. The proteins catalysing RNA editing are currently unknown. We suggest that the DYW C-terminal domain present in many PPR proteins could be the essential enzyme for this process. The sequence of this domain contains conserved residues that match the active site of cytidine dealinases. A study of the phylogenetic distribution of this domain in green plants, in particular in liverworts of which one class (the Jungermaniidae) edit their RNA, while the other (the Marchantiidae) do not, was performed. Our results suggest a correlation between the presence of the DYW domain and RNA editing in green plants.

P0136. Characterization of *suppressor of wooden leg 1*: a mutant showing impaired vascular development

A. B. Bishopp[1], A. P. Mähönen[1], K. M. Nieminen[1], M. Higuchi[2], T. Kakimoto[2], Y. Helariutta[1,3];
[1]Institute of Biotechnology, Helsinki University, Finland, [2]Department of Biology, Osako University, Japan, [3]Department of Biology, University of Turku, Finland.

The *Arabidopsis wooden leg* (*wol*) mutant root has a reduced number of provascular cell files and all cell files differentiate as xylem during vascular morphogenesis resulting in determinate root growth pattern (Scheres et al. 1995). *WOL* is allelic with *CRE1*/*AHK4* and encodes a cytokinin receptor (Mähönen et al. 2000, Inoue et al 2001, Suzuki et al 2001). In order to identify molecules acting downstream of CRE1, we performed a suppressor screen for the determinate growth habit of *wol.* Here we show the characterisation of one of these suppressor mutants, *suppressor of wol1* (*sow1*). In the *wol* background, *sow1* shows an increased number of vascular cell files in the root-hypocotyl junction with undifferentiated files present, as opposed to the exclusively protoxylem cell files present in *wol.* Alone, *sow1* shows defects in maintaining the balance between cell division and differentiation during root vascular morphogenesis.

P0137. Ca^{2+}-mediated signalling and programmed cell death induced in soybean cells by an endopolygalacturonase from *Sclerotinia sclerotiorum*

A. Zuppini[1], L. Navazio[1], L. Sella[2], C. Castiglioni[2], F. Favaron[2], P. Mariani[1];
[1]Department of Biology, University of Padova, Padova, Italy,
[2]Department Te. S.A.F., University of Padova, Padova, Italy.

Sclerotinia sclerotiorum is a ubiquitous necrotrophic pathogen secreting multiple pectinolytic enzymes that facilitate penetration, colonization and maceration of plant tissues. Among these enzymes, various isoforms of endo-polygalacturonases (PGs) are produced. A basic PG, early expressed in *S. sclerotiorum* during soybean infection, was used to analyse cellular responses in soybean cell cultures. PG treatment triggered a rapid increase in the concentration of cytosolic Ca^{2+} which was maintained over the basal level during the next hour. Loss of cell viability in the same time interval was observed, with a progressive increase in the percentage of dead cells over 12h. PG-induced cell death was associated with cytochrome *c* release from mitochondria and caspase-like protease activation, indicating that a programmed cell death (PCD) pathway was triggered. As demonstrated by the effect of the Ca^{2+} channel blocker La^{3+}, the increase of cytosolic Ca^{2+} level seems to be essential for the induction of PCD by PG. When a polygalacturonase inhibiting protein (PGIP) and the PG were simultaneously applied to cells, both Ca^{2+} increase and cell death were annulled.

P0138. Programmed cell death is induced by mild heat stress in soybean cells via a mitochondrial-mediated pathway

A. Zuppini, V. Bugno, **B. Baldan**;
Department of Biology, University of Padova, Padova, Italy.

Programmed cell death (PCD) is fundamental for normal growth and development of multicellular organisms and in response to environmental stresses. The pathway of PCD has been partially clarified in plants although the underlying molecular mechanisms are still poorly defined. We have investigated the signalling cascade induced by a mild heat treatment causing PCD in soybean cells. The data show that heat shock led to the onset of PCD in soybean cells involving H_2O_2 production and mitochondrial damage. Cytochrome *c* release is followed by the activation of the death-related caspase 9-like and caspase 3-like proteases. Concomitantly, cells were severely damaged with a progressive cell shrinkage, chloroplast alteration and detachment of the plasma membrane from the cell wall. Chromatin condensation and DNA laddering formation were observed. It is concluded that a mild heat stress induces PCD in soybean cells through a caspase-dependent mitochondrial pathway.

P0139. Stress-induced programmed cell death in the unicellular alga “*Chlorella*” *saccharophila*-like

A. Zuppini, **C. Andreoli**, B. Baldan;
Department of Biology, University of Padova, Padova, Italy.

Programmed cell death (PCD) processes have been reported extensively in animal and plant cells under different environmental stresses. However, the key elements of stress-induced PCD remain largely unresolved in unicellular organisms. In this study, the occurrence of PCD-like cell death was determined in the unicellular chlorophyte “*Chlorella*” *saccharophila*-like using specific indicators of plant and animal PCD. Our results show that, under heat and salt stresses, cells undergo a form of cell death with morphological features of apoptotic cell death, including an increase in chromatin condensation and margination, nuclei shrinkage and DNA fragmentation. Assays on the activity of caspase 3-like enzyme, a cell death-associated protease, showed an increase with the treatment and paralleled the morphological changes. Moreover, the caspase-like activity was inhibited by specific caspase inhibitors. The finding of a stress-induced caspase-mediated cell death pathway together with the occurrence of key components of eukaryotes PCD in a chlorophyte, suggest the hypothesis that key elements of cell death pathways were conserved during evolution.

P0140. Effect on the changes of antioxidant to chilling in *indica* and *japonica* subspecies under chilling temperature(*Oryza sativa* L.)

X. Li[1,2];
[1]Demao jiao, Nanjing, China, [2]Chuanchao Dai, Nanjing, China.

Six rice varieties namely *Japonica* Taibei 309, Wuyujing, *indica*IR64, Pusa, CA212 and *indica Hybrid* Shanyou 63 were used to study the effect by chilling temperature(8°C).The light intensity-photosynthesis curves, CO_2-photosynthesis curves, primarily photochemical chemical efficiency, active oxygen species, gluthione and ascorbate content in their seedlings were measured before and after chilling treatment. The results showed: relative to the rice varieties tolerant to chilling such as Taipei 309 and Wuyujing, the sensitive ones IR64, Pusa, CA212 exhibited a stronger inhibition of Maximum photosynthetic rate and a decrease of Fv/Fm, which led to the accumulation of AOS. It was also found that the content of glutathione disulphide in gluthione pool and that of dehydroascorbate in ascorbate pool of the leaves of these sensitive ones under chilling were induced to increase obviously. The correlation coefficient among the increases of GSSG, DHA and the decrease of Chl content, Chl content and ASA/DHA, GSH/GSSG were -0.701**, -0.656** ,0.811**and 0.728** respectively, significant at 0.01 probability levels.

P0141. Active transposon *Tok* in rice

S. Moon[1], K. Jung[1], D. Lee[1], H. Koh[2], G. An[1];
[1]Pohang University of Sci & Tech, Pohang, Republic of Korea, [2]Seoul National University, Seoul, Republic of Korea.

Rice is a major crop and a model plant for grass family. Recent completion of the rice genome sequencing revealed that rice genome contains about 16% transposon. But most of the transposable elements are inactive. In this report, we identified an active transposable element *delta-Tok*. *Delta-Tok* was inserted at the kinase domain of *MP2* that is homologue of *CLAVATA1,* causing multiple pistil mutant phenotype. *Delta-Tok* elements are members of the *Ds*-like transposable elements and short 664 bp long. *Tok* elements are about 3.5-4.0 kb long and contain an open reading frame encoding a putative transposase. Database search of *Nipponbare* identified 25 copies for *delta-Tok* and 9 copies for *Tok,* sharing terminal inverted repeat and subterminal domains. Our data suggest that *delta-Tok* and *Tok* are active transposable elements ubiquosly present in *Oryza* genus. These elements should have played important roles during evelotion and they may be used for insertional mutagenesis of rice.

P0142. Regulation of tobacco CDKA kinase activity by phosphorylation.

H. Harashima[1], K. Kawamura[1], M. Sekine[2], A. Shinmyo[1];
[1]Graduate School of Biological Sciences, Nara Institute of Science and Technology (NAIST), Nara, Japan, [2]Department of Bioproduction Science, Bioresources and Environmental Sciences, Ishikawa Prefectural University, Ishikawa, Japan.

We investigated the regulation of CDKA-associated kinase activity in tobacco BY-2 cells that had been partially synchronized by transferring stationary cells into fresh medium. We found that kinase activity of $p13^{suc1}$-bound proteins, which contain cyclin/CDKA complexes, increased significantly at the G1/S phase. Western analysis revealed that CDKA protein gradually accumulated during cell cycle re-entry, indicating that changes in protein levels were at least partially responsible for the elevated kinase activity. To determine whether post-translational modification of CDKA was also involved in modulating kinase activity, immunoblots were probed with phosphorylation-specific antibodies to either Tyr-15- or Thr-161-phosphorylated human Cdc2, the homolog of CDKA. While phosphorylation of Thr-161 increased rapidly during cell cycle re-entry, no phosphorylation of Tyr-15 was detected. These results suggest that CAK (CDK-activating kinase) activates CDKA kinase at the G1/S phase by phosphorylating Thr-161.

P0143. An E2F-Regulated reporter construct is transcriptionally activated following the transient expression of cyclin D in plants.

K. Kawamura[1], K. Uemukai[1], S. Kosugi[2], K. Kato[1], M. Ito[3], A. Shinmyo[1], M. Sekine[1,4];
[1]Graduate School of Biological Sciences, Nara Institute of Science and Technology(NAIST), Nara, Japan, [2]Institute of Advanced Biosciences, Keio University, Yamagata, Japan, [3]Graduate School of Bioagricultural Sciences, Nagoya University, Aichi, Japan, [4]Department of Bioproduction Science, Ishikawa Prefectural University, Ishikawa, Japan.

The E2F transcription factors play important roles in the regulation of gene expression in plants. Here, we show that the rice proliferation cell nuclear antigen (PCNA) promoter is activated by transient expression of tobacco NtE2F and Arabidopsis AtDPa in tobacco BY-2 cells. This transcriptional activation is repressed by co-transfection with a plasmid encoding the tobacco Rb-related protein (NtRBR1), whereas further co-expression of cyclin D overcomes this repression. Importantly, the rice PCNA promoter is activated when cells are transfected with cyclin D alone, and this activation is enhanced by co-transfection with plasmids encoding NtE2F and AtDPa. These results suggest that the effect of cyclin D expression is mediated not only by its associated kinase, which allows it to phosphorylate NtRBR1 thereby releasing the NtE2F/NtDP complex to activate transcription, but also by a mechanism which does not involve transfected NtRBR1.

P0144. Functional Analysis of CDK Inhibitors from *Arabidopsis Thaliana*

T. Nakai[1], A. Shinmyo[1], M. Sekine[1,2];
[1]Graduate School of Biological Sciences, Nara Institute of Science and Technology (NAIST), Nara, Japan, [2]Department of Bioproduction Science, Bioresources and Environmental Sciences, Ishikawa Prefectural University, Ishikawa, Japan.

Seven Kip-related protein genes (*KRP1-7*) encode *Arabidopsis* CDK inhibitors showing restricted similarities with an animal $p27^{Kip1}$. Here, we analyzed the functions of KRP proteins. To ascertain the significance of the C-terminal conserved region, we constructed deletion derivatives. Kinase-inhibition activity was lost in only 16 amino acids C-terminal deletion, whereas all tested N-terminal deletions retained the activity. Additionally, mutated proteins in KYNF/YD motif significantly reduced inhibition activity. These results suggested that inhibition of Cyclin/CDK was attributable to the C-terminal region, and KYNF/YD motif was essential. In binding assays, KRP1-7 proteins interacted with CyclinD2/CDKA complex but not with Cyclin D2 and CDKA protein alone. In kinase assays, GST-tagged KRP proteins inhibited kinase activity of Cyclin D2/CDKA and Cyclin D2/CDKB complexes in a different dose-dependent manner. Interestingly, GST-KRP1 and -7 proteins inhibited kinase activity of Cyclin D2/CDKA higher than that of Cyclin D2/CDKB. We will discuss the relationship between inhibition activity and binding ability to Cyclin/CDK complex in KRPs.

P0145. Protoplast culture and plant regeneration of the methionine resistant plantlets of *Astragalus melilotoides* Pall.

H. Jin[1], J. Jia[2];
[1]Shenzhen Fairy Lake Botanical Garden, Shenzhen, China, [2]Northwest University, Xi'an, China.

An efficient protocol for plant regeneration from protoplasts of the methionine resistant variant of *Astragalus melilotoides* was established. The friable calli induced from internode segments of variant plants were used for protoplast preparation. The protoplasts were isolated through enzyme digestion. Calli were formed after sustained divisions of protoplasts. High frequency of shoot differentiation was obtained from the protocalli on differentiated medium. The effects of different media, culturing methods and plating densities on protoplast divisions and plant regeneration were studied. The results show that agarose-beads culture method,KM8p medium supplemented with 1.0mg/L 2,4-D,0.5mg/L 6BA,0.3mol/L mannitol,2%(W/V)sucrose and 500mg/L casein hydrolysate at a plating density of 3×10^5 /mL are the appropriate conditions for protoplast division of the methionine resistant cell line. The division frequency is over 38%.The protoplast-regenerated plants still preserve resistance to methionine and ethionine. This research builds up the foundation for the resistant cell line as a parent of somatic hybridization.

P0146. Effects of *Chelidonium majus l.* extracts on the process of plants cells-division

A. Majd, S. Mehrabian;
Teacher training university, Tehran, Islamic Republic of Iran.

In this research we used ethanol and aqueous extracts of the root and shoot parts of *Chelidonium majusl*. Meristematic cells of Allium cepa`s young roots were treated by these extracts. Then the root tips were cut and fixed in glacial acetic acid: ethanol (1:3) for 24h and preserved in 70% ethanol for cytological preparation used of squash technique. 500 cells were analyzed for cell division and chromosome segregation results analyzed statically methods. Our results showed all cells treated 48-72 h by extracts were killed degenerated.

In cells that treated 24h, most of cells stopped in G2/M and couldn't complete their cell cycles and start cell division. Effects of root extracts were more than shoot extracts and effects of aqueous extracts were more than ethanol extract. All cell death phenomena were taken by Apoptosis. In third group (that treated by extracts for 4h) more cells stopped in Metaphase and the number of cells that stopped in G2/M were little. In control specimen all stages of a cell cycle were abundant and these cells continue their cycle which any block wasn't Sean.

P0147. Impact of ectomycorrhiza formation on monosaccharide transporter gene expression in poplar roots

U. Nehls, N. Grunze, M. Willmann;
Eberhard-Karls-Universitaet, Tuebingen, Germany.

Most trees of temperate and boreal forests form ectomycorrhizas, a symbiosis of plant fine roots with certain soil fungi. The essence of this interaction is the exchange of plant-derived carbohydrates for fungus-derived mineral nutrients.

Five monosaccharide transporter genes were isolated from poplar ectomycorrhizas by RT-PCR. The three most strongly expressed genes are up-regulated in symbiosis. The strongest effect was obtained with *PttMST3.1* (ten-times higher expression rate in non-infected roots compared to other genes), that revealed a further twelve-fold up-regulation by ectomycorrhiza formation. This strong increase of *PttMST3.1* expression in mycorrhizas, but not that of the other genes, requires an active plant/fungus interaction.

The up-regulation of hexose ransporter genes by mycorrhiza formation suggests, that root cells are able to compete with fungal hyphae for hexoses from the common apoplast during symbiosis. A hypothesis how the plant can coordinate sugar-efflux towards the fungal partner with a fungus-derived support with mineral nutrients at a local level will be presented.

P0148. Mutagenic Effects of Gamma Radiation in Mungbean (Vigna radiata (L) Wilczek)

A. J. Boddu[1], S. G. Auti[2];
[1]Padmashri Vikhe Patil College of Arts, Science & Commerce, Pravaranagar., Loni (Kd), Maharashtra State,, India, [2]Padmashri Vikhe Patil College of Arts, Science & Commerce, Pravaranagar., Loni (Kd), Maharashtra State,, India.

In the present investigation an attempt was made to induce mutations in mungbean (Vigna radiata (L) Wilczek) Variety Vaibhav,employing gamma radiation with an objective of obtaining novel and desirable mutants.Seeds of mungbean were irradiated with 30,40 and 50 kR doses of gamma radiation and sown in the experimental field to raise M1,M2 and M3 populations. Mutations were screened at three generations. All the three doses of gamma radiations were effective in producing various morphological mutations. But the 50 kR dose of gamma radiation was effective in producing a novel mutant that showed multiple morphological mutations like large sized flowers with dark yellow petals, dense thick hairy pods and black coloured seeds. They are named as lhb mutant (Large flowers,hairy pods and black seed mutants). Important morphological characters of lhb mutants are described and discussed in the text.

P0149. Towards a better understanding of nuclear mechanisms involved in legume seed development

O. Repetto[1], C. Firnhaber[2], H. Küster[2], C. Larré[3], R. Thompson[1], K. Gallardo[1];
[1]URLEG-INRA Dijon, 21000 Dijon, France, [2]Lehrstuhl für Genetik, Universität Bielefeld, D-33501, Germany, [3]URPVI-INRA, 44316 Nantes, France.

The quality of legume seeds is progressively established during seed development and the major seed proteins are known. However, the regulatory pathways controlling the expression levels of proteins related to seed development (e.g. storage proteins) are largely unknown and need to be investigated as a basis for improving legume seed quality traits. The aim of this work is to identify nuclear genes (e.g. transcription factors; modulators of chromatin structure) expressed at defined stages of seed filling in the model legume *Medicago truncatula*. These are under characterization by microarray-based analysis of nuclear gene expression and by affinity chromatography of nuclei enriched fractions followed by one- and two-dimensional electrophoresis. The identity of nuclear proteins will be determined from 2D gel fractionated spots by Quadrupole-Time Of Flight Mass Spectrometry and from protein extracts or 1D gel fractionated bands by nanoscale Liquid Chromatography tandem MS. The role of these nuclear genes in the control of seed development will be assessed by screening the TILLING collection in *M. truncatula* for mutants at the corresponding genetic loci.

P0150. Integrating New Knowledge into the rms Model of Branch Inhibition in Pea.

X. A. Johnson[1], E. Foo[2], M. Goussot[1], P. Grillot[1], S. E. Morris[2], C. A. Beveridge[2], C. Rameau[1];
[1]Institut National de la Recherche Agronomique, Versailles Cedex, France, [2]University of Queensland, Brisbane, Australia.

The study of shoot branching has primarily been the study of apical dominance and auxin inhibition. New mutants in pea (*ramosus*) and Arabidopsis (*more axillary branching*) are extending the signals involved in the control of this phenomenon. The anatomy and branching habit of pea makes it a practical model for physiological studies and the presence of an orthologous set of mutants in Arabidopsis allows for the cloning of these genes in pea using PCR techniques. The cloning of the *RMS* genes are providing evidence for new levels of regulation in the *rms* model and helping us to further elucidate this pathway of crosstalk that controls branching.

The *rms1* through *rms5* mutations increase both basal and aerial branching. This phenotype can be almost completely rescued by grafting a WT rootstock to *rms1*, *rms2* or *rms5* mutant shoots. The cloning and characterization of *RMS1*, *RMS4* and *RMS5* has provided us with new tools to test our hypotheses relating to IAA and IAA-independant regulation of branching.

P0151. Effect of Some Materials on *Sesamia cretica* Infesting Some Maize and Sorghum Varieties

H. A. Ezzeldin;
Fac.of Agriculture, Assiut, Egypt.

Effect of carbamate insecticide Methomyl,bacterial insecticide Agrein, Petrolium oil,Sisi6 and inorganic salt,Barium nitrate against the first and third larval instar of *S. cretica collected* from infested maize plants in the field.Results indicated that methomyl was the most toxic compound compared with the rest .LC50 values were 1.06x10^2 , 1.18x10^4 ,1.58x10^4 and 2.23x10^4 ppm for Methomyl,sisi6,Barium nitrate and Agrein,respectively.Effects of the same compounds against *S.cretica* on some maize and sorghum varieties were also tested in the field during 2002 and 2003 seasons.Results indicated that Methomyl was the most effective material in reducing the infestation representing89.73,92.92,83.29 and 92.30 % reduction during 2002 season on hybrid single 10,hybrid single 3080,hybrid third 313 and balady varieties of maize,respectively.The mean of reduction % in 2003 for Sisi6 and Barium nitrate were less than 46% in all tested varieties of sorghum.Factors affected reduction percentages of *S. cretica* and the recommended material for controlling the pest were discussed.

P0152. Transcriptional activation of tobacco E2F is repressed by co-transfection with the retinoblastoma-related protein

M. Sekine[1], K. Uemukai[2], H. Iwakawa[2], K. Kawamura[2], K. Kato[2], S. Kosugi[3], M. Ito[4], A. Shinmyo[2];
[1]Ishikawa Prefectural University, Nonoichimachi, Japan, [2]Nara Institute of Science and Technology (NAIST), Ikoma, Japan, [3]Keio University, Tsuruoka, Japan, [4]Nagoya University, Nagoya, Japan.

We have characterized NtE2F by using the tobacco PCNA promoter containing two E2F binding sites. Each E2F element conferred a different degree of contribution to the transcriptional activation, but mutation of both E2F elements greatly reduced the activation ability of the reporter gene at G1/S phase in synchronized tobacco BY-2 cells. Furthermore, in transient assays effective activation of the tobacco PCNA promoter was observed by co-transfection with the plasmids containing NtE2F and the newly identified tobacco NtDP. However, this transactivation is repressed by co-transfection with a plasmid encoding NtRBR1, and this repressor activity of NtRBR1 was cancelled when it was further co-transfected with a plasmid containing cyclin D but not with cyclin A or cyclin B. Our results suggest that two E2F binding sites in tobacco PCNA promoter are synergistically responsible for transcriptional activation at G1/S phase, and that, like mammalian cells, transfected cyclin D-associated kinase complexes probably phosphorylate NtRBR1, thereby releasing the E2F/DP complex to activate transcription.

P0153. Effects of P deficiency on cell production and expansion

M. Kavanová, A. A. Grimoldi, F. A. Lattanzi, H. Schnyder;
Lehrstuhl für Grünlandlehre, Technische Universität München, Freising - Weihenstephan, Germany.

Leaf expansion is severely inhibited by P deficiency, which can be alleviated by symbiosis with arbuscular mycorrhizal fungi (AMF). We tested whether leaf elongation rate (LER, mm h^{-1}) and its components: cell production rate (cell h^{-1}) and final epidermal cell length (mm $cell^{-1}$) are related to P concentration in the leaf growth zone of *Lolium perenne*, and whether these relationships are modified by AMF *Glomus hoi*. P concentration in the growth zone increased with increasing P supply and presence of AMF. LER was linearly related to P concentration in the growth zone and no P status-independent effects of AMF on LER were observed. P deficiency did not affect significantly meristematic cell size, and cells spent a longer time in the cell elongation zone due to a decreased displacement velocity. However, substantially reduced relative cell elongation rates resulted in a decreased final cell size in P deficient plants. Further, P deficiency decreased cell production rate, presumably due to lower cell division rates in the intercalary meristem. In conclusion, both cell production and cell expansion parameters were related to the P status of the growth zone.

P0154. The effect of cadmium and salicylic acid on some physiological parameters of Brassica napus

M. Ghorbanli[1], M. Farzami Sepehr[2], S. Akhond Nejad[3];
[1]Department of Biology, Faculty of Science,Islamic Azad University of Gorgan, Gorgan, Islamic Republic of Iran, [2]Department of Biology, Faculty of Agriculture,Islamic Azad University of Saveh, Saveh, Islamic Republic of Iran, [3]Department of Biology, Faculty of Science,Islamic Azad University of Tehran Shomal, Tehran, Islamic Republic of Iran.

Abstract:
In this investigation we studied the effect of cadmium and salicylic acid on some physiological phenomena of *Brassica napus* L.
In pot plants we measured the contents of Chl a , Chl b , carotene and Xantophyle contents in shoots and cadmium , proline and the activity rate of catalase and peroxidase enzymes and different growth parameters in shoot and root of treated plants .The lower concentration of SA increased of germination. On the other hand , the fresh weight of 10 days seedlings decreased with increasing of SA and Cd but the length of stem and fresh weight of 10 days seedlings increased at 50 µM SA. In pot plants with addition of 100µM Sa decreasing of dry weight , Chla , b , carotene ,xantophyle and proline contents were shown.
In 10 days seedlings , with increasing of Cd , the Chla contents decreased .With increasing of cadmium in soil , the cadmium contents in shoot and root of treated plants increased. Increasing of SA caused increasing of peroxidase activity in root but decreasing of this enzyme activity in shoot.

P0155. Promoter analysis of a JA- and ethylene-independent but wound-responsive tobacco peroxidase gene, *tpoxN1*

K. Sasaki[1,2], S. Seo[1,2], I. Mitsuhara[1,2], H. Ito[3], H. Matsui[3], Y. Ohashi[1,2];
[1]National Institute of Agrobiological Sciences, Tsukuba, Japan, [2]Program for Promotion of Basic Research Activities for Innovative Bioscience, Tokyo, Japan, [3]Department of Applied Bioscience, Graduate School of Agriculture, Hokkaido University, Sapporo, Japan.

Plants respond to mechanical wounding inducing accumulation of defense-related proteins including class III peroxidase (POX, EC 1.11.1.7). We isolated a tobacco *POX* gene, *tpoxN1*, whose expression is induced not only by infection of tobacco mosaic virus but also by wounding (Hiraga et al. 2000). Interestingly, *tpoxN1* transcript predominantly accumulated especially in stems within 1 h after wounding. But the induced expression was not affected by JA and ethylene (Sasaki et al. 2002), which are well known wound signals. Here, we show that wound-responsive cis-element of *tpoxN1* was present in the 49 bp at the proximal promoter region using transgenic plants carrying the *GUS* reporter genes driven by deletion series of the *tpoxN1* promoter. To the 49-bp fragment in *tpoxN1* promoter, wound-inducible nuclear factor(s) bound in a sequence specific manner in gel mobility shift assay. Competitive gel retardation assays indicated that the nuclear factor(s) bound 11-bp element in the 49-bp, which is also conserved in the distal region of the *tpoxN1* promoter. These results indicated that the 11-bp region would be important for the wound response of *tpoxN1* gene.

P0156. Physiological leaf spot in barley as a response to light stress.

M. G. Moran[1], J. I. Burke[2], P. J. Dix[1];
[1]Plant Cell Biology, Co. Kildare, Ireland, [2]Teagasc Crop Research Centre, Carlow, Ireland.

Physiological leaf spot (PLS) is a disorder of spring barley (*Hordeum vulgare* L.), which has become more pronounced in recent years. The initial symptoms are small chlorotic/brown spots on the upper four leaves, which may develop into necrotic lesions with an irregular shape. The symptoms do not necessarily occur every year and also vary in intensity between cultivars. A definitive aetiology for this disease has not yet emerged but it is suspected to have an abiotic origin as no microorganisms have been cultured from affected leaves. As PLS occurs on leaves that are directly exposed to sunlight it is thought high light stress could be a trigger for the condition. The study concentrates on two cultivars, Cooper and Crusader, which display differential sensitivity to PLS. A substantial difference in levels of ascorbate, type III peroxidases, and superoxide dismutase between the chosen cultivars was confirmed for the growing seasons 2003 and 2004. Current work is focused on looking at gene expression related to these biochemical findings.

P0157. The Effects of Salt Stress and Paclobutrazol on Some Morphological Parameters in Sensitive and Resistant Cultivars of Wheat

S. Hagihashemi[1], K. Kiarostami[1], S. Enteshari[2];
[1]Azzahra university, Tehran, Islamic Republic of Iran, [2]University department of agriculture of Valiasr, Rafsanjan, Islamic Republic of Iran.

The effect of salt stress and Paclobutrazol(PBZ) treatments in the two cultivars of wheat (resistant and sensitive to salt stress) were studied in this research. Wheat plants were irrigated with0,75,150 and 225 mmol / lit NaCl solutions and sprayed with 0,30,60 and 90 ppm Paclobutrazol then some morphological parameters were analyzed. Studied showed that in the sensitive cultivar salt stress caused reduction in fresh and dry shoot, root and sixth leaf weight, and shoot water content. While Paclobutrazol caused reduction in sixth leaf length and area, shoot length, special sixth leaf area and weight. We observed that Paclobutrazol increased fresh weight of shoot, root and sixth leaf weight, and water content of shoot and sixth leaf. Therefore we concluded that Paclobutrazol treatment can moderate the effect of salt stress on morphological parameters in sensitive cultivar of wheat.

P0158. Stress induced emission of biogenic VOC's - their temporal behaviour and the relation of VOC emissions from different biosynthetic pathways

G. Hummel[1], E. Kleist[1], H. Kneifel[1], R. Lawrenz[1], M. Miebach[1], S. Mönninghof-Pützer[2], D. Schlenkrich[1], J. Wildt[1];
[1]Institute Phytosphere, Jülich, Germany, [2]VWR International GmbH, Darmstadt, Germany.

Exposing plants (*Nicotiana tabacum* var. Bel W3, *Lycopersicon esculentum* var. Moneymaker, *Gossypium Hirsutum* var. Stoneville) to ozone induced VOC emission bursts. Ozone stress led to temporally increased emissions of methanol, VOC from the octadecanoid pathway (LOX products), methyl salicylate (MeSA) and sesquiterpenes. Aim of our work is to test whether or not good correlations exist between the stress induced emissions and plant internal precursor / signal molecules. Such good correlations would imply usage of gas phase data as a non-invasive tool for studying the activity and dynamics of biosynthetic pathways as response to abiotic or biotic stresses.
Using a computer assisted tool to develop or optimize HPLC methods for complicated separation (CHROMWORD HPLC software) we optimized the HPLC method. A lot of plant internal compounds were found to be increased in their concentrations after ozone stress. As a first result of our measurements we observed a good relationship between the content of salicylic acid in the plant and the emission of methyl salicylate.

P0159. Differential gene expression of transporters, the Halliwell-Asada pathway and iron homeostasis implicates Zn/Cd accumulation and tolerance in Arabidopsis halleri

K. Yeh, H. Chiang, S. Yang, J. Ruo;
Institute of BioAgricultural Sciences, Academia Sinica, Taipei, Taiwan Republic of China.

For survival, plants possess remarkable homeostatic mechanisms to maintain a suitable concentration of essential heavy metal ions in vivo. Certain plants, which accumulate very high levels of heavy metals have been named hyperaccumulators. By using Arabidopsis cDNA microarray, we compared the gene expression profiles of the hyperaccumulator, Arabidopsis halleri (ssp. halleri and gemmifera) with a non-hyperaccumulator, Arabidopsis thaliana. We demonstrate that differential regulation of genes involved in metal transport, translocation and antioxidation are associated the metal hyperaccumulation capacity in Arabidopsis halleri. Also, the activity of hydrogen peroxidases in Arabidopsis halleri was much higher than that in A. thaliana. The high peroxidase activity in A. halleri is also observed. This implicates the capacity to detoxify H2O2 produced in cadmium and paraquat treatments. Interestingly, Fe feedback regulation was observed in A. halleri.

P0160. LZF1, a light-regulated zinc finger transcription factor, acts downstream of HY5 in Arabidopsis

S. Wu, C. Chang, W. Huang, W. Chen;
Institute of Botany, Academia Sinica, Taipei, Taiwan Republic of China.

Global gene expression interrogation via DNA microarray has revealed genes with distinct or common patterns in photomorphogenesis. Our microarray data revealed that LZF1, a light- and HY5-dependent zinc finger protein, is up-regulated in response to light signal in Arabidopsis. Failed to be up-regulated in hy5 mutant plants, LZF1 apparently functions downstream of the bZIP transcription factor HY5. LZF1 is distally related to a group of more well-characterized transcription factors, the CONSTANS (CO) family. When the gene expression dosage of LZF1 is ectopically increased in Arabidopsis, the developmental program is severely affected by showing retarded growth and late flowering phenotypes. The accumulation of LZF1 protein exhibits a light-stable and dark-labile manner. LZF1-GFP protein is localized in the nucleus, which implies LZF1 functions inside the nucleus. Putative target genes of LZF1 are revealed by comparing the gene expression profiles of Arabidopsis cells with and without the overexpression of LZF1 proteins.

P0161. Investigating the role of a family of bHLH transcription factors in determining root epidermis cell fate.

L. Hoffmann, B. Menand, P. Linstead, L. Dolan;
John Innes Centre, Norwich, United Kingdom.

A major challenge in developmental biology is to understand the molecular basis of the specification and patterning of different cell types in multicellular organisms. In plants, the formation of the hair and non-hair cells in the Arabidopsis root epidermis is used as a simple model for studying cell fate specification. We have taken a genetic approach to investigate the molecular mechanisms that specifies cell fate in the root epidermis. We identified a family of basic Helix-Loop-Helix (bHLH) transcription factors acting at a late stage of the hair cell differentiation process. These include *ROOT HAIR DEFECTIVE 6* (*RHD6)* and four *RHD6-LIKE* (*RDL1, 2, 3* and *4)* proteins. My project is to understand how these transcription factors act in root hair development. Specifically, I will test the ability of RHD6 and RDL proteins to activate transcription, to form dimers, to be targeted to the nucleus and to bind DNA. I will use different approaches including yeast one- and two-hybrid systems, immunological techniques, DNaseI footprinting, microscopy and genetics.

P0162. Effectiveness of *Phragmites australis* plants in removing phosphates from a phosphate enriched aqueus solution and its relationship with photosynthetic metabolites

I. Nogués, C. Barta, F. Brilli, S. Fares, F. Loreto;
CNR – Istituto di Biologia Agroambientale e Forestale, Monterotondo Scalo (Roma), Italy.

Phytoremediation is the use of plants to remove pollutants and toxic materials from both soils and water. Excessive amounts of inorganic phosphorus in water can cause significant water quality problems, provoking reproduction and expansion in big quantities of algae and plants (eutrophication). Constructed wetlands for wastewater treatment are increasing all over the world, using aquatic plants as wastewater purifiers. On the other hand Phosphorus is an essential nutrient for plants that use it in different processes as photosynthesis.

In this study we have grown *Phragmites australis* plants under three different nutritional conditions: being supplied with 1 mg/l, 10 mg/l and 100 mg/l KH_2PO_4. A foliar analysis has been carried out to determine plant`s ability to assimilate this phosphate.

The total phosphate content in the leaves have been determined as well as the concentration of some photosynthetic metabolites as phosphoglyceric acid, pyruvate, ADP, ATP, glucose-6-phosphate. Preliminary results indicate that there is a direct relationship between the KH_2PO_4 levels in loads and both phosphate content in leaves and their photosynthesis.

P0163. Bioindication and biomonitoring studies carried out in rural and in urban sites by ozone sensitive clover clones (*Trifolium repens* cv Regal).

M. Vitale, M. Fabi, G. Gugliotta, F. Manes;
Dept. of Plant Biology - University of Rome, Rome, Italy.

This study has been carried out in the summer of 2001/04s by using O_3 sensitive white clover clones to estimate the O_3 effects on biomass and on frequency of leaf damage in natural, sub-urban and urban areas of Rome. All periods showed a Mediterranean climate having high values of temperature and solar radiation and scarce precipitations. This climate determined high values of O_3 concentrations with hourly average peaks up to 129 ppb, and an increase of O_3-induced leaf injury was also due to the establishing of limiting environmental conditions. The entity of leaf damage, however, turns out to be different in the areas. In urban and sub-urban sites, it was induced from the interaction of more factors, while in the rural ones it could be caused directly from O_3, taking into consideration also biogenic and anthropogenic volatile organic compounds. Temperature represents an important factor determining the entity of O_3-induced leaf injury on clover. Moreover, high atmospheric pollutants and temperature values along a linear gradient lasting coast to Rome urban area created a complex system that could mask the real O_3 effects on plants.

P0164. Arabidopsis gene *URO* promote the auxin response genes without increasing the concentration of free IAA

Y. Sun[1], Z. Yuan[2], B. Xu[2], W. Zhou[1], X. F. Li[1], H. Huang[2];
[1]life science college of East China Normal University, Shanghai, China,
[2]Shanghai Institute of Plant Physiology and Ecology of CAS, Shanghai, China.

The phytohormone auxin occupies a central place within plants' signaling transduction network. But we know little about the detail of the network. *uro* is an Arabidopsis semi-dominant mutant with some phenotype that always connected with auxin defaults . We found that there are strong epistasis DR-5 expression in whole young seedling and mature stem of *uro* mutant. At the same time, there are no evidence shows that the level of free IAA in *uro* is higher than in wild type, through IAA immunolocalisation test. *URO* gene promotes the auxin response genes without increasing the concentration of free IAA. *URO* gene may play an important role in connect auxin signal transduction pathway and the other signaling pathway. We cloned *URO* gene. it is an transcription factor with a C2H2 zinc finger domain. There is few homologous gene in other creatures besides plants. It is possible that the *URO* gene is a gene which carrying out a proper function of plants.

P0165. Studies for the conservation of Coccothrinax crinita ssp. crinita: an endangered Cuban palm.

A. Pinares[1], A. Leiva[1], J. Ortega[2], J. Roncal[2];
[1]National Botanic Garden of Cuba, Ciudad de la Habana, Cuba,
[2]Fairchild Tropical Garden, Miami, FL, United States.

The specie *Coccothrinax crinita* (Griseb. et Wendl. ex Wright) Becc. ssp. *crinita* is a palm endemic to Cuba. It is critically of threatened and appears in the list of species of most threatened palms of the insular territories of the Caribbean; because of this it is a priority for studying the conservation of this taxon. The goal of this research is to carry out a compare studies between natural population and *ex situ* population at the National Botanical Garden of Cuba to develop conservation programs. The studies were carried out in the collection of the Botanical Garden and in natural population. Important data were taken on the number of individuals, accompanying vegetation, risk factors and interference agents. Mature fruits were collected from both populations to carry out the germination assay and viability of the seeds. The chromosome number was determined by treatment of root tips.

Samples of healthy leaves were also collected for the study of genetic diversity by ISSR-PCR techniques. This results are very important for the conservation ex situ and in situ of *Coccothrinax crinita*. We to propose a new endangered category in relation with IUCN.

P0166. Cytokinin Signaling in Secondary Vascular Development

K. M. Nieminen[1], L. Kauppinen[1], M. Laxell[1], S. Tähtiharju[1], J. Immanen[1], Y. Helariutta[1,2];
[1]Institute of Biotechnology, University of Helsinki, Finland, [2]Department of Forest Genetics and Plant Physiology, Swedish University of Agricultural Sciences, Umeå, Sweden.

The secondary phase of plant development is initiated through the activation of a lateral meristem, the vascular cambium. Secondary vascular tissues are produced via cell divisions taking place in the cambium. The Arabidopsis genome encodes a cytokinin receptor gene family with three members (*CRE1/WOL/AHK4*, *AHK2*, *AHK3*). In a triple mutant lacking all three receptor genes, both the size and activity of apical meristems are reduced, consistent with the idea that cytokinins are positive regulators of meristem activity (Higuchi et al. 2004 PNAS USA 101: 8821-6).
We have investigated the role of cytokinin signaling in the secondary vascular development in two tree species, silver birch and poplar. We have identified from birch three (*BpHK1-3*), and from poplar five (*PtHK1-5*), genes which are highly homologous for the three Arabidopsis cytokinin receptor genes. We have shown that the *BpHK* genes are active in the cambial zone, and that the putative birch ortholog of CRE1, BpHK1, is functional as a cytokinin receptor in Arabidopsis. We are currently producing transgenic trees in which the cytokinin signaling is downregulated in the cambial zone.

P0167. Regulation of ion channels by ABC proteins in guard cells: Over-expression of AtMRP5 in tobacco increases drought sensitivity and decreases slow-anion channel activity.

S. Suh[1], A. Frelet[1], H. Grob[1], B. Mueller-Roeber[2], M. Klein[1], E. Martinoia[1];
[1]Institute of Plant Biology, University of Zurich, Zurich, Switzerland,
[2]Institute of Biochemistry and Biology, University of Potsdam, Potsdam, Germany.

Guard cells in the epidermis are responsible for the gas exchange and transpiration regulation. In Arabidopsis, AtMRP5 which is an ABC transporter belong to the multi-drug resistance protein (MRP) subfamily, expressed in guard cells. Knock-out mutants are more resistant to drought stress and stomata movement was insensitive to ABA and auxin. MRPs transport organic compounds using ATP, but are also candidates for modulating other membrane proteins, such as ion channels. To study in detail the mechanism of stomata modulation by AtMRP5, we over-expressed AtMRP5 in the *Nicotiana tabacum*. At both plant and leaf level, over-expression of AtMRP5 led to an enhanced transpiration rate. In AtMRP5 over-expression lines, stomata opened more in light and ABA dependent closure was reduced. Patch clamp technique was applied to test if ion channel activity is affected by over-expression of AtMRP5 in guard cells. K$^+$ outward current was slightly smaller in comparison to the wild type. In addition, the activity of slow anion channel was smaller in the AtMRP5 over-expressed plants. These results suggest that AtMRP5 contribute to the stomata opening by modulation of ion channels.

P0168. Development of microsatellite markers for assessing genetic diversity of alpine *Rhododendron* varieties

S. Fluch[1], K. Hristoforoglu[2], J. Wagner[3], M. Berenyi[1];
[1]ARC Seibersdorf research GmbH, Seibersdorf, Austria, [2]Höhere Bundeslehr- und Versuchsanstalt für Gartenbau, Vienna, Austria, [3]Leopold-Franzens-Universität Innsbruck, Institut für Botanik, Innsbruck, Austria.

Rhododendron hirsutum and R.ferrugineum are Rhododendron species endemic to alpine areas in Austria, Slovenia, Italy and Switzerland. The species is of ecological and economical interest, as, due to its natural habitat it can be used as plant cover for skiing slopes, where it prevents erosion. It is also of interest for gardeners for being planted in rock gardens.
In order to assess the existing genetic diversity of the species in Austria, we were developing a SSR marker system. We constructed an enriched library from Rhododendron spp. From this library, 176 clones were sequenced, but only 27 inserts showed microsatellite sequences of considerable length. The other 149 sequences only contained short repeats.
25 sequences were used for primer design. These primers were tested for variability on a restricted set of rhododendron accessions. 17 of the 25 designed primers revealed variable fragments in the chosen test set, but only 11 of these regions were producing a nice clear banding pattern and could be used for further analysis.

P0169. Protection of *Medicago truncatula* against *Fusarium acuminatum* and defense gene expression profiling in response to an elicitor from *Paenibacillus* sp. strain B2

S. Selim, S. Gianinazzi, D. van Tuinen;
UMR INRA 1088/CNRS 5184/Université de Bourgogne Plante-Microbe-Environnement CMSE-INRA, 17 rue Sully, BP 86510, 21065 Dijon Cedex, France, Dijon, France.

ABSTRACT
The ability of a plant growth-promoting rhizobacterium to induce plant resistance against a biotic stress was studied. An antagonistic lipo-polypeptide (paenimyxin factor) from *Paenibacillus* sp. strain B2 was used to elicit defence related responses of the model legume *Medicago truncatula*. For this purpose, a pathosystem between *M. truncatula* and *Fusarium acuminatum* was established. Plant roots were incubated with different concentrations of the paenimyxin factor for 24 hrs prior to inoculation with *F. acuminatum*. At a concentration of 1 µM, paenimyxin had a protective effect, suppressing 95% of the morphological infection symptoms, whereas, the factor had an inhibitory effect on plant growth at a concentration higher than 10 µM. Plant gene expression was quantified by semiquantitative RT-PCR. Genes involved in the biosynthesis of phytoalexins (PAL, CHS and CHR), coding proteins having an antifungal activity (pathogenesis-related proteins and chitinase) or cell wall invertase were highly upregulated after the paenimyxin treatment. The mechanism involved in plant protection by the paenimyxin factor against *F. acuminatum* are discussed.

P0170. Early events in the molecular interaction between the biocontrol agent *Trichoderma harzianum* and soybean cells

L. Navazio[1], B. Baldan[1], R. Moscatiello[1], A. Zuppini[1], S. L. Woo[2], P. Mariani[1], M. Lorito[2];
[1]Dipartimento di Biologia, Universita' di Padova, Padova, Italy,
[2]Dipartimento di Arboricoltura, Botanica e Patologia Vegetale, Sez. Patologia Vegetale, Universita' di Napoli Federico II, Portici (Napoli), Italy.

Trichoderma spp. are commercially applied as biopesticides to control a variety of plant pathogens. The effects of *Trichoderma* colonization on plants include an improvement of plant growth and metabolism and the induction of systemic and localized resistance to phytopathogenic fungi, bacteria and viruses. We investigated the early events occurring during the interaction between *Trichoderma harzianum* and cultured soybean cells, by applying to cells the culture media of this fungus, grown alone or in direct antagonism with the necrotrophic pathogen *Botrytis cinerea*. The results indicate that molecules released in the fungal culture media are perceived by plant cells as elicitors and activate a Ca^{2+}-mediated signalling. Specific responses such as intracellular H_2O_2 accumulation and programmed cell death involving caspase-like proteases are triggered downstream the Ca^{2+} signal. Both Ca^{2+} signature and cell responses are modified by the addition to cells of the culture medium from a knock-out mutant of *Trichoderma*, defective for the production of a 42-kDa endochitinase.

P0171. Resistance to potato late blight detected in a wild potato genetic resource, *Solanum caripense*: preliminary results

J. Nakitandwe;
ARC, Seibersdorf Research, G.m.b.H., Seibersdorf, Austria.

Resistance to *Phytophthora infestans,* causing late blight, exists in the gene pool of wild *Solanaceae*. . However, only a small number of these have been used so far for introgression of resistance (R) genes into cultivated potato, *Solanum tuberosum*, leaving late blight a big constraint all over the world. We are locating genes for resistance to *P. infestans* in *S. caripense*, a wild, non-tuber-bearing relative of potato and tomato. On a biparental population of 206 siblings, AFLP and SSR primers were used to obtain 360 markers for construction of a genetic linkage map. The markers mapped on eleven linkage groups for the maternal, and all twelve for the paternal parent. Resistance tests with four *P. infestans* isolates revealed high intensities of sporulation on susceptible plants regardless of lesion size, suggesting that the resistance in question may directly be sporulation-related. The maps will be used to locate genetic markers associated with resistance and enable gene isolation and cloning.

P0172. Comparative expression profiling of rice near isogenic lines reveals genes related to bacterial blight and fungal blast resistance

N. Y. Zeng[1], M. Y. Cheung[1], K. K. Wong[2], K. J. Zhao[1,3], C. L. Lei[3], S. M. Chow[1], Q. Zhang[3], Z. Z. Ling[3], S. S. M. Sun[1], **H. M. Lam**[1];
[1]Department of Biology, The Chinese University of Hong Kong, Shatin, Hong Kong Special Administrative Region of China, [2]Department of Pediatrics, Section of Hematology/Oncology, Baylor College of Medicine, Houston, TX, United States, [3]Insitute of Crop Science, The Chinese Academy of Agricultural Sciences, Beijing, China.

Comparative cDNA microarray analysis was performed to study the possible correlation between gene expression profiles and rice disease resistance related phenotypes. Near isogenic lines carrying different *Xa* (resistant to bacterial blight) or *Pi* (resistant to fungal blast) genes, and their susceptible parents were analyzed in parallel to minimize differences due to variation in genetic backgrounds. Clustering analysis showed that different disease resistance related phenotypes exhibited distinct gene expression profiles, providing evidence to support the notion that global transcriptional re-programming is a major component of signal transduction leading to disease resistance. Classification analysis was also adopted in this study and successfully identified reporter clones with high prediction power. Using the combined advantages of unique genetic materials collected and the power of cDNA microarray technology, we have set up the prototype of a research platform that can be used to perform comparative analysis of disease resistance related phenotypes based on gene expression profiling, and to identify important genes in due course.

P0173. Contribution of target transgene position and structure to RNA-directed promoter methylation and TGS

U. Fischer[1], R. Schmidt[2], **M. F. Mette**[1];
[1]Institute of Plant Genetics and Crop Plant Research, Gatersleben, Germany, [2]Max-Plank-Institute of Molecular Plant Physiology, Golm, Germany.

RNA-directed transcriptional gene silencing (TGS), the repression of transcription of a gene in correlation with promoter DNA methylation in the presence of double stranded (ds) RNA with homology to the respective promoter, has been studied extensively in plant transgene systems employing the nopaline synthase promoter (NOSpro) in Arabidopsis thaliana and tobacco. Not all target transgenes show the same susceptibility to RNA-directed TGS, indicating that the chromosomal location of target transgenes and / or the particular arrangement of NOSpro copies in the target transgenes might contribute to the silencing process. Well-characterized target transgenes with the same structure integrated at different chromosomal positions or with differing structures integrated at the same chromosomal positions are presently being challenged by a silencer transgene providing NOSpro dsRNA in Arabidopsis thaliana. Current results of the analysis of induced transcriptional repression and NOSpro DNA methylation will be presented. The work is supported by DFG grant SFB 648 TP C4.

P0174. Centromere breakage and gene silencing induced by T-DNA insertion in *Arabidopsis thaliana*

M. Murata[1,2], E. Yokota[2], F. Shibata[2];
[1]Research Institute for Bioresources, Kurashiki, Japan, [2]CREST/JST, Kawaguchi, Japan.

In addition to two aberrant chromosomes, two types of minichromosomes were generated by T-DNA insertion into the major centromeric satellite of chromosome 2 in *Arabidopsis thaliana*. FISH (fluorescence *in situ* hybridization) with 5S and 18S rDNAs and BAC clones as probes clearly revealed that both of the minichromosomes have originated from the short arm of chromosome 2 (2S). One minichromosome (mini2S-A) contained the whole short arm, but the size of the satellite (180-bp repeat) cluster was much shorter (<1 Mb) than that of the original chromosome 2. The inserted T-DNA was found at the distal end of the satellite that has been healed with telomeric DNA. This suggests that the T-DNA insertion induced the centromere dysfunction and breakage. Interestingly, expression of both *GFP* and *nptII* genes on the inserted T-DNA were suppressed in some of the transformed plants, but not in others. The state of the transgenes is now being analyzed, but this sort of gene silencing must be induced by chromatin and DNA modifications between the centromeric and *de novo* telomeric regions.

P0175. The Mobility of a Non-TIR Mutator-like DNA Transposon in Arabidopsis

K. Park, B. Thomas;
McGill University, Montreal, PQ, Canada.

Most Mutator-like elements (MULEs) are characterized by terminal inverted-repeats (TIRs) and the generation of a target site duplication (TSD) upon insertion. However, in the Arabidopsis and other plant genomes, some MULEs appear to lack TIRs but have the same characteristic TSD length and the MULE-specific transposase gene, mudrA. We show that a DNA transposon called non-TIR MULEs in Arabidopsis, acquired a host gene encoding a polypeptide with a conserved peptidase-C48 domain characteristic of ULP-like host genes. In order to confirm whether these MULEs are active, a transposon display technology was employed to map any new insertion or excision event in wildtype (ecotype Columbia-0) and in mutant backgrounds known to activate mobile elements; namely ddm1, met1, cmt3 and a met1/cmt3 double mutant. From this survey one member from one MULE family was found to be mobile and only in the cmt3/met1 double mutant background. This is the first indication of non-TIR MULE mobility.

P0176. Chlorophyll a fluorescence proves that growth-promoting endophytes alleviate Cd stress in Cicer arietinum Linn.

M. K. Rai[1], R. J. Strasser[2], D. Dangre[1];
[1]Amravati University, Amravati, India, [2]Department of Bioenergetics, University of Geneva, Switzerland.

Chl a is used as rapid and non-destructive biomarker for the assessment of stress caused by different environmental factors. Cd stress was induced in *C. arietinum* (Chick-pea), which is the third important crop of India. Stress of Cd causes chlorosis and necrosis to the plants.

The chl a measurements were taken after 10 days of inoculation with the help of Handy PEA. Cd stress was given to each plant after 14 days from sowing, excluding control (without stress) of each variety. The concentration of Cd was increased after a period of 5 days by 10 µg to increase stress. We used *Piriformospora indica, Glomus caledonium* and *Glomus mosseae* as inocula to evaluate effect of Cd stress on *C. arietinum*. The observations were recorded in Handy PEA at the regular interval of 7 days up to 30 days. But when Cd conc. was increased to 100 µg, observations were recorded on each 4th day. The fluorescence rise was analyzed by ‘Biolyzer’ program.

The main aim of the present study was to assess the efficiency of endophytes on *C. arietinum* exposed to Cd stress.

P0177. Direct Shoot Organogenesis for Aster ericoides cultivar “Monte Cassino”

R. J. Salazar Fernández, T. E. Vargas, M. Oropeza;
Instituto de Biología Experimental, Universidad Central de Venezuela, Caracas, Estado Miranda, Venezuela.

Direct organogenesis was induced from "in vitro" leaf explants of Aster ericoides cultivar “Monte Cassino” cultured on MS (1962) medium supplemented with 6-bencilaminopurine (BA) (2,5 mM, 4,5 mM), a-naphthaleneacetic acid (NAA) (2,5 mM, 1 mM), indole-3-acetic acid (IAA) (17,1 mM) and gibberellic acid (GA) (14,43 mM) and then solidified with agar (6 g l-1) or gelrite (2 g l-1). After 30 days, the best response to direct shoot induction was observed on MS medium supplemented with BA 2,5 mM and NAA 2,5 mM. In this medium was got an average of 4 shoots (10%) after 45 days of culture. On MS medium supplemented with GA 14,43 mM and BA 2,5 mM solidified with agar, the shoots also developed directly from explants (7 %), but they were hyperhydrated. The highest number of shoots (17% and 33%, respectively) was obtained on MS medium supplemented with BA 2,5 mM and NAA 1 mM and solidified either with agar or gelrite, but they developed from callus tissue. These results show that direct organogenesis is obtained on MS medium with BA and ANA. Also, direct organogenesis is obtained on MS medium solidified either with agar or gelrite, but the gelrite contributes to shoots vitrification.

P0178. Boundaries and phyllotaxy in Arabidopsis

A. Peaucelle, H. Morin, K. Nikovics, J. Traas, P. Laufs;
INRA, Versailles, France.

In plants the arrangement of organs around the stem (phyllotaxy) follows a predicted pattern.

We studied phyllotaxy in Arabidopsis WS ecotype and observed variability in the phyllotaxy pattern. Then we characterised mutants -pny/blr, caf1/dcl1 and hyl1- presenting altered phyllotaxy: clusters of primordia and random divergence angle between successive primordia. All three mutants present a common feature: enlarged boundaries characterised by wider CUC1 and 2 expression domains. Partial complementation of the abnormal phyllotaxy in hyl1 and pny was obtained by reducing the boundary domain. Furthermore phenocopies of the mutant were obtained by inducting the enlargement of the boundary domain in wild-type plants.

These results suggest the existence of a feedback mechanism linking the boundary domain with the process of phyllotaxy control. As auxin has been shown crucial for phyllotaxy, we are currently investigating the involvement of auxin in this mechanism.

P0179. The planktonik and bentic organisims of Lake Van

A. Ozturk[1], P. Battal[2];
[1]Yuzuncu Yil Universitesi, Fen-Edebiyat Fakultesi, Biyoloji Bolumu, 65080,, Van, Turkey, [2]Yuzuncu Yil Universitesi, Fen-Edebiyat FAkultesi, Biyoloji Bolumu, 65080,, Van, Turkey.

In the present study, the identification of approximately 70 taxa were identified. Most of them are phytoplankton. The specimen were collected from Lake Van between 1990 and 1995. The specimen were identified under light microscope and phographed. The identification of specimen were made in species, genus and/or family.

Water samples were collected from different altitude in selected 18 stations of Van Lake between 1990-1995 collected and identified planctons and their density are given on tables. The highest number of genus or species are following:

1. Oscilatoria limosa
2. O. tenuis
3. Anabaena affinis
4. Spirulina major
5. Microcystis sp.
6. Closterium sp.
7. Cymatopleura sp.
8. Navicula sp.
9. Synedra sp.
10. Cyclotella sp.
11. Gleocapsa sp.
12. Anchistrodesmus sp.
13. Pinnularia sp.
14. Colurella sp.

The preparates of samples has been performed and their photograpies were taken.

P0180. Characterization of candidate transcriptional regulators of stem development and fiber differentiation in Arabidopsis thaliana

C. J. Douglas[1], E. Li[1], J. Ehlting[2,1];
[1]University of British Columbia, Vancouver, BC, Canada, [2]Institut de Biologie MolÃ©culaire des Plantes, C.N.R.S., Strasbourg, France.

Stages of vascular and interfascicular fiber differentiation can be identified along the axis of bolting stems in Arabidopsis. To gain insights into the regulatory events that control this pattern, we used transcript profiling employing an Arabidopsis full genome longmer microarray to assay global changes in gene transcription over the course of stem development and fiber differentiation. Among 5000 differentially expressed genes, we identified 182 up-regulated transcription factors (TF) that represent candidate regulators of fiber development. A subset of these TF candidates has been associated with fiber development and/or secondary wall formation in other studies. These candidates in include members of the MYB, bHLH, AP-EREBP, KNAT, and C3H families. T-DNA knockout lines of most candidates have been identified and are under analysis to determine if and how these genes control fiber differentiation. We have also identified putative orthologues of many of the candidate TF in the completed poplar genome sequence. Investigation of these genes will allow greater insight into their potential roles in secondary wall and wood formation in this model tree.

P0181. Target specificity of RNA silencing in transgenic plants with coat protein gene of *Sweet potato feathery mottle virus*

M. Nishiguchi[1], T. Kake[1], A. K. N. Haque[1], Y. Tanaka[2], S. Sonoda[3];
[1]Ehime University, Matsuyama, Japan, [2]Wakasa Ener.Res.Cen., Tsuruga, Japan, [3]Okayama University, Kurashiki, Japan.

We have previously reported the graft transmission of the target specificity of RNA silencing in transgenic *Nicotiana benthamiana* plants with the coat protein (CP) gene of *Sweet potato feathery mottle virus*. To furthter characterize its transmission, we first investigated a silenced line of 4.09, of which the target specificity is the 3’ 400 bp of the transgene. Northern blot analysis showed a RNA band (700 bp) in this line shorter than that (1,200bp) of a high expressor (4.11). Further analysis with different probes showed that the RNA band hybridized with the 5’ 400 bp but not with the 3’ 400 bp of the CP gene. Secondly transgenic silenced lines with 5’ part of the CP gene were produced and grafted onto 4.09 rootstocks. No changes of RNA banding patterns in scions and rootstocks were observed, indicatiing no interactions of silencing signals between the two different silenced lines. Grafting of 4.09 scions onto the silenced scions with the 5’ part is in progress to see any further degradation of RNA from the 5’ part of the transgene in 4.09. The results will be presented and discussed in relation to the transmission of target specificity for RNA degardation.

P0182. Phospholipase C from Physcomitrella patens: physiology and knockout

C. Brüggemann, M. Hau, A. Repp, E. Hartmann;
Institut für Biologie - Pflanzenphysiologie, Freie Universität Berlin, Germany.

In eukaryotes phosphoinositide-specific phospholipase C (PI-PLC) plays an important role in various signal transduction pathways. Plant PI-PLCs are part of signalling osmotic stress, gravity- and light perception. The moss Physcomitrella patens contains at least five genes encoding PI-PLCs, four of which are sequenced. Analysis of the amino acid sequences revealed two separate groups (PpPLC1 and 4, PpPLC2 and 3). One member of each group was characterised enzymatically (PLC1 and PLC2), showing that they belong to biochemically different PLCs (Mikami et al. 2004).

We generated plc1, plc2 and plc3 gene-targeted knockouts via homologous recombination in Physcomitrella. The loss of PpPLC1 results in developmenting defects implying a role in cytokinin signalling, gravitropism and chloroplast development (Repp et al. 2004). The knockout of PpPLC2 has no obvious phenotype under standard growth conditions. However, the treatment with stress mediating substances like abscisic acid or mannitol, indicated that PpPLC2 is involved in ABA-dependent stress signalling. The physiological role of PpPLC3 is currently under investigation and will be discussed.

P0183. Effect of three AM fungi on growth, distribution of glandular hairs and essential oil in *Ocimum basilicum* L. var. Genovese

A. Copetta, G. Lingua, G. A. G. Lanati, G. Berta;
Università del Piemonte Orientale, Alessandria, Italy.

The essential oils of basil are widely used in the cosmetic, pharmaceutical, food and flavouring industries. Little is known about the potential of arbuscular mycorrhizal (AM) fungi to affect the production of essential oil in aromatic plants. The effects of colonization by three AM fungi *Glomus mosseae* BEG 12, *Gigaspora margarita* BEG 34 and *Gigaspora rosea* BEG 9 on shoot and root biomass, abundance of glandular hairs and essential oil yield of *Ocimum basilicum* L. var. Genovese were studied. The AM fungi induced various modifications of the considered parameters, but only *Gi. rosea* significantly affected all of them in comparison with control plants or the other fungal treatments. It significantly increased biomass, root branching and length, and the total amount of essential oil (especially camphor and Ŭ-terpineol). Increased oil yield was associated to a significantly larger number of peltate glandular trichomes (main sites of essential oil synthesis) in the basal and central leaf zones. Results showed that different fungi can induce different effects on the same plant and that the essential oil yield can be modulated according to the colonizing AM fungus.

P0184. Arbuscular mycorrhizae in non-mycotrophic plant species

D. Püschel, J. Rydlová, M. Janoušková, M. Vosátka;
Institute of Botany, Academy of Sciences, PrŢhonice, Czech Republic.

Arbuscular mycorrhizal (AM) symbiosis is supposed to be the most widespread mutualistic relationship in plant kingdom, however, members of some plant families do not normally form mycorrhizae. Non-mycotrophic plant species are the first colonisers of newly established man-made ecosystems, which lack AM fungi. Interaction of AM fungi with non-mycotrophic species iniciating primary succession on coal-mine spoil banks (*Atriplex sagittata*, Chenopodiaceae and *Sisymbrium loeselii*, Brassicaceae) was studied in two microcosm experiments. These plants were inoculated either 1) with spores, fragments of extraradical mycelium (ERM) and colonised root pieces (the way commonly used in most experimental studies) or 2) via the network of ERM pre-established on a mycotrophic plant. The results show that both non-mycotrophic plant species can be colonised via the ERM network and form fully developed mycorrhizal structures including arbuscules. Temporal development of intraradical colonisation and effect of AM on plant growth differed between plant and fungal species.

The research is supported by grant No 526/04/0996 (Grant Agency of the Czech Republic).

P0185. Plastid reorganization in root cortical cells colonized by arbuscular mycorrhizal fungi

T. Fester;
Leibniz-Institute of Plant Biochemistry, Halle, Germany.

Plastids are reacting to the colonization of root cortical cells by arbuscular mycorrhizal (AM) fungi by (i) a marked proliferation leading to network-like organelle structures and (ii) the biosynthesis of AM-specific apocarotenoids of unknown functions. The combination of metabolite and transcript profiling revealed that apart from apocarotenoids, plastids produce higher amounts of fatty acids and amino acids in AM roots. These compounds are apparently necessary for formation of the symbiotic interface, explaining the marked multiplication of lens-shaped plastids close to young arbuscules. Apocarotenoid formation, in contrast, is activated during the later phase of arbuscule degradation. The tubular plastids formed then are in part decorated by rings of the plastid division protein FtsZ and thus possibly involved in repeated fusion/division events. Plastid metabolism, in this phase, is possibly involved in recycling degraded fungal material. Formation of apocarotenoids during arbuscule degradation might be connected to the concomitant accumulation of hydrogen peroxide.

P0186. Gene expression in arbuscular mycorrhizal fungi

A. Klüver[1], M. Tamasloukht[1,2], D. Sieh[1], G. Bécard[3], P. Franken[1];
[1]Insitute of Vegetable and Ornamental Crops, Großbeeren, Germany, [2]Federal Institute of Technology (ETH) Zurich , Institute of Plant Sciences, Lindau, Switzerland, [3]Equipe de Mycologie Végétale, UMR 5546 CNRS/Université Paul Sabatier, Castanet-tolosan, France.

Arbuscular mycorrhiza (AM) is a mutualistic symbiosis between roots of most vascular land plants and obligate biotrophic fungi of the phylum Glomeromycota. In order to elucidate the molecular basis of the interaction, we are studying gene expression patterns. Three projects will be presented which are focussed on the identification and characterization of fungal genes. Differential display analysis indicated that fungal respiratory pathway genes are induced by root exudates in the presymbiotic phase of *Gigaspora rosea*. These results were confirmed by oxygraphy and staining of mitochondria. Numerous genes were identified in extraradical hyphae of *Glomus intraradices* during the symbiotic phase by suppressive subtractive hybridization, which are suggested to be involved in biofertilization and bioprotection. A family of GST encoding genes could be identified which were induced by heavy metals. A third project deals with the intraradical hyphae and a number of genes involved in C metabolism of the fungus have been characterized by Real Time PCR.

P0187. Mitochondrial large subunit rDNA sequences as novel marker genes in the Glomeromycota

P. A. Raab, A. Brennwald, D. Redecker;
Botanical Institute, Basel, Switzerland.

Partial sequences of the large subunit of mitochondrial rDNA (mtLSU) were obtained from the arbuscular mycorrhizal fungi Glomus proliferum and Glomus intraradices (Glomeromycota) cultivated in root organ cultures. Three isolates of G. intraradices were analyzed. There was no evidence of intra-isolate sequence heterogeneity as it is found in variable regions of nuclear ribosomal genes in the Glomeromycota.

In G. intraradices, but not in G. proliferum, two introns were found in the partial mtLSU sequence. One of them contained an ORF for a putative site-specific endonuclease of the LAGLIDADG family. Phylogenetic analysis of the endonuclease sequence showed its closest known relatives to be hosted in other fungal mitochondrial introns.

The apparent absence of intra-individual variation and the gene structure of alternating short conserved and variable regions with strong length variation make the mtLSU valuable as a future marker gene for molecular identification purposes. The intronic sequences may be useful as an even more sensitive molecular marker for phylogeography and population studies.

P0188. Root exudates of mycorrhizal tomato plants exhibit a different effect on Fusarium oxysporum f. sp. lycopersici than root exudates from non-mycorrhizal tomato plants

S. Scheffknecht, R. Mammerler, S. Steinkellner, H. Vierheilig;
Institut für Pflanzenschutz, Wien, Austria.

Compounds in root exudates are important signals in plant-microbe interactions. Thus, changes in the root exudation pattern can affect the outcome of plant-microbe interactions.

Root colonization by arbuscular mycorrhizal fungi changes the root exudation pattern of plants. Root exudates of mycorrhizal plants have been shown to exhibit a different effect on the hyphal growth of AM fungi, on sporulation of Phytophthora species and chemotropism of bacteria and zoospores, than root exudates from non-mycorrhizal plants.

We found that root exudates of mycorrhizal tomato plants differently affect the spore germination of Fusarium oxysporum f. sp. lycopersici than root exudates from non- mycorrhizal tomato plants. This effect did not dependent on the improved P-status of the mycorrhizal tomato plant. A first characterization of the bioactive compounds was performed.

The impact of alterations of the root exudation pattern in mycorrhizal plants on soil microorganisms is discussed.

P0189. Enhanced Hexose Supply in Tobacco Roots has no Effect on Mycorrhization

S. Schaarschmidt[1], U. Sonnewald[2,3], B. Hause[1];
[1]Leibniz Institute of Plant Biochemistry, 06120 Halle (Saale), Germany, [2]Institute of Plant Genetics and Crop Plant Research, 06466 Gatersleben, Germany, [3]current address: Friedrich-Alexander-University Erlangen-Nürnberg, 91054 Erlangen, Germany.

In the mutualistic association of arbuscular mycorrhiza (AM), the fungus assists the plant with the acquisition of mineral nutrients from the soil, whereas the plant supplies the fungus with carbohydrates. Sucrose is most likely hydrolyzed by apoplastic invertases and hexoses are then taken up by intraradical fungal structures.

To analyze the role of invertases in the mycorrhizal association, we used transgenic tobacco (*Nicotiana tabacum*) plants expressing an apoplast-located yeast-derived invertase under the control of the inducible *alc* promoter system derived from *Aspergillus nidulans*. After root-specific induction of the invertase, an enhanced invertase activity and an increase in the ratio of hexoses to sucrose was found. Upon inoculation with *Glomus intraradices*, however, the altered sugar levels did not show any effect on the mycorrhization degree and the formation of fungal structures. Moreover, the contents of AM-specific free fatty acids and fungus-induced cyclohexenones remained unchanged.

P0190. The effect of mycorrhization on the production of essential oils in herbal plants

T. Khaosaad[1], H. Vierheilig[1], J. Novak[2];
[1]Institut für Pflanzenschutz, Vienna, Austria, [2]Institute for Applied Botany, Vienna, Austria.

In the production of essential oil crops three parameters are of importance, the composition of the essential oil, the content of the essential oil in the plant and the essential oil yield as the product of content and the production of biomass. Arbuscular mycorrhizal fungi (AMF) do not only affect plant growth, but also the accumulation of secondary plant compounds from different chemical groups. We tested the effect of an arbuscular mycorrhizal fungus on yield and essential oil composition of two economic plants, oregano and sage, both used as medicinal as well as aromatic plants. Plants were inoculated with AMF (Glomus mosseae)and kept in the greenhouse and fertilized with a standard nutrient solution without phosphor (control group and AMF group) and a standard mix with phosphorous to be able to compare any effect with the effect of phosphorous fertilization. The shoot dry weight, the P-concentration in the shoot, the degree of root colonization by the AMF and the qualitative and quantitative content of essential oils in leaves were determined.

P0191. Influence of pesticides on arbuscular mycorrhiza of selected Populus clones and soil microbial community structure

B. Kieliszewska-Rokicka[1,2], M. Welc[2], J. Figaj[1], J. Larsen[3], S. Ravnskov[3], S. Stobiecki[4], L. Rachwaǧ[1];
[1]Institute of Dendrology, Polish Academy of Sciences, Kórnik, Poland, [2]Institute of Biology and Environmental Protection, Academy of Bydgoszcz, Bydgoszcz, Poland, [3]Danish Institute of Agricultural Sciences, Research Centre Flakkebjerg, Slagelse, Denmark, [4]Institute of Plant Protection, PoznaŒ, Poland.

Selected *Populus* species and hybrids may have a high potential for phytoremediation of soils and groundwater contaminated by pesticides. As poplars in nature form both, ectomycorrhizal (ECM) and arbuscular mycorrhizal (AM) symbioses, the tolerance of mycorrhizal fungi and associated bacteria to the xenobiotics is one of key condition in application programs. In this study four poplar clones, inoculated by indigenous mycorrhizal fungi and by and introduced AM isolate (*Glomus intraradices,* BEG 87) were grown in soil highly contaminated by pesticide substrate, originated from a pesticide tomb in Poland. The degree of colonisation of roots by mycorrhizal fungi, estimated both, by microscopic observation and by signature lipid fatty acids analyses indicated inhibition ECM development and significant decreased of AM colonisation by indigenous mycorrhizal fungi in contaminated soils. The introduced AM isolate revealed a considerable tolerance to the pollutants. The response of AM colonisation to the pesticides varied with the poplar clones. Significant decrease of fungal and bacterial specific lipid fatty acids in the contaminated soils was also observed.

P0192. Interaction of endomycorrhizal fungi and salt stress on nutrient acquisition and growth of *Pistacia vera L.*

H. Abbaspour, F. Fallahyan, H. Fahimi;
Azad University (Science and Research Branch and Damghan Branch), Tehran, Islamic Republic of Iran.

Salt stress is considered as one of the most important abiotic factors limiting plant growth and yield in many areas of the world. It has been shown that vesicular arbuscular mycorrhizal(VAM) fungi decrease plant yields losses under salinity. The effects of VAM *Glomus etunicatum* inoculation on growth and mineral acquisition of *Pistacia vera L.* grown under salinity condition was studied. Different concentration of NaCl as 0(control), 50(low), 100 (medium) and 200mM(high) were employed for salinity stress. Plants were grown in a sterilized, low-P sandy soil in a greenhouse. The mycorrhizal colonization was higher in the control than in saline soil conditions. Dry weight of shoots, roots and also leaf area of mycorrhizal(M) plants were higher than nonmycorrhiza(NM) ones in both control and salinity conditions. The contents of N, P, K, Zn and Fe were higher in M than NM plants in control, low and medium salinity conditions. Concentration of Na in shoots of M plants was lower than NM grown under salinity condition. Generally, it can be said that M plants of *Pistacia vera* showed higher tolerance toward salinity than NM plants and their growth improved by VAM colonization.

P0193. Involvement of auxins in signaling during AM symbiosis

J. Ludwig-Müller[1], M. Güther[1], J. J. Campanella[2], L. Hull[2], S. Wexler[2], S. M. Smith[2], M. Kaldorf[3];
[1]Technische Universität, Dresden, Germany, [2]Montclair State University, Montclair, NJ, United States, [3]Universität Leipzig, Leipzig, Germany.

The establishment of an arbuscular mycorrhizal (AM) symbiosis requires a continuous exchange of signals between host roots and fungi. Plant hormones might be suitable candidates for such signals. Inoculation of Zea mays with Glomus intraradices resulted in the significant increase in the percentage of lateral roots during early stages of colonization which coincided with an increase in the levels of the auxin indole-3-butyric acid (IBA). Addition of TFIBA, an inhibitor of IBA-induced root growth and lateral root induction, to roots inoculated with AM-fungi reduced the formation of fine roots and the amount of endogenous free IBA as well as the percentage of colonization. We have started to isolate transcripts from maize and the model legume Medicago truncatula roots differentially induced by IBA and AM by cDNA-AFLP and microarray analysis. In addition, we have begun to analyze a family of five auxin conjugate hydrolases from Medicago truncatula biochemically and compared their expression during AM and nodule formation. Their differential expression during nodulation indicate that they might be important players to regulate auxin homeostasis in a symbiosis.

P0194. Mycorrhizal status of four species of a rare plant community in a Natura 2000 habitat

C. Moser[1], K. Haselwandter[2];
[1]Department of Organismic Biology, Salzburg, Austria, [2]Department of Microbiology, Innsbruck, Austria.

Arbuscular mycorrhizal fungi (AMF) appear to influence plant community structure and diversity. Hence it is of special importance to analyse natural fungal communities in order to be able to provide inoculum if needed.

We determined the mycorrhizal status of Laserpitium siler, Teucrium montanum, Acinos alpinus and Sesleria varia, species of the rare plant community Laserpitietum sileris developed on an alpine chalk gravel slope. Root and soil samples were collected at three phenological stages of plant development and AMF spores were isolated. Colonization intensity by AMF and dark septate endophytes (DSE) was determined and roots of the same plant individuals were used for an amplification of partial sequences in the AMF rRNA genes.

Roots of all plants were colonized by AMF and DSE throughout the growing season with the highest values of total colonization on fructiferous plants. For an indication of the biodiversity of AMF present in roots molecular data will be presented and discussed.

P0195. The regulation of mycorrhization in supernodulating soybean mutants

C. Meixner, **H. Vierheilig**;
Institut für Pflanzenschutz, Wien, Austria.

In the Rhizobium-legume interaction a so-called autoregulatory mechanism is well documented. Autoregulation of nodulation means, that already existing nodules systemically suppress subsequent nodule formation in other parts of the root system. Mutants of some legumes lost their ability to autoregulate the nodule number and thus display a supernodulating phenotyp.

An autoregulatory mechanism has also been reported for the AM symbiosis. In a split-root system prior root colonization on one side suppresses further root colonization on the other side. Interestingly an established mycorrhizal association can systemically suppress not only further mycorrhization but also nodulation, pointing towards similar regulatory mechanisms in the two associations.

We studied the autoregulation of mycorrhization in supernodulating soybean mutants and soybean wildtyp plants in order to see whether the rhizobial and the mycorrhizal autoregulatory mechanisms are linked.

P0196. Isolation of radish genes involved in phytochelatin synthesis and their possible use in phytoremediation via transplastomic technology

J. Nishizuka, **T. Terachi**;
Department of Biotechnology, Faculty of Engineering, Kyoto Sangyo University, Kyoto, Japan.

Phytochelatins (PCs), i. e. (gGlu-Cys)2-11-Gly, are a family of metal-complexing peptides, and play an important role in detoxification of toxic metals in plants. PCs are enzymatically synthesized from glutathione (GSH) or GSH-related compounds, and they form stable complex with heavy metals in the cytosol. These complex are subsequently sequestered into the vacuole. In this paper, we report the isolation of three cDNAs encoding enzymes, g-glutamyl-Cys synthase (g-ECS), glutathione synthetase (GS) and phytochelatin synthase (PCS), from radish, which involved in phytochelatin synthesis, and describe an attempt to integrate these genes into the chloroplast genome of tobacco. We also report an attempt to obtain a plant containing a synthetic oligonucleotides to produce a synthetic phytochelatin (EC8) in the chloroplast. The purpose of present study is to obtain genetically engineered plants showing higher concentration of PCs in the plastid. The possible use of these plants for phytoremediation will be discussed.

P0197. Molecular and genetic diversity of a genomic sequence similar to *SHATTERPROOF* (*SHP1*) in *Phaseolus vulgaris* L.

L. Nanni[1], A. Losa[2], E. Bellucci[1], M. M. Kater[2], P. Gepts[3], R. Papa[1];
[1]Dipartimento di Scienze degli Alimenti, Università Politecnica delle Marche, Ancona, Italy, [2]Dipartimento di Scienze Biomolecolari e Biotecnologie, Università degli Studi di Milano, Milano, Italy, [3]Department of Plant Sciences, Section of Crop and Ecosystem Sciences, University of California, Davis, CA, United States.

Compared with their wild progenitors, domesticated crops show marked phenotypic differences even if they belong to the same biological species. These differences, known as the domestication syndrome, results from selection for adaptation to cultivates environments. One of the key traits of the domestication syndrome is the seed dispersal mechanism (shattering), which was lost in common bean and in many other domesticated species. Two MADS-box genes involved in the control of silique shattering have been identified in *Arabidopsis thaliana* (*SHP1* and *SHP2*). Based on EST sequences, we identified in *Phaseolus vulgaris* two genomic sequences similar to *SHATTERPROOF* (*SHP1*) of *Arabidopsis thaliana*. We were also able to amplify and sequence a single product from several genotypes of *Phaseolus* spp. and a few other legumes. Furthermore, we developed two markers spanning indels that were used to locate the identified sequence on the *Phaseolus vulgaris* core linkage map (BAT93 X Jalo EEP558) and study its molecular diversity in a larger sample of wild and domesticated accessions from both Andean and Mesoamerican gene pools.

P0198. Transposable element domestication in plant genomes

R. K. Cowan, D. R. Hoen, D. J. Schoen, T. E. Bureau;
McGill University, Montreal, PQ, Canada.

While transposons have traditionally been viewed as genomic parasites or junk DNA, the discovery of transposon-derived host genes have fuelled the ongoing debate over the evolutionary role of transposons. In particular, mobility-related open reading frames have been known to acquire host functions. We report that genome-wide searches for *Mutator* transposase-derived host genes in *Arabidopsis thaliana* (Columbia-0) and *Oryza sativa* ssp. *japonica* (cv. Nipponbare) (domesticated rice) identified 121 sequences, including the taxonomically conserved *MUSTANG1. S*yntenic *MUSTANG1* orthologues in such varied plant species as rice, poplar, *Arabidopsis,* and *Medicago truncatula* appear to be under purifying selection. However, *MUSTANG1* belongs to one of only two *Mutator*-like gene families with members in both monocotyledonous and dicotyledonous plants, indicating that *Mutator*-like elements seldom evolve into taxonomically widespread host genes.

P0199. How genes paint grape berry

M. Salmaso[1], S. Varotto[1], M. Lucchin[1], R. Velasco[2];
[1]Department of Environmental Agronomy and Crop Prduction, Padova, Italy, [2]Istituto Agrario di San Michele all'Adige, Trento, Italy.

Anthocyanins are the main pigments in flowers and fruits. In grape the quantity and composition of anthocyanins influence berry skin colour. VlmybA genes, belonging to C1 family, are involved in the regulation of anthocyanin biosynthesis in grape via expression of the UFGT gene. In particular a retrotransposon (Gret1)-induced mutation in VvmybA1 seems to be associated with the loss of pigmentation in some white cultivars of *Vitis vinifera*

We want to verify the presence of 3'LTR of Gret1 in some cultivars from North-Est Italy to investigate if black cultivars are evolved from white ones. Furthermore, in order to verify the "Gret1 hypothesis", an expression analysis of the genes belonging to the anthocyanin pathway is in progress in a progeny of a cross between a white and a black cultivar and in 30 different cultivars using Real Time-PCR. Our preliminary results indicate a direct correlation between a *MybA* gene and berry colour. Moreover the alignement of the 5' region of VlmybA gene amplified from white and black cultivars induces us to hypothesize a different genetic event, besides the retrotransposon, between white and black cultivars in the coding sequence of VlmybA

P0200. Gene duplication by rice *Mutator*-like DNA transposons: implications for host gene evolution and function

N. Juretic, D. R. Hoen, T. E. Bureau;
McGill University, Montreal, PQ, Canada.

Mutator-like elements (MULEs) containing duplicated host gene fragments have been documented in maize, Arabidopsis and rice, but the evolutionary impact of this phenomenon is presently unclear. In a genome-wide analysis of rice MULEs, we have identified 1,337 elements containing duplicated host gene fragments, 5% of which are expressed. Sequence analysis of the expressed duplications strongly suggests that they do not encode functional proteins; nevertheless, it does not exclude the possibility of a function at the RNA level. Endogenous non-coding transcripts are known to suppress the expression of genes with which they share short regions of high nucleotide sequence similarity, and increasing evidence indicates that this mechanism is much more pervasive than initially believed. We show that transcribed MULE duplications possess features that could allow them to regulate the expression of rice genes in a manner analogous to miRNAs and endogenous trans-acting siRNAs. Since their expression is regulated differently from the progenitor host genes, they may provide an additional level of complexity to gene regulatory networks.

P0201. Identification of Genes Relating to the Sexual Reproduction of a Unicellular Charophycean Alga, *Closterium peracerosum-strigosum-littorale* complex, by Microarray Analysis.

H. Sekimoto[1,2], Y. Tanabe[3,4], Y. Tsuchikane[3], H. Fukuda[5,6], T. Demura[5], M. Ito[3];
[1]Department of Chemical and Biological Sciences, Faculty of Sciences, Japan Women's University, Bunkyo, Tokyo, Japan, [2]Department of Life Sciences, Graduate School of Arts and Sciences, University of Tokyo, Meguro, Tokyo, Japan, [3]Department of General Systems Studies, Graduate School of Arts and Sciences, University of Tokyo, Meguro, Tokyo, Japan, [4]Graduate School of Science and Technology, Chiba University, Chiba, Japan, [5]Plant Science Center, RIKEN, Yokohama, Japan, [6]Department of Biological Sciences, Graduate School of Science, University of Tokyo, Bunkyo, Tokyo, Japan.

Heterothallic strains of *Closterium peracerosum-strigosum-littorale* complex (*C. pslc*) are unicellullar charophycean algae, having two sexes: mating type plus (mt$^+$) and mating type minus (mt$^-$). Two sex pheromones (PR-IP and PR-IP Inducer) involved in the progress of sexual reproduction of the *C. pslc* have been well characterized. The PR-IP inducer induces the release of PR-IP from mt$^+$ cells, whereas PR-IP induces the release of gametic protoplasts from mt$^-$ cells, during the sexual reproduction. To understand genetic program concerning the sexual reproduction, cDNA microarrays containing a total of 2806 cDNAs were prepared. Cy-5-labeled cDNA populations were prepared from cells proceeding sexual reproduction and cells treated with purified sex pheromones. As a result, 44 genes that showed a 4-fold increase in expression over the time-course were identified. Among them, expression levels of 11 genes were elevated only in mt$^-$ cells by the addition of PR-IP, whereas that of 20 genes including a putative receptor-like protein kinase were elevated only in mt$^+$ cells by the addition of PR-IP inducer. Further detailed analyses are now in progress.

P0202. Desiccation-Responsive Gene Expression In An Intertidal Brown Alga (Heterokontophyta): Population-Level Expression Patterns And Sequence Variation.

A. Lago-Lestón, E. Serrao, G. Pearson;
Center of Marine Science, Universidade do Algarve, Faro, Portugal.

Stress-tolerant brown algae in the genus *Fucus* are subject to recurrent desiccation during low tides in the intertidal zone (losing up to 95% of their tissue water). However, almost nothing is known about the molecular response to stressors in these algae. The species *F. vesiculosus* is widely distributed, from Arctic to warm temperate shores, and from marine to low salinity habitats (estuaries and the Baltic Sea). We constructed subtractive cDNA libraries from several populations responding to desiccation stress, and conducted within- and between-population screening of positive clones on macroarrays. The results suggest considerable variation in transcript profiles between populations from contrasting locations/habitats, when tested under common-garden conditions. While few genes could be identified directly from the SSH clones, analysis of an EST set of over 1000 sequences from 3 libraries showed considerable variation within contigs (base substitutions, indels, and evidence for alternative transcription products), some of which were population-specific. Progress in gene annotation and the potential for marker development are reported.

P0203. Photosynthetic activity and primary vs. secondary pigments of the alpine snow alga Chlamydomonas nivalis cf.

D. Remias, C. Lütz;
Institute of Botany, Innsbruck, Austria.

Snow algae inhabit most of the cold regions worldwide where long lasting snow fields are common. Ecophysiology of snow algae has been studied intensively in North America and occasionally at polar regions. Snow algae from European Alps have been studied mainly by means of light microscopy to describe systematic relationships.

Our studies on red snow algae (*Chlamydomonas nivalis*) from the high Alps of Austria show data on temperature and light dependence of photosynthesis as well as plastidal and extraplastidal pigment composition.

Both photosynthesis and respiration data support the cryophilic adaptation of snow algal cells, nevertheless *C. nivalis* produces oxygen without any inhibition up to 20°C for one hour or at irradiation up to 1800 µmol m^{-2} s^{-1}.

Chlorophyll and primary carotenoid pigment composition is the same as in most *Chlorophyta*. Additionally, a high amount of free and esterified astaxanthin was found, located in cytoplasmic lipid globules. These pigments may shield the chloroplast against photoinhibition. Light microscopical observations show that the cell walls are frequently covered with tightly bound inorganic particles.

P0204. Compartmentation of the glycolytic pathway in heterokontophytes

C. Río Bártulos[1], H. Lünsdorf[2], U. Brandt[1], M. Liaud[1], R. Cerff[1];
[1]Institut für Genetik, Technische Universität Braunschweig, Germany, [2]GBF-Gesellschaft für Biotechnologische Forschung, Braunschweig, Germany.

In heterokontophytes we characterized gene families encoding multiple (up to five) distinct isoforms of the glycolytic enzymes triosephosphate isomerase, glyceraldehyde-3-phosphate dehydrogenase, 3-phosphoglycerate kinase, enolase and pyruvate kinase. By employing GFP reporter gene techniques we were able to show that for each enzyme one isoform is transported into mitochondria of the diatom Phaeodactylum tricornutum. This strongly supports our previous suggestion (Liaud et al 2000) that at least the C3-part of glycolysis from triosephosphate to pyruvate runs through mitochondria in heterokont algae. Moreover, we were able to show by electron microscopy that envelopes from chloroplasts (4 membranes) and mitochondria (2 membranes) from Phaeodactylum tricornutum are closely attached. The stacked envelope membranes contain channels connecting both organelles suggesting a direct metabolic link between photosynthesis and respiration. These data suggest that the host cell of heterokont algae had mitochondria with a (partial) glycolytic pathway.

Liaud et al.(2000); Mol.Biol.Evol. 17, 213-223.

P0205. Novel allergens of raspberry are cross-reactive with homologues in birch pollen and apple fruits

Y. Ma[1], C. Radauer[2], G. Marzban[1], K. Hoffmann-Sommergruber[2], H. Katinger[1], M. Laimer[1], **A. Mansfeld**[3];
[1]Institute of Applied Microbiology, University of Natural Resources and Applied Life Sciences, Vienna, Austria, [2]Center of Physiology and Pathophysiology, Medical University of Vienna, Vienna, Austria, [3]Plant Biotech Unit, Institute of Applied Microbiology, University of Natural Resources and Applied Life Sciences, Vienna, Austria.

Recently the description of occupational asthma due to the inhalation of raspberry powder was reported by Sherson et al., but no raspberry allergen has so far been identified and characterized. Our aim was to identify allergens of raspberry that can cause clinical symptoms and to investigate cross-reactivity of the raspberry allergens to birch pollen allergens.

Raspberry fruit extracts were prepared and subjected to SDS-PAGE. Immunoblot analysis with a sera pool of birch pollen and apple fruits allergic patients showed several IgE binding components with molecular weights ranging from 9 to 48 kDa. The most frequently detected protein had a molecular weight of 34 kDa and significant homology to the hevamine family of latex allergens. Another detected protein with a molecular weight of 17 kDa had significant homology to the major latex-like protein and the Bet v 1 allergen family. Immunoblot with a mouse anti-Bet v 1 monoclonal antibody showed strong binding to the 17 kDa and 48 kDa proteins.We describe the initial identification of allergens in raspberry that may be important as cross-reactive allergens and novel members of the birch pollen-related food allergens.

P0206. Molecular aspects of plant food allergens

H. Breiteneder[1], E. N. C. Mills[2];
[1]Medical University of Vienna, Vienna, Austria, [2]Institute of Food Research, Norwich, United Kingdom.

Plant food allergens belong to a very limited number of protein families and many possess distinct biochemical and physicochemical properties. These include thermal stability and resistance to proteolysis which are enhanced by an ability to bind ligands such as metal ions, lipids, or steroids. Other types of lipid interaction including membranes or lipid vesicles may promote the allergenic properties of certain food proteins. Structural features related to stability are intra-molecular disulfide bonds and N-glycosylation. Some plant food allergens such as the cereal seed storage prolamins are rheomorphic proteins with polypeptide chains that adopt a variety of secondary structures resembling unfolded or partially folded proteins. Another type of plant food allergen is characterized by the presence of repetitive structures, the ability to form oligomers and the tendency to aggregate. A summary of the current knowledge regarding molecular properties of food allergens will be presented.

Acknowledgements: This work was supported by the Austrian Science Fund grant SFB F01802 and the BBSRC through the competitive strategic grant to IFR.

P0207. Recombinant food allergens and hypoallergenic variants

K. Hoffmann-Sommergruber[1], Y. Ma[1], G. Gadermaier[2], S. Bolhaar[3], B. Bohle[1], A. Knulst[4], F. Ferreira[2];
[1]Department of Pathophysiology, Vienna, Austria, [2]Institute of Genetics, University of Salzburg, Salzburg, Austria, [3]Department of Dermatology/Allergology,, University Medical Center, Utrecht,, The Netherlands, [4]Department of Dermatology/Allergology, University Medical Center Utrecht, Utrecht, The Netherlands.

The physicochemical characterization of food allergens uses methods such as circular dichroism, mass spectrometry, 2D-gel electrophoresis, N-terminal sequencing and HPLC analysis. For some of the allergens experimentally based structures are already available. This information can be used to determine the relevant B- and T-cell epitopes leading to the prediction of hyper- and hypoallergenic members of a protein family. Five point mutations were introduced in the Mal d 1 wildtype, the major apple allergen and the resulting mutant was produced as a recombinant protein in *E.coli* and the allergenic properties of both proteins were investigated in IgE-immunoblotting assays, ELISA, peripheral blood monocytes proliferation assays and skin prick tests. Significant differences were found between Mal d 1wt and Mald 1mut. Our findings suggest that it is possible to modulate the IgE binding properties of allergens by single amino acid substitutions at crucial positions. Such mutated proteins may serve as a template for engineering hypoallergens for immunotherapy retaining T cell reactivity but decreasing the risk of anaphylactic side effects.

P0208. Localisation of the major allergen Art v 1 in *Artemisia vulgaris* and transgenic tobacco plants

M. Ortner, M. Affenzeller, A. Gimeno, G. Obermeyer;
Molecular Plant Physiology, Div. Allergy & Immunology, Dept. Molecular Biology, 5020 Salzburg, Austria.

The major allergen of *Artemisia vulgaris* (mugwort) pollen, Art v 1, is a 108 amino acid protein consisting of two domains: 1. a cysteine-rich N-terminus with sequence homologies to members of the plant defensin family and 2. a highly glycosylated, proline-rich C-terminus domain containing several extensin-like repeats (Himly et al. 2003, FASEB J. 17: 106-108). Additionally, a signal peptide at the N-terminus was identified that directs the processed Art v 1 to the secretory pathway. Despite of the sequence homologies of the two domains, the physiological role of Art v 1 is still very unclear. To get more information on the possible function, the expression of the native Art v 1 protein was monitored in various tissues (root, stem, leaf, flower, pollen) of mugwort at the RNA and protein level. Using RT-PCR and immunodetection methods, Art v 1 was only detected in mugwort pollen. Additionally, recombinant

Art v 1 was produced in transgenic tobacco plants to obtain sufficient amounts of recombinant Art v 1 for testing its putative anti-fungal and anti-bacterial activity.

P0209. TPK/KCO family: K+ channels in Arabidopsis thaliana

C. Voelker, D. Schmidt, B. Mueller-Roeber, K. Czempinski;
University of Potsdam, Institute of Biochemistry and Biology, Golm, Germany.

In Arabidopsis thaliana six members of structurally divergent potassium channels have been identified by sequence homology to AtTPK1, formerly described as AtKCO1. The five TPK-like proteins present four transmembrane segments and two K+-selective P-domains as their basic subunit structure. AtKCO3 presents only two transmembrane segments and a single K+-selective P-domain. Among the six channels, five show the presence of Ca2+-binding motifs in the C-termini and a putative 14-3-3 binding site in their N-termini.
Our project aims to analyse the function of the TPK/KCO channels using molecular, biochemical and physiological methods in transgenic plants including detailed expression analysis, subcellular localisation studies and reverse genetic approaches. Studies on AtTPK/KCO-GFP fusion proteins demonstrated that e.g. AtTPK1 is localised in the vacuolar membrane and AtTPK4 in the plasma membrane. Methods like Split-YFP-system, RET and THS are used to investigate protein interaction within the family and with regulatory proteins e.g. 14-3-3 proteins. Results from the molecular characterisation of this gene family will be presented.

P0210. Determination of Golgi targeting signals from a mannosidase II from A. thaliana

J. Schoberer, R. Strasser, H. Steinkellner;
IAGZ, Wien, Austria.

Arabidopsis thaliana Golgi Ŭ-mannosidase II (GMII) is a glycosylhydrolase that is present in plants as well as in mammals and is involved in the formation of complex *N*-glycans, the major posttranslational modification of proteins. In order to examine Golgi targeting and retention domains of GMII, the putative cytoplasmic (C)-transmembrane (T)-stem (S)-region (CTS) of the enzyme and deletions thereof were fused to GFP and transiently expressed in the tobacco-related model species *Nicotiana benthamiana*. Confocal laser scanning microscopy analyses of the fusion proteins CTS-GFP, CT-GFP, TS-GFP, T-GFP, and C-GFP as well as the fusion constructs C10TS-GFP and C 10T-GFP that included only 10 amino acids of the C region, revealed that the C10T region is sufficient to sustain Golgi retention of GMII. The T domain alone exhibited an incomplete retention, whereas the C region showed a homogenous staining of the cytoplasm suggesting that this region alone did not confer any Golgi retention by itself. These data indicate the definitive requirement of the T domain in Golgi targeting/retention and that the 10 amino acids of the C region confer an auxiliary role.

P0211. Ultrastructure of chromoplasts in *Crocus sativus* L., *C. cartwrightianus* Herb. and *C. thomasii* Ten.

M. Grilli, A. Canini;
Department of Biology, Rome, Italy.

Crocus sativus contains crocetin and crocin carotenoids inside chromoplasts of red stygmas.Saffron is known only as cultivated species.Cytogenetical and molecular biology studies have led to the hypothesis that saffron originated by mutation or hybridisation of C.cartwrightianus.But also C. thomasii,which morphology is more similar to saffron, has been considered as ancestor.In this study the ultrastructure of chromoplasts of C. sativus,C.cartwrightianus and C.thomasii stygmas have been examined.Chromoplasts of C.sativus result in many vesicles and plastoglobules.Chromoplasts of C.cartwrightianus have plastoglobules ,tubules and one or more dark body,spiral shaped, often crossIng all the chromoplast. C.thomasii chromoplasts have mainly plastoglobules , electrontransparent vesicles encircled in a thin envelope, some thin fibrils and characteristic tubules heavy twisted.The comparison of chromoplasts of the supposed related species indicates that although similar is the basic organisation,each species has some different elements and, on whole,chromoplasts of C.thomasii are more similar to those of C.sativus.

P0212. Different Subcellular Localisation of Two Arabidopsis PP2C Phosphatases

V. Kazanaviciute, A. Schweighofer, I. Meskiene;
Vienna Biocenter, Vienna, Austria.

Studies on plant protein phosphatases type 2C (PP2Cs) suggest that they are involved in the regulation of diverse signaling pathways. Arabidopsis contains the largest PP2C family in Eukaryota. However; the information about them is very limited. AP2C1 specifically interacts with and negatively regulates the activity of stress-activated MAPKs. Function of AP2C3, a homologue from the same cluster, is not known yet. One of the key characteristics of proteins, which can help to elucidate their possible functions, is their subcellular location. Here we analyse intracellular localisation of these two protein phosphatases in plants by protein fusions with GFP. AP2C3-GFP protein is localised to the nucleus suggesting that it may act on MAPKs within this compartment and can possibly be involved in the regulation of gene expression. AP2C1-GFP tagged proteins could be detected in a highly dynamic cellular compartments that most resembles newly re-discovered structures, called stromule. It is thought that stromule production may be essential for optimising signal transduction processes that require intracellular movement of substrates or signals.

P0213. Reconstruction of spatial structure of plant FtsZ-proteins

O. N. Demchuk, A. Y. Nyporko, Y. B. Blume;
Institute of Cell Biology and Genetic Engineering, Kyiv, Ukraine.

3-D models of two forms of plant FtsZ-proteins localized in chloroplasts and in cytosol of *Arabidopsis thaliana* L. were developed. Crystal structure of bacterial FtsZ-GDP complex (PDB-code 1FSZ) was used as matrix. Secondary structures of both plant protein forms contain ten ɓ-strands. However chloroplast molecule forms ten Ŭ-helices and four 3_{10}-helices, whereas in cytosolic molecule one Ŭ-helix (Ŭ0-helix before GDP-binding domain) and C-terminal 3_{10}-helix are absent. It was found that T2-loop structure of nucleotide-binding pocket of chloroplast FtsZ-protein contains non-charged amino acid residue (Ala) in position 111 instead charged amino acid residue in cytosolic form (Arg) and polar residue in bacterial FtsZ-protein (Gln) in respective positions. Accounting relatively low sequence homology of plant and bacterial FtsZ-proteins (~47%) developed 3-D models demonstrate high coincidence not only between structures of whole molecules FtsZ-proteins and bacterial matrix, but between structures of nucleotide-binding pockets as well. Respectively, they can be used for further modeling of plant FtsZ-proteins with specific low molecular ligands.

P0214. Identification of plastid envelope proteins required for the import of protochlorophyllide oxidoreductase PORA into the chloroplast of barley and *Arabidopsis*

S. Reinbothe[1], C. Reinbothe[2];
[1]Laboratoire de Génétique Moléculaire des Plantes, Grenoble cedex 9, France, [2]Lehrstuhl für Pflanzenphysiologie, Universität Bayreyth, D-95447 Bayreuth, Germany.

Chloroplasts are semiautonomous cell organelles which must import the major part of their protein constituents from the cytosol. Import is for most cytosolic precursors dependent on ATP and mediated by cleavable amino-terminal transit sequences. Biochemical and genetic evidence in *Arabidopsis thaliana* suggests the existence of multiple protein import complexes which could differ by an interchange of receptor components. Here we report that the NADPH:protochlorophyllide (Pchlide) oxidoreductase precursor, pPORA, uses a distinctive import site. Chemical crosslinking and various other approaches revealed that pPORA interacts with several hitherto unknown components. Among them is a 47 kDa protein implicated in synthesis of photoprotecvtive vitamin E and a 52 kDa Rieske type non-heme ison oxygenase related to the inner plastid envelope translocon protein Tic55, the lethal leaf spot protein Lls1 and chlorophyllide *a* oxygenase (Cao), all of which have been localized to chloroplasts. It is the aim to discuss the role of Ptc52 in the regulation of pPORA import.

P0215. Analysis of a putative plastidic transporters affecting photosynthesis in *Arabidopsis thaliana*

D. Marquardt, A. Schneider, U. I. Flügge;
Institute of Botany II, Cologne, Germany.

Membranes are the major barriers between the cytoplasm and cell organelles. Therefore, a variety of transporters are needed to mediate the exchange of metabolites, ions and proteins between these compartments.

We are analysing a family of five proteins with putative transport function in *Arabidopsis thaliana*. A comparison between several prediction programmes (http://aramemnon.botanik.uni-koeln.de/) revealed that these proteins contain more than five transmembrane spanning regions and different subcellular targeting signals. For each member homozygous T-DNA insertion mutants were isolated. Plastidic targeting for two proteins of this family (AtDAP1, AtDAP2) was confirmed experimentally by GFP fusion constructs. The corresponding T-DNA insertion mutants exhibit drastic phenotypes characterised by dwarfish growth, reduced chlorophyll and starch content and a significantly lowered electron transport rate. Therefore, these mutants are named dwarf affected in photosynthetic electron transport rate (DAP).

P0216. The plastidic phospho*enol*pyruvate/phosphate translocator (PPT) in *Arabidopsis*: a regulatory element of mesophyll development?

T. Löttgert, L. Voll, S. Knappe, K. Fischer, A. Schneider, R. E. Häusler, U. I. Flügge;
Institute of Botany II, 50931 Cologne, Germany.

A. thaliana contains two PPT genes. *AtPPT1* is mainly expressed in the vasculature of leaves and roots, but not in mesophyll cells whereas *AtPPT2* is expressed throughout the leaf blade, but not in roots. The *A. thaliana cue1* mutant, lacking PPT1, exhibits a reticulate leaf phenotype with dark green paraveinal and pale green interveinal regions. This phenotype could be rescued transiently by feeding aromatic amino acids or by overexpressing plastid-targeted pyruvate,orthophosphate dikinase producing PEP from pyruvate in the stroma. This observation reinforced the proposed role of PPT as the provider of PEP to plastids as precursor for the shikimate pathway. However, contents of aromatic amino acids and secondary plant products were only selectively affected in *cue1*. We propose that the absence of AtPPT1 leads to a deficiency only in certain products of the shikimate pathway, the synthesis of which is restricted to certain cell types. It is likely that derivatives of the phenylpropanoid metabolism fulfill hormonal or signal-like functions triggering correct mesophyll development. The impact of a candidate compound on the transcriptome will be presented.

P0217. Isolation and characterization of Arabidopsis apm mutants with defects in peroxisome biogenesis

S. Mano[1,2], C. Nakamori[1], M. Kondo[1], M. Nishimura[1,2];
[1]Natl. Inst. Basic Biol., Okazaki, Japan, [2]Grad. Univ. Advanced Studies, Okazaki, Japan.

Plant peroxisomes have a variety of functions in various metabolic pathways, including metabolism of storage oils, photorespiration, scavenging hydrogen peroxide and biosynthesis of jasmonic acid. Based on the observation of peroxisomes visualized with GFP in Arabidopsis, it is revealed that peroxisomes change the size, shape, number and position within the cell. Little is, however, known about the mechanism for peroxisome biogenesis in higher plants. To identify the genes controlling peroxisome biogenesis, we isolated a number of Arabidopsis mutants with aberrant peroxisome morphology (apm mutants). apm mutants were categorized into four classes as follows, (1) long peroxisomes (apm1) ; (2) larger peroxisomes (apm3, apm6) ; (3) altered distribution in cells (apm5) ; and (4) observation of GFP fluorescence in the cytosol as well as in peroxisomes (apm2, apm4, apm7). Among these mutants, we reported that apm1, whose peroxisomes are long and reduced in number, had the mutation in dynamin-related protein 3A (DRP3A), one of sixteen dynamins in Arabidopsis. In this presentation, we would like to discuss the phenotype of apm mutants.

P0218. Analysis of new protein families homologous to plastidic phosphate translocators in Arabidopsis thaliana

M. Santaella, I. Rollwitz, N. Walczyk, U. I. Flügge, **K. Fischer**;
Botanical Institute, Cologne, Germany.

Several proteins (PTh) that show homology to nucleotide-sugar transporters (NSTs) and to plastidic phosphate translocators (pPTs) were recently identified in Arabidopsis and other organisms. The PTh proteins split into three new families named the KD, KT and KV/A/G families according to conserved sequence motifs that might be involved in substrate binding. Two of these transporters belonging to the KV/A/G family possess a N-terminal presequence that might direct the proteins to plastids. In order to analyze the function of these two proteins, the cellular and tissue specific expression of the corresponding genes were determined by RT-PCR and promoter-reporter gene fusion studies. Furthermore, transport experiments with the heterologously expressed proteins should shed light on the substrate specificities of these transporters.

The characterization of mutant lines with insertions in these genes revealed no distinct phenotype, suggesting overlapping functions of the proteins. The analysis of mutants lacking more than one gene might provide new insights in the physiological role of these newly identified transporters.

P0219. Functional Characterization of *Arabidopsis* Proteins homologuous to Bile Acid Transporters

I. Rollwitz[1], D. Hille[1], U. Flügge[1], H. Bohnert[2], K. Fischer[1];
[1]Botanical Institute, University of Cologne, Cologne, Germany,
[2]Institute of Plant Biology, University of Illinois, Urbana-Champaign, IL, United States.

The Na$^+$-Bile Acid Transporter (BAT) family contains over 50 members in animal, plant and bacterial species. BATs in mammals catalyze an electrogenic Na$^+$-bile acid symport in intestinal, liver and kidney tissues. These transporters exhibit broad specificity, taking up taurocholate and other bile acids as well as a variety of other organic compounds. *A. thaliana* possesses a small BAT family consisting of five proteins. All of them have N-terminal presequences directing the proteins (and marker proteins like GFP) to plastids and mitochondria. Obviously, in plants, in contrast to animals, these proteins are exclusively located in cellular organelles. To elucidate the physiological function of these transporters, different knock out lines of the candidate genes were analyzed to complete the picture we got from expression studies. Furthermore, transport experiments with the heterologously expressed proteins should shed light on the substrate specificities of these transporters.

P0220. Peroxisomal citrate synthase and peroxisomal malate dehydrogenase are required for fatty acid metabolism in Arabidopsis

I. Pracharoenwattana[1], J. E. Cornah[2], S. M. Smith[3];
[1]Institute of Molecular Plant Sciences, University of Edinburgh, Edinburgh, United Kingdom, [2]CNAP, Department of Biology, University of York, York, United Kingdom, [3]Department of Biochemistry and Molecular Biology, School of Biomedical and Chemical Sciences, UWA, Perth, Australia.

Arabidopsis seeds in which two peroxisomal citrate synthase (*pCSY*) genes are knocked out are dormant, and they do not metabolise their stored lipid. Germination can be achieved by removing the seed coat and supplying sucrose. The mutant seedlings are resistant to 2,4-dichlorophenoxybutyric acid (2,4-DB), indicating a block in peroxisomal ß-oxidation. Therefore pCSY is not just a glyoxylate cycle enzyme but is also required for fatty acid respiration and to break dormancy. It is hypothesised that peroxisomal malate dehydrogenase (pMDH) serves to oxidise NADH produced by ß-oxidation, and does not oxidise malate to provide oxaloacetate for the glyoxylate cycle. Arabidopsis mutants in which two *pMDH* genes are knocked out are unable to establish as seedlings unless exogenous sucrose is supplied. Seedlings are insensitive to 2,4-DB, showing that ß-oxidation is defective, and fail to metabolise stored lipid. The metabolism of [2-^{14}C]-acetate into sugars and organic acids is normal in mutant seedlings, indicating that the glyoxylate cycle is active. These results show that pMDH is not required for the glyoxylate cycle, but is required for fatty acid ß-oxidation.

P0221. Characterization of the plant ESCRT-III complex: protein interaction studies between its putative Arabidopsis thaliana components

N. Schlager, J. A. Torres-Acosta, V. Winter, M. T. Hauser;
BOKU, Institute of Applied Genetics and Cell Biology, Vienna, Austria.

Protein sorting to multivesicular bodies (MVBs) requires the coordinated action of three protein complexes, ESCRT-I, -II, -III (Endosomal Sorting Complex Required for Transport). Based on analyses in yeast, up to 14 class E VPS (Vacuolar Protein Sorting) proteins have been assigned to this protein degradation and recycling pathway. A current model proposes that sorting starts with the binding of VPS27 to ubiquitinated proteins which recruits ESCRT-I to MVB membranes and activates ESCRT-II. Later it initiates the assembly of at least four small coiled-coil proteins forming ESCRT-III which separates after VPS4 association. In plants nothing is known about the presence and function of an ESCRT mediated MVB protein sorting pathway. In comparative genome analyses we identified all putative homologs of the ESCRT proteins in the fully sequenced genomes of Arabidopsis and rice. To further gain insights into the composition of ESCRT-III we carried out more than 100 yeast two hybrid protein interaction studies with its putative Arabidopsis components and propose a model for their arrangement in a plant ESCRT-III complex.
Supported by the Austrian Science Fund (FWF).

P0222. Induction of dehydrin-like protein in rice seedlings under low temperature

M. Momma;
National Food Research Institute, Tsukuba, Japan.

Proteomic analysis was conducted on rice seedling grown under abiotic stress in relation to dehydrin induction. Dehydrin, a group 2 late embryogenesis abundant protein, is supposed to have protective functions in plant tissues. After germination under salt-containing medium, rice seedlings were transferred to low temperature. Proteins were profiled by two-dimensional electrophoresis and immunoblotting with antibody for conserved lysine motif of dehydrin. Growth of the seedlings was remarkably inhibited with 0.8% NaCl. The electrophoresis profile of seedlings on 0.8% NaCl showed weaker spots for 16, 18, 27 kDa polypeptides and denser spots for 61kDa and 36-37kDa proteins than control. No significant difference in protein profile was observed between the seedlings grown on 0 and 0.5% NaCl. After they were incubated at low-temperature, however, increase of heat-stable proteins and induction of acidic dehydrin were observed in those transferred from 0.5% NaCl medium. The induction of dehydrin in acclimated seedlings implied the possibility to enhance the low temperature tolerance of rice seedling by moderate salt treatment.

P0223. Provision of anti p5cs and application of it in the analysis of the expression of the p5cs gene in transgenic versus nontransgenic olive under osmotic stress.

M. Farzaneh;
National Institute of genetic Engineering &Biotechnology, Tehran, Islamic Republic of Iran.

Osmotic stress is an important limiting factor. To cope with these environmental stresses, application of molecular plant breeding is necessary. In response to osmotic stress elicited by condition of high salt, the expression of P5CS gene altered in olive plants. for this, constructs (S,E,X) were prepared by introducing P5CS sequence in to PBI121 . Constructs cloned in binary vector were transformed to the disarmed agrobactrium tumefaciens. Olive embryo were transformed with A.tumefaciens harboring the various gene constructs and salt-tolerance plants were regenerated in media containing adequate concentration of salt .The total protein was extracted from fresh leaves of both control and transformed regenerated plants . and measured using of brad ford to subjected to two dimentional polyacrylamide gel electrophoresis .
To probe the effect of p5cs overexpression on salinity stress tolerance, poly clonal antibody developed in rabbit against p5cs protein. The result of immunological methods for specific detection of p5cs gene , strongly indicated P5CS up- regulation in stressed transformed plants versus non transformed plants.

P0224. Differential polypeptide expression in olive plantlet under osmotic stres

F. Hadi[1], F. Rastegar jazii[2], N. Motamed[3];
[1]tehran university and- National Institute of genetic Engineering &Biotechnology, Tehran, Islamic Republic of Iran, [2]- National Institute of genetic Engineering &Biotechnology, Tehran, Islamic Republic of Iran, [3]tehran university, Tehran, Islamic Republic of Iran.

For study olive plantlet response under osmotic stress condition. in first step the embryos of the olive C.V.Zard were cultured on solid 1/2MS media, after one month, some of the green plantlets were transferred to the solid ½ MS containing 200 mM Nacl,the plantlets were subcultured weakly, after two weak, according to different components of olive plantlets ,several methods used to extract total proteins from both plantlets under stress condition and non stress condition. Equal quantity of total protein from both two samples was subjected to 2DE and protein profile of stresed plantlets was compared to non-stresed plantlets. Appearance, disappearance, up and down regulation of polypeptides were interpreted as response of plantlet to the induced stress and the difference in polypeptides profile of plantlet under stress versus control plantlet was also considered. Along with the above observation a significant difference in specific polypeptides pattern of stresed plants was observed with that of control indicates that effect of salinity on gene expression in olive plantletes.

P0225. Molecular mapping of genes related to salt tolerance in rice

M. H. fotokian[1], A. Taleei[2], B. Ghareyazie[3], Z. Li[4];
[1]Shahed university, Tehran, Islamic Republic of Iran, [2]Tehran university, Tehran, Islamic Republic of Iran, [3]Agricultural Biotechnology Institute of Iran, Karaj, Islamic Republic of Iran, [4]International Rice Research Institute, Los banos, Philippines.

The present study was conducted to identify the genetic factors controlling the traits related to salinity tolerance. A total of 6 quantitative traits, including Sodium and Potassium concentration in root(NaR,KR) and shoot(NaS,KS), Na-K ratio in root and shoot, were scored in an BC_2F_4 population from a cross between IR64, Tarom Molaei. A total of 62 BC_2F_4 lines were genotyped by means of 114 SSR markers. Transgressive segregation was observed in all traits. Using Multiple Interval Mapping, a total of 16 putative QTLs were detected, of which 3 were for KS, 3 for NaS, 3 for KR, 4 for NaR, 1 for NaS/KS, 2 for NaR/KR. The amount of variation explained by individual QTLs ranged from a low of 9% to a high of 57%, and many of the QTLs accounted for more than 15% of the variation. This study indicated that favorable QTL alleles could be transferred from local variety into an improved variety for improvement of quantitative trait loci like salinity tolerance by the advanced backcross QTL strategy and molecular breeding.

P0226. Characterization and functional analysis of Arabidopsis thaliana MAP kinase MPK10

V. Stanko, C. Giuliani, F. Kragler, E. Heberle-Bors;
Max F. Perutz Laboratories, University Departments at Vienna Biocenter, Vienna, Austria.

Mitogen-activated protein kinase (MAPK) cascades are universal signal transduction modules present in all eukaryotes. These protein phosphorylation cascades integrate extracellular stimuli into cellular responses. In plants MAPKs are involved in the responses to various biotic and abiotic stresses, hormones, cell division and developmental processes.
The focus of our work is the *Arabidopsis thaliana* gene MPK10, a representative member of the group A MAPKs. We isolated and characterized knock-out mutant lines (SALK collection), via PCR and sequencing approaches. These analyses showed that expression of MPK10 is not impaired, however the insertion of the T-DNA into the gene leads to a shift of the open reading frame, thus to a non functional transcript We also created over expression lines and dominant negative mutant versions with an amino acid exchanged in the catalytic site of the kinase. We isolated some transgenic lines, which we are currently characterizing.

P0227. Mechanisms, specificities and rates of nuclear DNA content variation in flowering plants

K. Devos, J. Ma, J. Bennetzen;
University of Georgia, Athens, GA, United States.

We have used comparative analyses of orthologous genomic segments from several grass species to identify the rates and natures of indel generation. These results have been compared to changes in DNA sequence that we have observed in rice and Arabidopsis LTR-retrotransposons, a family of transposable elements that can serve as surrogates for the entire genome. The data indicate that genome growth is primarily associated with polyploidy and transposable element amplification. This growth competes with a slow but continuous loss of DNA sequence by small deletions, most associated with illegitimate recombination or unequal homologous recombination. Different species vary in their rates and primary mechanisms of both DNA addition and removal. Moreover, different regions and components within grass genomes undergo very different rates and dominant mechanisms of indel accumulation. These studies provide a mechanistic framework to understand the exceptionally dynamic genomes found in the nuclei of flowering plants.

P0228. 5S rRNA gene diversity in the genus Secale and which are its closest haplomes

B. R. Baum[1], Y. Wei[2], Y. Zheng[2];
[1]Agriculture & Agri-Food Canada, Ottawa, ON, Canada, [2]Triticeae Research Institute, Sichuan Agricultural University, Dujiangyan, China.

Secale contains the cultivated cereal Rye along with a number of wild species. This genus is a member of the Triticeae tribe. The purpose of the present investigation was assess the diversity of the 5S DNA units within the genus, to determine haplomes closest to it also based on the 5S DNA units and to compare the findings with different taxonomies and position of the genus within the Triticeae tribe. *Secale* contains long R1 and short R1 units which although vary are not useful for distinguishing species and below. Phylogenetic inferences were drawn from Bayesian and maximum likelihood analyses. The closest related haplomes are the **P** haplome inferred from the 5S short R1 units, and the **St** haplome inferred from the long R1 units. Thus *Secale* appear the be phylogenetically close to the predominantly diploid genera *Pseudoroegneria*, containing the **St** haplome, and to *Agropyron* containing the **P** haplome. Somewhat less related are the **J** haplome, typical to *Thinopyrum*, and possibly the **V** haplome typical to *Dasypyrum*. Traditional taxonomies classify *Secale* and *Dasypyrum* (Mosquitograss) next to each other which is in some contrast with the present findings of the 5S DNA units.

P0229. Preliminary study of relative DNA content variation in some European populations of *Lactuca serriola*

A. Lebeda[1], N. Gasmanová[1], I. Dole alová[1], J. Janeļ ek[2];
[1]Palacký University, Faculty of Science, Department of Botany, lechtitelŢ 11, 783 71 Olomouc, Czech Republic, [2]Plant Breeding Station, Fulnecká 95, 742 47 Hladké ivotice, Czech Republic.

L. serriola is extremelly variable wild species and is considered as a progenitor of cultivated lettuce (*L. sativa*). The investigation includes the analysis of relative nuclear DNA contents of 99 *L. serriola* accessions collected in 12 European countries. Results obtained by flow cytometry were based on DAPI staining technique. Data on 2C relative DNA contents showed significant variation (from 4.34 to 6.85) among individual populations. The set studied was divided into 21 groups differing in relative DNA contents. Significant differences in the mean DNA content were found among populations originating from different countries. One of the lowest values (4.66) is characteristic of material from Switzerland, the highest (6.85) for Slovak Republic. Nuclear DNA contents in *L. serriola* was not clearly related to their taxonomic status (f. *serriola*, f. *integrifolia*). Research was supported by projects MSMT 153100010 and MSM 6198959215.

P0230. Accumulation of chloroplast DNA sequences on the Y chromosome of the dioecious Silene latifolia

Z. Kubat[1], E. Kejnovsky[1], R. Hobza[1], M. Lengerova[1], S. Sato[2], S. Tabata[2], K. Fukui[3], S. Matsunaga[3], B. Vyskot[1];
[1]Institute of Biophysics, Academy of Sciences of the Czech Republic, Kralovopolska 135, 612 65 Brno, Czech Republic, [2]Kazusa DNA Research Institute, 2-6-7 Kazusa-kamatari, Kisarazu, Chiba 292-0818, Japan, [3]Department of Biotechnology, Graduate School of Engineering, Osaka University, 2-1 Yamadaoka, Suita, Osaka 565-0871, Japan.

Horizontal transfer of plastid and mitochondrial DNA sequences into plant nucleus is a well-described phenomenon. It has been accepted that the position of integrated organelle DNA is random and frequently directed to (peri)centromeric regions of all of the chromosomes. The model dioecious plant *Silene latifolia* possesses a pair of heteromorphic sex chromosomes, X and Y, in an early stage of evolutionary divergence. The Y chromosome is largest in the *S. latifolia* genome and this fact could predict an accumulation of repetitive sequences in the Y-non-recombining region. In this study, we present a chloroplast derived BAC clone preferentially and strongly hybridizing to the Y chromosome of *S. latifolia*. Using X and Y laser microdissection followed by DOP-PCR we prepared DOP-X and DOP-Y libraries, which were later screened for chloroplast DNA sequences. By virtue of low sequence divergence of selected DOP clones and original chloroplast sequence, we come to a conclusion of a recent transfer of chloroplast DNA to the Y chromosome of *S. latifolia*.

P0231. The albino enigma - DNA deletions and translation-deficiencies in microspore-derived plants

B. J. Hofinger[1], E. Ankele[2], M. Pfosser[3];
[1]Department of Botany- University of Natural Resources and Applied Life Sciences, Vienna, Austria, [2]Institute of Microbiology and Genetics - University of Vienna, Vienna, Austria, [3]Biologiezentrum - OÖ Landesmuseum, Linz, Austria.

In monocotyledonous plants, which were regenerated from cultured microspores, albinism is a frequently observed phenomenon. Frequently, large rearrangements or deletions were found in the plastid genomes of microspore-derived albino plants. In a significant number of albino plants, however, no deletions could be detected. We examined gene expression in plastids of wheat albino plants. Analysis of steady-state RNA levels of several plastid genes showed a deviant transcript pattern compared to green plants. The altered plastid RNA profile can be explained by the lack of an active plastid-encoded RNA polymerase. Examination on the protein level revealed the absence of plastid-encoded proteins. Particularly, the absence of an essential component of plastid ribosomes strongly suggests a complete deficiency of plastid protein synthesis, which can explain the absence of the plastid-encoded RNA polymerase. These results indicate that monocots are able to survive without plastid protein synthesis when sugar is supplied in the growth medium.

P0232. Androgenesis in vitro of Siberian larch (Larix sibirica Ledeb.)

A. N. Ivanova, A. Vyazovetskova, I. Trety'akova;
V.N. Sukachev Institute of forest SB of RAS, Krasnoyarsk, Russian Federation.

At present androgenesis in vitro takes an important place in plant biology. It was induced in many angiospermious plants. With the help of androgenesis in vitro the selection process is accelerated, new sorts and lines of grasses are created. The male buds of Siberian larch do not have an organic dormancy in the fall-winter period and under favorable conditions they are able to complete the development of the male generative structures. Cultivation of microsporophylles on the MS medium containing 0,2-0,5 mg/l of hormone 2,4-D during a month results in induction of androgenesis in vitro in Siberian larch. The increase of hormone concentration causes development of necrotic processes. Data on androgenesis in vitro of Siberian larch, as of a representative of gymnosperms were obtained for the first time. At cultivating microsporophylles of Siberian larch on the MS medium with concentration 0,2-0,5 mg/l 2,4-D the embryos of two development types were obtained.

P0233. The ARIADNE family in Arabidopsis thaliana: A characterization of putative E3 ligases

C. Mladek, M. T. Hauser;
BOKU Institute for Applied Genetics and Cell Biology, Vienna, Austria.

ARIADNE (ARI) proteins were recently identified in fruitfly, mouse and man. They are characterized by two C_3HC_4 RING-finger motifs separated by a in between region (IBR). ARI proteins share their RING-IBR-RING domain with PARKIN and there is increasing evidence that ARI/PARKIN proteins function as E3 ubiquitin ligases. On the basis of homology and motif searches, we identified 16 *AtARI* genes in *Arabidopsis*. Using real-time quantitative PCR we determine the expression level of the family in different organs. The subcellular localization of ARI1, ARI2 and ARI12 was studied with peptide-specific antibodies on *Arabidopsis* cell cultures and revealed that ARI1 has a speckled localization in the cytoplasm. ARI2 is found exclusively in the nucleus, whereas ARI12 exhibits nuclear and a weak speckled staining in the cytoplasm.

To address the function of this gene family we initiated a reverse genetic approach by screening for knock out alleles. The phenotypic characterization of single and the progress on double and triple mutant analyses will be presented.
Supported by the Austrian Science Fund (FWF P14477-GEN)

P0234. Two A. thaliana members of a novel protein family are potentially involved in nucleobases transport

V. G. Maurino[1], **E. Grube**[1], B. S. Schumacher[2], U. I. Flügge[1], M. Desimone[2];
[1]Botanisches Institut, Universität zu Köln, Cologne, Germany, [2]ZMBP, Universität Tübingen, Tübingen, Germany.

Nucleobases and derivatives play essential roles in the cells of all living organisms. In plants, crucial transport processes like the uptake of purines and pyrimidines for salvaging, the long distance transport of purine degradation products, and the allocation of cytokinins are not well understood. In this work, two novel putative transporters for nucleobases encoded in the Arabidopsis genome have been identified. Both coding sequences restored the capacity to take up adenine when expressed in a S. cerevisiae mutant defective in adenine uptake (fcy2). Competition studies showed that other purines and derivatives are also transported. To assess the subcellular localization, transient expressions in N. tabacum BY-2 protoplasts of GFP fusions under the control of the CaMV 35S promoter were conducted. RT-PCR analysis and promoter activity studies revealed the organ and cellular expression of both genes. Whereas one of the genes is expressed in all plant organs, the second shows a more regulated expression pattern, which is maximal in roots and flowers. Interestingly, expression of one member is strongly induced by exogenously applied auxin.

P0235. Comparison of detected QTLs for the traits pre-harvest sprouting and dormancy in wheat (Triticum aestivum L.) and barley (Hordeum vulgare L.)

U. Lohwasser, M. S. Röder, A. Börner;
Institute of Plant Genetics and Crop Plant Research (IPK), Gatersleben, Germany.

A set of 114 recombinant inbred lines (RILs) of the ITMI mapping population (International Triticeae Mapping Initiative, Mexico) was grown under field conditions in Gatersleben in 2003 and under greenhouse conditions in 2004. The lines were evaluated for the domestication traits pre-harvest sprouting and dormancy (germinability). Main QTLs could be localized for pre-harvest sprouting on chromosome 4AL and dormancy on chromosome 3AL. The location of the pre-harvest sprouting gene on chromosome 4AL found in other cultivars was confirmed. Also known dormancy effects on chromosome 3AL in the cultivar “Chinese Spring” were approved. In addition, 94 double haploid lines (DH) of the OWB-population (Oregon Wolfe Barley) grown under field and greenhouse conditions are in study to discover QTLs for these traits. The OWB-population is a well characterised, phenotypically polymorphic mapping population that has been used for a whole range of mapping and QTL studies. A comparison of the detected QTLs between wheat and barley is proposed.

P0236. Repetitive DNA behaviour inducted by metals in *L. riparium* and *F. hygrometrica* gametophytes

P. Bassi[1], A. Basile[2], M. Ferraro[3], E. Napolitano[4];
[1]Dept. of Plant Biology - University, Roma, Italy, [2]Dept. of Plant Biology - University of Naples, Naples, Italy, [3]Dept. of Genetic and Molecular Biology - University "La Sapienza", Roma, Italy, [4]Dept. of Plant Biology - University "La Sapienza", Roma, Italy.

In order to investigate the relationship between environment and genome, we studied the repetitive DNA behaviour in answer to metals in two Bryophytes: the aquatic *L. riparium* and the terricolous *F. hygrometrica*. Working in *in vitro* cultured gametophytes, we showed that a direct "cause and effect" relation exists between metal stress and repetitive DNA behaviour. In fact, A-T and G-C specific fluorochrome treatment showed that cadmium or lead are able to induce a selective amplification of some GC-rich repetitive DNA sequences forming peculiar agglomerates inside the nucleus. As soon as the metals are removed from the culture medium, the DNA amplification stops and the new formed repetitive DNA, that is quantitatively proportional to the time of plant exposure to metals, is gradually eliminated from the cell. *In situ* hybridization and Southern Blotting experiments showed that also rDNA is involved in the described phenomena. Electron microscopy and X-ray TEM microanalysis show that metals are able to reach heterochromatic areas of genome. Our data support the theories considering repetitive DNA as a possible mediator between environment and gene expression.

P0237. Identification of heat shock proteins in camu-camu (*Myrciaria dubia* (H.B.K.) McVaugh)

M. L. da Silva[1], E. R. Almeida[2], K. Yuyama[3], S. Astolfi Filho[4];
[1]Universidade Federal do Amazonas, Manaus, Brazil, [2]EMBRAPA - CENARGEN, Brasília, Brazil, [3]INPA, Manaus, Brazil, [4]UFAM, Manaus, Brazil.

The functional genome of camu-camu, native specie of the Amazonian, enables the identification of new genes of biotechnological interest by means of the sequencing of Expressed Sequence Tags (EST). The sequences were identified by the system of alignment tBLASTx - NCBI, and analyzed as regards the homology in the LALING program. The camu-camu EST project this in course, were present partial results of the identification of the ESTs that encoding heat shock protein. The *Md*3i95 sequence was similar to sHSP17,5CI of *C. papaya* (GI:38639430). The *Md*3i403 clone was similar to sHSP17,6CI of *L. esculentum* (GI:4836472). The *Md*3i20 and *Md*3i717 sequences were similar to sHSP18,5CI of *G. max* (GI: 18653); and the *Md*3i700 sequence was similar sHSP22 of *G. max* (GI:18660). The *Md*3i732 sequence was similar to HSP70 of *V. labrusca* (GI: 14581676); and the *Md*3i87 and *Md*3i768 sequences were similar to HSC70-2 of *A. thaliana* (GI: 30679645) and HSC70-3 of *V. radiata* (GI: 45331284), respectively. The *Md*3i152, *Md*3i09 and *Md*3i85 sequences were similar, respectively, to HSP80 of *E. esula* (GI: 6934297), HSP82 of *N. tabacum* (GI:19879), and HSP83 of *P. nil* (GI: 169295).

P0238. QTLs contributing to pearl millet [*Pennisetum glaucum* (L.) R. Br.] grain yield under varying moisture conditions during grain filling

T. Nepolean[1], C. T. Hash[1], F. R. Bidinger[1], R. S. Yadav[2], S. Chandra[1], C. J. Howarth[2], K. Skot[2], E. Waterman[3], L. Hui[3], K. M. Devos[4];
[1]International Crops Research Institute for Semi-Arid Tropics, Hyderabad, India, [2]Insititute of Grassland and Environmental Research, Aberyswyth, United Kingdom, [3]John Innes Center, Norwich, United Kingdom, [4]University of Georgia, Athens, GA, United States.

The objective of this study was to identify QTLs for yield and yield-correlated traits that would maximize/stabilize grain yield across a range of moisture conditions during grain filling. The study used testcrosses of 78 skeleton-mapped F2-derived F4 progenies from the (ICMB 841-P2 × 863B-P1)-derived pearl millet mapping population. These were evaluated in managed fully-irrigated non-stress conditions, as well as late-onset (mild) and early-onset (severe) terminal drought stress conditions, over four years in the dry-season drought nursery at ICRISAT-Patancheru to map genomic regions associated with grain yield and related traits. Three QTLs for grain yield detected on LG1, LG2 and LG3 were stable across moisture environments and years and co-mapped with other yield-related trait QTLs. There was useful complementarity between the 863B alleles at a strong panicle harvest index QTL on LG1 and the harvest index QTL on LG2, and the ICMB 841 allele at the harvest index QTL on LG3. Stability of pearl millet grain yield under a range of grain-filling moisture conditions should be enhanced by marker-assisted pyramiding of the favorable alleles at these three QTLs

P0239. Isolation of putative type 2-metallothionein-encoding sequences and their spatial expression pattern in the seagrass *Posidonia oceanica* after metal treatment

R. Cozza[1], T. Pangaro[1], P. Maestrini[2], A. Cavallini[2];
[1]Department of Ecology, University of Calabria, Cosenza, Italy,
[2]Department of Agricultural Plant Biology, University of Pisa, Italy.

Metallothioneins (MTs) are proteins with low molecular mass and high cysteine contents that bind to heavy metals and probably play a role in their metabolism and detoxification. We isolated eleven MTs-like sequences from copper- or cadmium-exposed plants of the seagrass *P. oceanica*, a marine Angiosperm playing a major role in maintaining infralittoral ecosystems in the Mediterranean Sea. These sequences show high similarities with genes encoding type 2-MTs. Neighbor-joining analysis indicates that at least two subfamilies occur within *Posidonia* type 2 MTs, showing however a strong sequence uniformity. For each subfamily we analyzed two gene (*Pomt2b* and *Pom2f*) by Southern blotting and hybridization using a DIG-labeled riboprobe. The same riboprobes were used to determine, by *in situ* technique, the expression domain in *Posidonia* plants both *in vivo* and exposed to cadmium in aquarium. *Pomt2b* and *Pom2f* show tissue specific expression and a high induction during Cd treatment. Our results suggest that *Pomt2b* and *Pomt2f* play an important role in maintaining the metal homeostasis and detoxification in *P. oceanica* shoot and leaves.

P0240. Characterization and tissue expression pattern of two aquaporin-encoding genes in the seagrass *Posidonia oceanica*

T. Pangaro[1], **R. Cozza**[1], P. Maestrini[2], L. Natali[2], A. Cavallini[2];
[1]University of Calabria, Cosenza, Italy, [2]Department of Agricultural Plant Biology, University of Pisa, Italy.

Beyond simple diffusion across a lipid bilayer, water transport through cell membranes is related to aquaporins. Aquaporins belong to a highly conserved group of membrane Major Intrinsic Proteins In contrast to terrestrial plants, no aquaporins or aquaporin-encoding genes have been isolated from marine plants. *Posidonia oceanica* is a marine angiosperm, largely widespread in the Mediterranean Sea. We have isolated by PCR-RACE two genes encoding putative proteinaceous water channels, *Po*PIP1;1 and *Po*TIP1;1. *Po*PIP1;1 is unique in the genome of *P. oceanica*, while *Po*TIP1;1 belongs to a subfamily of at least four members. Both genes are constitutively expressed in the leaves, and are more transcribed in young than in differentiated tissues.

We have also determined, by *in situ* technique, the expression domain of PoPIP1;1 e PoTIP1;1 in different organs of the plant. *Po*PIP1;1 is preferentially localized in the apical meristem and in the rhizome, whereas *Po*TIP1;1 is localized in the root; both the aquaporins are expressed in the leaf mesophyll, suggesting an important role of these aquaporins in the uptake and water homeostasis in *P. oceanica* plant.

P0241. Distinct patterns of DNA methylation characterise populations of Posidonia oceanica (L.) Delile derived from anthropically stressed and intact areas.

M. Greco[1], **A. Chiappetta**[1], D. Giannino[2], M. B. Bitonti[1];
[1]University of Calabria, Cosenza, Italy, [2]Istituto di Biologia e Biotecnologia Agraria, Monterotondo scalo (RM), Italy.

Posidonia oceanica (L) Delile is an important marine phanerophyte of the Mediterranean area. In the last years a regression of meadows has been caused by the increasing anthropization and Posidonia has been proposed as an effective bio-indicator to monitor sea environments. DNA methylation is a fundamental mechanism for gene expression regulation and plant development. In this context, we investigated the changes in DNA methylation between two populations of Posidonia derived from anthropic-stressed and intact areas respectively during three different periods in the year

DNA methylation of shoot apical meristems and young leaves was monitored by immunocytological and MSAP analysis. A set of morphometric and nucleotipic features were also investigated The populations of anthropizated meadows showed cytosine hypermethylation and chromatin re-modelling with respect to those of intact areas. Moreover, MSAP signal-band profiles revealed that the DNA methylation grade of the former was higher than controls, thus suggesting that the methylation increase in Posidonia may be used as a molecular marker to predict and evaluate altered environmental condition

P0242. Assembly of a cDNA-microarray to test abiotic stress in pepper (*Capsicum annuum* L.)

A. H. Sziderics, S. Fluch, M. Berenyi, F. Rasche, A. Sessitsch, E. Wilhelm;
ARC Seibersdorf research GmbH, Biogenetics and Natural Resources, Biotechnology, A-2444, Seibersdorf, Austria.

The aim of our study is the assembly of a stress-array with homologous and heterologous cDNA probes. Literature research resulted in more than 1000 interesting drought stress related genes in various species. Corresponding ESTs available in the PICME-clone depository (www.picme.at) were selected by BLAST alignment. Clones of differentially expressed genes of pepper isolated by cDNA-SSH serve as control. The stress-array will be evaluated with a stress-tolerant (Ziegenhorn Bello) and a stress-sensitive (Milder Spiral) pepper variety. To correlate gene expressions with the physiological status of the plants, selected stress genes (real time-PCR) and proline content, peroxidase activity and osmotic potential were measured. In addition the effect of several endophytic bacteria on these two pepper varieties were tested. Preliminary tests revealed two strains of growth promoting bacteria, which will be further investigated.

P0243. Large scale screening for carotenoid genes in tomato: Map-based cloning and characterization of *white-flower* (*wf*) and *high-pigment* 3 (*hp3*)

N. Galpaz, N. Menda, Q. Wang, G. Ronen, D. Zamir, J. Hirschberg;
Departments of Genetics, The Hebrew University of Jerusalem, Jerusalem, Israel.

To identify genes that regulate carotenoid biosynthesis in plants we have isolated novel mutations that affect colors of flower and fruit in tomato (*S. lycopersicum*, CV M82) by screening more than 200,000 tomato plants following EMS or fast-neutron mutagenesis. Twenty one mutants with altered flower pigmentation and 39 mutants with fruit color changes have been identified. Carotenoid composition in leaves, petals, anthers and fruits of each mutant was determined by HPLC. Two mutants, *high pigment 3* (*hp3*) and *white flower* (*wf*) were further studied. Mutant *hp3* accumulates 40% more carotenoids in the fruit compared with the wild type and its flowers and leaves contain high level of zeaxanthin and antheraxanthin at the expense of violaxanthin and neoxanthin due to a mutation in zeaxanthin epoxidase. Consequently, ABA is reduced in this mutant and its leaves are more sensitive to strong light. Wild-type tomato flowers accumulate high concentration of neoxanthin. In contrast, *wf* flowers contain low levels of ß-carotene. Cloning of *wf* revealed that it encodes a flower-specific ß-carotene hydroxylase. Tomato has two beta-carotene hydroxylase genes: one is constitutively expressed in leaves and the other is exclusively transcribed in flowers. The elucidation of the molecular basis of the *wf* mutation underscores the evolution by gene duplication of a chromoplast-specific carotenoid biosynthesis pathway.

P0244. Plant myosin VIII: from cell-cell communication to stress response

D. Volkmann[1], A. Hlavacka[1], P. Wojtaszek[2], **F. Baluska**[1];
[1]University of Bonn, Bonn, Germany, [2]University of Poznan, Poznan, Poland.

AtATM1 is the first cloned and sequenced plant myosin and represents the founding member of the class VIII of myosins. Polyclonal antibodies have been raised against its unique C-terminal tail domain and used for the localization of AtATM1 via light and electron microscopy. AtATM1 localizes preferentially to the plasma membrane at cell periphery domains enriched with callose. In particular to the newly formed cytokinetic cell walls, auxin transporting end-poles in the root apex, phloem sieve plates, as well as to plasmodesmata and pit-fields of the inner cortex near unloading phloem elements of root apices. Moreover, it emerges as endocytic motor of plant cells. Under stress situations, like microgravity environment and hyperosmolarity, AtATM1 is relocalized within cells suggesting that AtATM1 may also have multiple functions in stress response and stress adaptation.

P0245. Expression patterns of Arabidopsis thaliana myosin promoter fusions with GUS reporter gene in transgenic plants

B. Ilau, E. Ojangu, H. Paves, E. Truve;
Tallinn University of Technology, Tallinn, Estonia.

Myosin proteins are eukaryotic actin- and ATP-dependent molecular motors. Myosins have been divided into at least eighteen classes. All the Arabidopsis thaliana myosins fall into two groups - class VIII and class XI. Arabidopsis thaliana encodes 17 putative myosins, four in class VIII and thirteen in class XI.

Although myosins in animal cells have been studied in detail, little is known about the specific functions of myosins in plant cells. It has been suggested that class XI myosins are involved in cytoplasmic streaming while class VIII myosins are associated with the plasma membrane and plasmodesmata at the post-cytokinetic cell wall.

To determine the expression patterns of Arabidopsis thaliana myosins we have constructed several transgenes in which the reporter gene GUS is expressed under the control of different myosins promoter sequences. A part of myosin promoter-GUS transgenes show constitutive expression but in some cases the expression is tissue specific.

P0246. Mutations in a class XI and in a class VIII myosin genes affect the root hair growth in Arabidopsis thaliana

E. Ojangu, K. Järve, H. Paves, E. Truve;
Tallinn University of Technology, Tallinn, Estonia.

Myosins are eukaryotic molecular motors moving along actin filaments. Reddy and Day (2001) described with in silico analysis that there are 17 possible sequences, which could code myosins in Arabidopsis thaliana genome. All 17 possible Arabidopsis myosins belong to two classes - class VIII containing 4 myosins and class XI containing 13 myosins.

The specific functions of Arabidopsis myosins are unclear. Here we descibe phenotypes of homozygous T-DNA insertional mutants of two different myosin genes. Three different T-DNA insertional mutants of a same class XI myosin gene show similar but quantitatively different impaired root hair growth: length of root hairs of four-day-old mutant seedlings was 77, 50, and 41% of wild type root hairs, respectively. T-DNA insertional mutant of a class VIII myosin gene shows also decreased growth of root hairs with length of root hairs 55% of wild type root hairs.

It is known that plant tip growth is dependent on actin-based organell/vesicle movement - thereby we suggest involvement of the class XI and class VIII myosins in cell elongation and tip growth. The specific roles of each myosin still remains to be resolved.

P0247. Identification of plant formin genes involved in the feeding site formation induced by root-knot nematodes

B. FAVERY, L. CHELYSHEVA, P. LECOMTE, F. JAMMES, J. DE ALMEIDA-ENGLER, P. ABAD;
INRA-UNSA-CNRS, Sophia-Antipolis, France.

Plant-parasitic nematodes *Meloidogyne* spp. induce an elaborate permanent feeding site characterized by the redifferentiation of root cells into multinucleate and hypertrophied giant cells. We have isolated by a promoter trap strategy an *Arabidopsis thaliana* formin gene, *AtFH6*, which is upregulated during giant cell formation. Formins are actin-nucleating proteins that stimulate *de novo* polymerization of actin filaments. We showed here that three type-I formins were upregulated in giant cells and that the AtFH6 protein was anchored to the plasma membrane and uniformly distributed. Suppression of the budding defect of the *Saccharomyces cerevisiae bni1φ bnr1φ* mutant showed that AtFH6 regulates polarized growth by controlling the assembly of actin cables. Our results suggest that AtFH6 might be involved in the isotropic growth of hypertrophied feeding cells via the reorganization of the actin cytoskeleton. Therefore, determining how plant parasitic nematodes modify root cells into giant cells represents an attractive system to identify genes that regulate cell growth and morphogenesis.

P0248. New evidence that 2,3-butanedione monoxime is not a general plant myosin inhibitor

W. Krzeszowiec, K. A. Banas, H. Gabrys;
Department of Plant Physiology and Biochemistry, Faculty of Biotechnology, Jagiellonian University, Cracow, Poland.

2,3-butanedione monoxime (BDM) is considered as a general inhibitor of myosin ATPase activity. BDM inhibitory effect has been used as evidence of myosin involvement in processes such as cell migration and focal adhesion in animal cells. However, some processes turned out to be insensitive to BDM in plant cells, e.g. cytoplasmic streaming in Chara coralline and light-dependent chloroplast repositioning in Elodea sp. These processes are known to be mediated by the actomyosin system. On the contrary, peroxisome motility in Allium and Golgi stack movemets in Nicotiana BY2 cells are inhibited by BDM. In the model plant Arabidopsis thaliana chloroplast photo-orientation movements are not based on cytoplasmic streaming. Nevertheless, actomyosin is an essential part of the chloroplast movement system. The aim of our study was to determine if BDM could be used in investigations of light-induced chloroplast responses in Arabidopsis. Using photometric method we found out that amplitudes and kinetics of accumulation and/or avoidance responses are unaffected by BDM. Summarizing, no general myosin inhibitor has been established so far, at least in plant cell studies.

P0249. The *Oryza sativa Myosin* XI B (*OsMyo*XIB) controls pollen development by photoperiod-sensitive protein localization

S. Y. Jiang, M. Cai, S. Ramachandran;
Temasek Life Sciences Laboratory, 1 Research Link, National University of Singapore, Singapore, Singapore.

We have identified an *OsMyo*XIB mutant in a phenotype screen of gene trap *Ds* insertion lines. This mutant showed male sterility under short day length conditions (SD) and fertility under long day length (LD). Under both SD and LD, the *OsMyoXIB* transcript was detected in all layers of anther wall, connective tissues, and young microspores. However, under SD, the OsMyoXIB-GUS fusion protein was localized only in the epidermal layer of anther tissues due to lack of 3'UTR and dilute domain sequences after *Ds* insertion. As a result, the mutant pollen development was affected thus exhibited male sterility. Under LD, the fusion protein was localized normally in all cell layers. Despite the normal localization, the protein was partially functional due to the lack of dilute domain, resulting in limited recovery of pollen fertility. Our results suggested that the photoperiod-sensitive expression of OsMyoXIB was controlled post-transcriptionally by 3'UTR and dilute domain sequences.

P0250. Phylogenetic origins of dioecy in Silene

A. Rautenberg[1], D. Filatov[2], B. Oxelman[1];
[1]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden, [2]School of Biosciences, University of Birmingham, Birmingham, United Kingdom.

The aim of this project is to provide a phylogenetic/taxonomic framework for the evolution of dioecy within Silene (Caryophyllaceae). There are several dioecious taxa within the genus, traditionally classified in the sections Elisanthe and Otites. To understand how dioecy has evolved, these dioecious taxa need to be compared with their closest relatives. Available data suggest that the dioecious taxa within Elisanthe do not form a monophyletic group with the hermaphrodites in the section. Instead they seem more related to section Conoimorpha. This study is based on data from several Silene genes: (i) a gene sex-linked in the dioecious Elisanthe species (SlXY1) and a homologous autosomal gene in hermaphroditic taxa, (ii) intron sequences from the genes encoding the second largest subunits in the RNA polymerase gene family (RPA2, RPB2, RPD2) and (iii) chloroplast DNA. Remarkably, preliminary data suggest recombination between phylogenetically distant SlXY1 lineages.

P0251. Adaptations to salinity in halophytic grass *Puccinellia limosa* Schur. (Holomb.)

Z. P. Dajic Stevanovic[1], S. Vrbnicanin[1], M. Kresovic[1], B. Stevanovic[2];
[1]Faculty of Agriculture, Belgrade, Serbia and Montenegro, [2]Faculty of Biology, Belgrade, Serbia and Montenegro.

Seasonal changes of root and shoot ion content of halophytic grass *Puccinellia limosa* were monitored in the samples collected from its natural habitats, situated in the north Serbia during the vegetation season.

The total salt content of the soil ranged from 0.37% to 0.64%, whereas sodium concentration of the soil solution varied between 129 mmol and 218 mmol. Average content of some ions in the shoot, such as Na$^+$ (127.5 ± 64.1 µmol g^{-1} dry weight), Ca^{2+} (88.3 ± 46.5 µmol g^{-1}) and Mg $^{2+}$ (61.1 ± 17.3 µmol g^{-1}) was lower comparing with the root, in difference to the content of potassium and, especially chloride whose concentrations in shoot were significantly higher. The Na/K ratio of the shoot was < 1, which is typical for halophytic monocots, and it is being increased along with enhanced Cl- accumulation during the vegetation season, causing growth inhibition.

Ion retention in the root, high root capacity for ion accumulation, including calcium, low rate of salt movement to the shoot, as well as the doubled endoderm and mechanism of salt exclusion, are important features of *Puccinellia limosa*, limiting the deliver of ions to the photosynthetic tissues.

P0252. Structure and Histochemistry of the foliar laminae and vegetative propagation of *Phyllonoma laticuspis*, medicinal species.

E. Alcántara- Flores[1], A. E. Brechú-Franco[1], G. Laguna-Hernández[1], A. Villegas-Monter[2];

[1]Facultad de Ciencias, México, D.F., Mexico, [2]Colegio de Posgraduados, Texcoco, Estado de México, Mexico.

Phyllonoma laticuspis foliage is used by mexican ethnic groups to heal mainly skin wounds like hurt and smallpox but also disease like diabetes and cancer. Chemical analysis of foliar laminae have demonstrated positive pharmacological activity. Histological and histochemical studies have been done to characterize the foliar laminae and propagation technics through stakes and layers were applied for conservation. Foliar laminae were include in paraplast and they were dyeing for its observation. Stakes and layers were treated with indolbutiric acid (IBA) using different concentrations. Since the inflorescence arises from foliar laminae, structural characteristics were searched in order to distinguish if this organ is an stem or a leaf. Foliar laminae is dorsiventral and hypostomatic, presents tannins in the margin and peciolo and shows the entrance of three vascular beams in the base, elements that sign it has a leaf. The stakes didn't take root , while layers showed an 88% of rooting. Although *Phyllonoma laticuspis* is a hard species to take root, it could be propagated with the applied treatments and to benefit.

P0253. Drug accumulation by natural populations and cultivars of Cannabis and Ephedra species.

K. N. Sarsenbav, M. G. Kairova, L. Kozhamjarova, C. Steup;
Institute of Botany and Phytointroduction, Almaty, Kazakhstan.

It was studied natural populations 7 species of Ephedra, Cannabis ruderalis and 4 fibre cultivars of Cannabis sativa. The leaves samples of Ephedra were taken from different provinces, Cannabis ruderalis from Shu valley and south-east part of Kazakhstan. European varieties of Cannabis sativa cultivated in Shu valley. By the method of biochemical markers it was shown genetical differences between populations and species. Analysis of leaves composition revealed accumulation of tetrahydrocannabinol, ephedrine and their isomers. Separate isomers were identified quantitatively and qualitatively. Analysis of the populations and cross pollinated hybrids on a huge area give possibility to prove that drug accumulation is a genetical feature. Accumulation of separate isomers depends on hereditary pecullarities. Sometimes this is a dominant feature, sometimes codominant, but with a very active isoenzyme-syntase of this isomer (usually they have a common precursor). In this case several compounds are synthetasing simultaneously, but the substrate is one and activity of isoenzymes is different. As a result different amounts of isomers.

P0254. The cellular basis of interspecific differences in leaf size among C_3 grass species

S. Sugiyama;
Hirosaki University, Hirosaki, Japan.

This study examined cellular mechanisms resulting in interspecific variation in leaf length among 16 C_3 grass species. The cell length profile of the mesophyll layer in the leaf growth zone was observed by Nomarsky interference microscopy, and various cell parameters related to division and elongation were calculated using a kinematic method. Leaf length showed a three-fold difference among the species. This difference in leaf length was mostly due to the difference in cell number and not to the difference in cell size. The difference in cell number among the species reflected the difference in cell division activity in leaf meristem, which was mostly determine by the number, not the rate, of cell cycle. Cell elongation processes showed close coordination with cell division activity. About 70 % of the variation in mesophyll cell size was determined only by the number of cells in the division zone. Species with high cell division activity had smaller mesophyll cells, which were caused by short cell elongation period.

P0255. Photoperiodic activation of protein kinase C expression in short-day plants

O. I. Kovzun[1], V. A. Negretsky[2], V. M. Pushkarev[1];
[1]Institute of Endocrinology and Metabolism, Kiev, Ukraine, [2]Institute of Botany, Kiev, Ukraine.

Mechanism of flowering induction is up to this time incomprehensible. Wide spectrum of components of this induction does not exclude significant role in this transduction passway of photoperiodic signal through protein kinase systems. The aim of this work was to study protein kinase C (Ŭ and ɖ) isoforms in leaves and stem of different short-day plants during photoperiodic induction. Among other components for alpha-protein kinase C activation the significant place have Ca2+ ions, whenever process of eta-PKC activation is Ca2+ independent. Plants for investigation were short-day Nicotiana tabacum L. M. Mamoth, Perilla crispa and Chenopodium rubrum L. which obtained photoperiodic induction by 1 , 2, 5, 10 and 15 short cycles (8 h of light and 16 h of darkness). PKC expression was studied by immunobloting. As a result expression of 2 PKC isoforms in leaves and stem of plants were shown. Activation of Ca2+ dependent alpha-PKC during flowering induction signifies possible role of this protein kinase in floral signal transduction. The study of eta-PKC activity in plants is conducted at first and elucidation of this isoform role in flowering induction will be continued.

P0256. Seed morphology of Neotropical species of *Bulbophyllum* Thouars (Orchidaceae - Dendrobiinae)

E. C. Smidt, E. L. Borba, C. van den Berg;
Universidade Estadual de Feira de Santana, Feira de Santana, Brazil.

We examined the morphology of eighteen american species of the Pantropical orchid genus *Bulbophyllum*, covering all Neotropical sections, using SEM (Scanning Electron Microscopy). Seed morphology is quite uniform in shape and ornamentation, with seeds ovoid to fusiform, presenting long testa cells without inter-cell gaps and verrucose walls. Seeds of all species had at least one dichotomized wall and displayed a spiraled conformation. Seed size varies between 91 to 200 µm in length and 46 to 83 µm in width. Cell number is usually eight in the wide axis and one in the long axis. This study is the apparently the first to examine seeds of Neotropical species of *Bulbophyllum* by SEM and we found seeds much smaller than those reported in the literature for the subtribe, actually being one of smallest orchid seeds reported. We did not find seed characters that could be successfully used as diagnostic markers for taxonomic groups (new world sections *Didactyle*, *Xiphizusa*, *Micrantha* and *Bulbophyllaria* sensu Pabst & Dungs). Only within section *Bulbophyllaria sensu* Hamer & Garay seeds were distinct by presenting a larger size, even though they did not display differences in shape.

P0257. Maintenance the integrity of endemic and endangered species of Orchidaceae in Northeast Brazil - reproductive aspects

V. Silva-Pereira, E. C. Smidt, E. L. Borba;
Universidade Estadual de Feira de Santana, Feira de Santana, Brazil.

We studied the isolation mechanisms in two pairs of endemic and endangered orchid species: *Cattleya elongata* / *C. tenuis* and *Sophronitis pfisteri* / *S. sincorana*. All species are pollinated by *Bombus brevivillus*: the *Cattleya* species by queens and the *Sophronitis* species by males and workers bees. The first pair presents strong floral similarity, floral synchrony, inter-compatibility and parapatric distribution, reproductive isolation being given by different habitats, as suggested by the occurrence of hybrids in disturbed areas. *S. pfisteri* and *S. sincorana* present dissimilar floral morphology, floral synchrony and sympatric distribution, reproductive isolation being given by partial inter-incompatibility and pre-pollination mechanisms: pollinarium deposition occurs on different places of the insects due to different length of the flower column - mesonotum for *S. pfisteri* and scutellum for *S. sincorana* - and inter-specific experimental crossings resulted in low fruit set and seed viability, preserving the genetic integrity of both species.

P0258. Morphological, physiological, and molecular biological characterization of a new thraustochytrid-like species, strain 12B that accumulates high levels of docosahexaenoic acid.

Y. Yamada[1], Z. Perveen[2], H. Ando[2], T. Takagi[3], Y. Itoh[4], Y. Yamamoto[4], R. Hiratsuka[5], K. Kogame[2], T. S. Kaneko[1], H. Okuyama[2];
[1]Japan Women's Univ., Tokyo, Japan, [2]Hokkaido Univ., Sapporo, Japan, [3]The Univ. of Tokyo, Tokyo, Japan, [4]ROM Co. Ltd., Sapporo, Japan, [5]The Jikei Univ. Sch.of Med., Tokyo, Japan.

Thraustochytrids are known for their high accumulation of omega-3 long chain polyunsaturated fatty acids such as docosahexaenoic acid (DHA), a fatty acid which has been focused on its commercial use and physiological roles. We isolated one thraustochytrid-like microorganism (strain 12B) from a fallen leaf taken from estuary water of Okinawa, Japan. The DHA contents of strain 12B were up to 50% of the total fatty acid. Its productivity of DHA was 3.15 g/L/day at 30°C. Morphological analyses revealed that strain 12B possessed a unique ectoplasmic net structure, which has never described in any other thraustochytrid species. The electron microscopic observation of strain 12B showed that a spherical cell was surrounded by multilayered cell walls. The cytoplasm filled with multiple oil globules and mitochondria. Mitochondria had tubular cristae. Some cells were multinucleate. The molecular phylogenetic analysis based on partial sequencing of the 18S rRNA gene showed that strain 12B was comparatively related to Schizochytrium limacinum SR21 and thraustochytrid A5-20. Thus it is considered that strain 12B is a new thraustochytrid species.

P0259. *Cuscuta jalapensis* parasite on *Coffea arabica* in Veracruz, México

M. López-Curto[1], C. Esquivel-Huesca[1], D. Díaz-Pontones[2], J. Márquez-Guzmán[1];
[1]Facultad de Ciencias. Universidad Nacional Autónoma de México, Ciudad de México, Mexico, [2]Ciencias de la Salud. Universidad Autónoma Metropolitana, Ciudad de México, Mexico.

Cuscuta jalapensis has been detected parasiting coffee bean plants in Coatepec, Mexico. It is widely known that this parasite affects productivity of different crops. Coffee culture is quite important in Mexico so we decided to search how *Cuscuta* stablishes in coffee plantations. How deeply goes the haustoria into the host. What about the enzimatic mechanism of penetration. We also studied the embryology of this plant; our goal was to study some aspects of the biology of *Cuscuta jalapensis* and its invasion strategies on coffee cultures. Samples in LRW resin were sliced 2µm width for light microscope observations; we observed haustoria at SEM and, we detected activity of peroxidase enzime in 8µm cryostat slices, Sigma Immunochemicals technique. This orange filiform herb invades coffee plants through herbs and shrubs, on suitable hosts develops haustoria that penetrates beyond vascular bundles reaching medula. We identify peroxidase enzime involved in the generation of an entry pathway. We found a high incidence of abortion and observe perennation and autoparasitism. The only way to avoid infestation is to cut off infested plants and eliminate herbs aside

P0260. Light line in the seed coat of *Ipomoea purpurea* L. (Roth) Convolvulaceae

R. M. Ponce[1], J. Márquez[1], M. E. Engleman[2];
[1]Facultad de Ciencias, México, D. F., Mexico, [2]Colegio de Posgraduados, Montecillo, Edo. de México, Mexico.

The palisade layer of the seed coat is responsible for the water impermeability. *I. purpurea* and others Convolvulaceae have hard seeds because it is necessary mechanical scarification for their germination. In this paper, we describe the palisade cells development and their light line of *I. purpurea* seed coat, by light, confocal laser scanning microscopy and electron microscopy.

The youngest stages of the seed development have not light line. After the middle of the seed coat development it appears and the light line is more evident in the mature seed.

The palisade layer in *I. purpurea* is two or three stratified. The secondary cell wall of the palisade cells in *I. purpurea* is characterized by thickening of the radial cell walls.

Aniline blue dyed a band in the upper part of outer palisade cells then we consider that

light line is a callose deposition zone , among others compounds, running in a periclinal direction through the secondary cell wall.

P0261. The effect of plant water status on growth of olive fruit cells and tissues

H. F. Rapoport[1], **R. Gucci**[2];
[1]Instituto de Agricultura Sostenible, CSIC, Cordoba, Spain, [2]Dipartimento di Coltivazione e Difesa delle Specie Legnose, University of Pisa, Pisa, Italy.

Studies were performed with olive plants, either container-grown or in the field, whereby the amount of water supplied was adjusted to induce transient or permanent water deficit during fruit development. Fruit volume, fresh weight, dry weights and transverse equatorial areas of the endocarp and mesocarp were measured at the completion of endocarp sclerification (8 weeks after full bloom, AFB) and at fruit maturity (21-22 weeks AFB). Cell size and cell number were determined with optical microscopy and computer image analysis. Water deficit during 4-9 weeks AFB, reaching pre-dawn leaf water potential (PLWP) of -3.1 MPa, reduced fruit fresh weight, fruit volume, and mesocarp transverse area at both stages, but endocarp area only at 8 weeks AFB. For moderate water deficit ($-1.0 < \text{PLWP} < -3.2$ MPa) imposed 8-19 weeks AFB, the mesocarp-to-endocarp ratio (fresh weight basis) was greater than that obtained under either well-watered (PLWP > -1.1 MPa) or severe deficit conditions ($1.8 < \text{PLWP} < -4.0$ MPa). At the cellular level, water deficit appeared to reduce mesocarp cell size, and only occasionally and to a lesser extent mesocarp cell number.

P0262. Morfo histological comparison of edible fruits consumed in México of two species of cactaceous

E. A. H. Ruiz[1], C. M. Barbosa[1], D. E. Flores[1], C. C. P. Rios[1], J. G. Márquez[2], C. Z. Pelayo[1], **L. G. Ponce de León**[1];
[1]Universidad Autónoma Metropolitana Iztapalapa, Mexico, Mexico, [2]Universidad Nacional Autónoma de México, Mexico, Mexico.

Stenocereus griseus and Escontria chiotilla are species of cactus producing edible fruits. In order to make a morpho histological comparison, samples of flowers and fruits were taken in different development stages and with them fresh and processed material were prepared. E. chiotilla has bracts and S. griseus thorns in the pericarpel. The flower of S. griseus has red petals and the unilocular ovary with numerous campilotropic ovules is larger than the E. chiotilla, ovary that is 2 cm in diameter and has yellow flowers in both species. The berry of S.griseus distinguishes by the presence of fibers between the pericarpel and the loculus. The pulp contains different proportions of betaxanthin and betacyanin pigments depending on fruit type while E. chiotilla flesh contains same proportion of pigments since it is a monotype. S. griseus seeds have esclerenchyma tissue in the seminal coat that confers hardness and a fluted and heavier cuticle than in E. chiotilla seeds. The development of seeds in S. griseus is asynchronous. Differences in the development process are described and quality parameters such as titratable acidity, total soluble solids and color are compared.

P0263. Phenology, pollination ecology and breeding system of Polyalthia coffeoides and P. korinti (Annonaceae)

R. M. K. Saunders[1], S. Ratnayake[1], N. Gunatilleke[2], S. Wijesundara[3];
[1]University of Hong Kong, Hong Kong, China, [2]University of Peradeniya, Peradeniya, Sri Lanka, [3]Royal Botanic Gardens, Peradeniya, Sri Lanka.

Comparatively little is known of the reproductive biology of palaeotropical Annonaceae. Populations of *Polyalthia coffeoides* and *P. korinti* have been studied in dry and intermediate zone forests of Sri Lanka. The petals separate early in development, but subsequently close to form a pollination chamber over the reproductive organs. Formation of the chamber is coincident with elevated internal temperatures and scent production over a two-day period. GC-MS analysis of the odour reveals the presence of volatiles that mimic beetle sex pheromones. The primary effective pollinator of both species is an *Endaeus* weevil (Coleoptera: Curculionidae), with pollen grains generally observed around the mouthparts and legs. The weevils are abundant and active around the flowers in the late evening and overnight. The flowers are protogynous, and studies of pollen/ovule ratios suggest that both species are facultatively xenogamous; this is corroborated by controlled pollination experiments, which reveal greater fruitset following cross-pollination than self-pollination. Variation in ISSR molecular markers indicates that both species have a mixed mating system.

P0264. The ultrastructural study of Shoot Apical meristem cells and their changes affected by Vitamin C in Faba bean

Z. Nazem Bokaee[1], A. Majd[2];
[1]Al -Zahra University, Tehran, Islamic Republic of Iran, [2]Islamic Azad University, Sciences and Researches Campus, Tehran, Islamic Republic of Iran.

Faba bean (*Fabaceae*) is annual herb and cultivated as vegetables. It has a great nutritional value and is considered as a rich source of protein in human's diet.

Ascorbic acid (vitamin C) may be found in all compartments of plant cells and participates in a several processes such as cell division and growth, etc.

In this study, seeds of Faba bean var.saraziri were cultivated in Dezfoul farm, Khozestan. Plants were treated by different concentrations of vitamin C (0-10-50-100-200 mg/L).

Meristemic samples were taken at vegetative and reproductive stages, and were studied by means of S.E.M. and T.E.M. microscopes.

The results showed that vitamin C caused changes in structure leading to meristem expansion and more flowers were produced through promoting meristematic mass cleavage and increasing flower primordial.T.E.M. studies showed that the most changes were occurred in mitochondria, proplasts and cell walls. Increasing the number of nucleoli is one of the vitamin C molecular effects in these cells.

Keywords: apical meristem,vitamin C, Faba bean

P0265. Essential oil and secretory reservoirs in some *Hypericum* species

E. OsiŒska, B. Ğotocka;
Warsaw Agricultural University, Warsaw, Poland.

The content of essential oil was assessed in *Hypericum perforatum* (0.3%d.w), *H. elegans* (traces), *H. olympicum* (0.1%d.w), *H. elatum* (traces) and *H. patulum* (traces). Location and ultrastructure of secretory reservoirs were microscopically examined in leaves, petals and stems. Reservoirs were formed in protophloem of veins and stem in every species examined, and in bushy species additional reservoirs were produced by stem cambium in secondary phloem. The mesophyll-located reservoirs spanned the whole thickness of leaf in *H. perforatum*, *H. elegans* and *H. olympicum*, while in *H. elatum* and *H. patulum* they were much smaller but more numerous. Generally, the ultrastructure of epithelial cells varied little between organs or species. The walls of epithelial cells facing reservoir cavity (that in every case could contain a mixture of electron-dense and electron-transparent secretion) were considerably loosened. Distinctive attribute of epithelial cells was presence of leucoplasts with homogenous stroma that in some organs was penetrated with a network of extensive but delicate invaginations of the envelope's inner membrane.

P0266. Morphological, developmental and anatomical differences between female and male form of nettle (*Urtica dioica* L.).

W. Roslon;
Warsaw Agricultural University, Warsaw, Poland.

Morphological, developmental and anatomical differences between female and male form of stinging nettle were investigated. Morphological differences concerned height of shoots, shape and size of leaves, number and location stinging hairs on leaf blade, and type of inflorescences. Shoots of male form were higher than those of female one. The leaf surface was also bigger in male form. More stinging hairs were observed on leaves of female form. The inflorescences of this form were short, close and decurrent, whereas those of male form, were dispersed and square with the shoots. Developmental differences concerned development and fall of leaves as well as appearance of inflorescences. Up to the period of blooming number of leaves in both investigated forms was similar. The inflorescences of male form appeared earlier than those of female form. Male and female forms of nettle didn't differ in respect of anatomy of investigated organs.

P0267. Analysis of the regulatory network controlling ovule identity in *Arabidopsis Thaliana*

A. Losa[1], R. Battaglia[1], V. Brambilla[1], M. Fornari[1], M. M. Kater[2], L. Colombo[1];
[1]Dipartimento di Biologia Sezione Botanica Generale, Milano, Italy,
[2]Dipartimento di Scienze Biomolecolari e Biotecnologie, Milano, Italy.

Ovule development is a complex process, in which several important events occur: ovule identity determination, pattern formation and morphogenesis. Recently the ovule identity genes have been identified in *Arabidopsis thaliana*, which are three redundant transcription factors belonging to the MADS-box gene family: *SEEDSTICK* (*STK*), *SHATTERPROOF1* (*SHP1*) and *SHP2.* In the *stk*, *shp1*, *shp2* triple mutant the ovules are converted into carpelloid structures, whereas in *STK* ectopic expression the sepals are converted into carpelloid structures containing ovules. Several studies have shown that MADS-box transcription factor act through the formation of multimeric complexes. Also the MADS-box factors controlling ovule identity form these complexes. The assembly of these complexes are mediated by SEPALLATA MADS-box factors. The aim of the presented work is to identify the target genes of these ovule identity complexes.

P0268. The influence of ABA and GA_3 on activities of arginine and ornitine decarboxylases (ADC and ODC) and dormancy breaking of seeds of European beech *(Fagus sylvatica* L.).

Z. Szczotka, K. Krawiarz;
Institute of Dendrology PAN, Kórnik, Poland.

Dormancy is a feature of many seeds, especially those of forest tree species. The ripe seeds of European beech are in deep dormancy that requires for breaking a cold stratification (temperature 3ºC and over 30% humidity). The correlation of arginine (ADC) and ornitine decarboxylases (ODC) activities and effect of abscisic acid (ABA) and gibberellin (GA_3) during dormancy breaking were determined. Whole nuts were treated with ABA (50 µmol) or GA_3 (100 µmol) and water as a control and were stratified at 3ºC. GA_3 was found to stimulate activity of both enzymes and to break the seeds dormancy while ABA, in contrary, was found to act in opposite way. Our earlier studies on the mechanisms of dormancy breaking and metabolism of polyamines as dormancy regulators as well as the results presented here indicate that a possible involvement of both studied enzymes in a regulation of dormancy of European beech seeds.

P0269. Branches anatomy of *Fraxinus uhdei* (Wenzing) Lingelsheim and *Prunus persica* Batsch. infected by *Cladocolea* spp. (Mistletoe)

C. De la Paz Pérez Olvera, J. Ceja Romero;
Universidad Autónoma Metropolitana Iztapalapa, Div. C. B. S., Depto. de Biología, México, D. F., Mexico.

True mistletoes are parasitic flowering plants. Seeds are disseminated by birds and deposited on host plants reducing their growth. Samples of 5 branches of *Fraxinus uhdei* and *Prunus persica* were collected in Mexico City. Blocks of 1 cm^3 were obtained. Slides with typical cuts of the infected zone and the healthy zone were made. The wood of the two species has ring porous, their vessels are solitary and radial multiples, vessels pits are alternate. Its perforation plates are simples, rays have 1 to 4 cells and are heterogeneous and present fibre tracheids. The vessels in *P. persica* have helical thickenings and the outline is angular and the axial parenchyma is scanty diffuse. In *F. uhdei* the vessel outline is rounded and the axial parenchyma is of many types. The wood of mistletoe present diffuse porous. Vessels are solitary and clusters with the outline rounded, with pits alternate and simple perforation plates, present vascular tracheid. The axial parenchyma is in bands, present fibre tracheids. Rays are heterogeneous with 1 to 4 series. Both parenchyma types have abundant starch. The host anatomy is modifing when mistletoe penetrates, forming abundant contents.

P0270. Leaf Anatomy of the Turkish Endemic *Iris schachtii* Markgraf

H. Colgecen, **G. N. Tug**;
Faculty of Science, Ankara, Turkey.

Iris schachtii Markgraf is an endemic Irano-Turanien plant species spreading in Central Anatolia, Turkey. Flower color shows variations within the species. In flowers bicolority is observed; yellow and purple, but these are not important for the separation of species into subspecies or variants. Leaf anatomy of the individuals having each color was examined. Leaves are linear-lanceolate and show parallel venation. Epidermal cells of unifacial ensiform leaves axially elongated and end walls are straight. Small papillae are present on epidermis. Stomata are amaryllis type. Stomata appeared under the epidermal cell layer. Epidermal cell numbers and stomata numbers per mm^2 of leaves are determined. Bundles of sclerenchyma cells occur at leaf margins and vascular bundles. Vascular bundles are lined in rows. Xylem of vascular bundles is directed towards the leaf center.

P0271. On seed vascularization in the family *Pinaceae*

A. N. Sorokin[1], A. V. F. Bobrov[2];
[1]Main Botanic Garden nm. Tcitcin N. V. RAS, Moscow, Russian Federation, [2]M. V. Lomonosov Moscow State University, Moscow, Russian Federation.

We have investigated the seed anatomy of over 70 species of 11 narrowly understood genera in the *Pinaceae* family. Our studies demonstrate the presence of two vascular bundle derivatives in the spermoderm of *Abies* Mill., *Cedrus* Trew, *Keteleeria* Carrière and *Pseudolarix* Gordon, located in the inner layers of mesotesta along the ridges of the seed. Vascular bundles are developed in the seed coats of the representatives of different genera to various extents, and are composed of a varying number of elements (from 2-3 in *Abies religiosa* (Humb., Bonpl. & Kunth) Schlechtendal & Cham. and *Pseudolarix amabilis* (J. Nelson) Rehder to 15 in *Abies sibirica* Ledeb. and *Cedrus deodara* (Roxb.) G. Don in Loudon). The vascularization of the spermoderm of the mentioned genera, with the exception of *Pseudolarix*, had already been noted by M. P. Radais in the 19 century. However, in the majority of the more recent publications on the *Pinaceae* seed anatomy that we surveyed, these data were not taken into account or discussed. We are the first to describe the vascular bundles in the seed coat of *Pseudolarix*. Our discovery shows the importance of further research in this direction.

P0272. Ultrastructure of conidial ontogeny of *Septoria dictamni* Fckl. pathogenic to *Dictamnus angustifolius* G.Don.

Y. V. Rakhimova, S. Abiev;
Institute of Botany and Phytointroduction MES, Almaty, Kazakhstan.

The ontogeny, delimitation, and release of conidia from conidiophores in pycnidium of *Septoria dictamni* were studied with light and transmission electron microscopy. Conidial ontogeny of *S.dictamni* was holoblastic and annellidic. Annellides arose from the inner cell layer of pycnidium. The primary conidia were simple holoblastic (without proliferations). They were produced as extensions from conidiogenous cells or as the swelled apex of the annellide, and projected into the central cavity of pycnidium. The next conidia were produced by percurrent proliferations. Some proliferations of the conidiogenous cells were sympodial. For every new conidium (excluding primary conidium), a completely new two-layered wall was formed. Annellations in *S.dictamni* were distinct. Delimiting septa associated with Woronin bodies were observed in the bases of each seceded conidia. Conidia in pycnidium of *S.dictamni* were liberated schizolytically.

P0273. Some anatomical and ultra-structural peculiarities in epigeoid, epilit, epixyl and epiphyt mosses from Ara mountain (Armenia)

A. V. Poghosyan[1], G. H. Oganezova[2];
[1]Yerevan State University, Department of Botany, Yerevan, Armenia,
[2]Institute of Botany, NAS RA, Yerevan, Armenia.

.Some attempts for revealing adaptive peculiarities of structure for the mosses growing in the Ara mountain (the central part of Armenia, altitude - 1600 to 2570 m a. s. l., the *Quercus macranthera* shooting forest, mountain steppes, alpine meadows and other) were made. The study of leaves structure of the 58 species of mosses from few ecological groups (epigeoids, epilites, epixyls, epiphytes) by light microscope did not give desirable results. Later, the stem ultra-structure of the 15 species of mosses was studied by scanning microscope HITACHI S-405A. Vascular structure differentiation for the essential epigeoid species and absolute absence of such type of the tissues for the epilite mosses was revealed. For the representatives of remaining groups different levels of the vascular system development were registered. They compensate deficit of water by their capacity of absorbing it through surface. The prevalence of the last type of mosses species in Ara mountain is an evidence of it's flora liability to xerophytisation.

P0274. Leaf anatomy of some species of *Tillandsia bulbosa* Hook. (Bromeliaceae) complex from Mexico

J. Ceja Romero;
Universidad Autónoma Metropolitana Iztapalapa, Div. C. B. S., Departamento de Biología, México, D. F., Mexico.

Tillandsia is the largest genus of the Bromeliaceae with ca. 518 species distributed in tropical and subtropical America. This work present the leaf anatomy of *T. balbisiana*, *T. bulbosa*, *T. butzii*, *T. caput-medusae*, *T. diguetii*, *T. seleriana* and *T. weberi*, species characterized by their sheaths forming a bulbous rosette and their blades involute. For each one of the species, samples of the middle third of the blade were fixed and processed according to the conventional hystological techniques to obtain permanent anatomical slides. A comparative analysis was made. All taxa have peltate trichomes on the upper and lower leaf surface. The stomata are of the tetracytic type and are restricted to abaxial surface. The epidermal cells present ondulated walls, thin cuticle, inner periclinal wall thickened and a silica body per cell. The mesophyll are differentiated in multiple layers of chlorenchyma and water storage parenchyma. The vascular bundles are arranged in a single row and present a bundle sheath of fibers. Raphides were found in mesophyll cells. Also differences in the stomatic index, size of the vascular bundles and size of bundle sheaths were found

P0275. Germination of a Tropical Mistletoe, *Cladocolea loniceroides* (Van Tieghem) Kuijt Loranthaceae

R. V. Cid[1], J. G. Márquez[1], M. Ponce[1], M. E. Engleman[2];
[1]Facultad de Ciencias, México, d.f., Mexico, [2]Colegio de Posgraduados, Montecillo, Edo. México, Mexico.

This mistletoe grows as a hemiparasite on various trees that may have economic value for fruit, lumber or as ornamentals. The tree´s physiology may be affected so severely that it eventually dies.
Many aspects of floral biology, germination and establishment have not been described for this plant. In this paper, we describe germination, penetration of the host, and establishment.
Samples of mature fruits germinating and developing on the host were obtained. Standard Microtechnique, light and Scanning Electron Microscopy (SEM) are used. We describe results with microphotography.
The fruit adheres to the host with viscin and mucilage, which originate in the middle layer of the fruit wall. A holdfast is formed during the germination. By means of haustorium and a penetration organ, the haustorium penetrates and becomes anchored in the xylem. A knowledge of these mechanisms of establishment may help devise methods of control of this mistletoe.

P0276. Anomalous grow in Bassia sieversiana (Pallas) W. A. Weber

I. Toma;
University Al. I. Cuza, Faculty of Biology, Iasi, Romania.

Bassia sieversiana is an herbaceous species belonging to Chenopodiaceae family which is known to present anomalous secondary thickness of the axial organs. In the stem the first cambium occurs early in ontogenesis. The succeeding cambia arise discontinuously, but subsequently they become circular. Before that, the initial cambium begins to produce thick walled and lignified ray cells in the phloem ring; these rays are linked with the xylem one and finally they include an area of secondary phloem. The succeeding cambium appears by dedifferentiation from parenchimatic cells of the internal cortex. The activity of the multiple cambia provides intraxylary phloem areas, disposed in concentric rings. It is thought that succeeding cambia can produce a thicker stem or root than a single cambium. In the analyzed material we have found a slow but constant decrease of the number and diameter of the xylem vessels resulted at the end of cambial activity; these increase in the first stage of new cambium activity. These features could be considered as an adaptative response to the interspecific competition.

P0277. Micromorphology and histochemistry of the glandular trichomes of *Cedronella canariensis* (L) Webb & Berth. from Madeira.

I. Sevinate-Pinto[1], T. Antunes[1], J. D. Santos Dias[2], A. M. Dinis[2];
[1]Faculdade de Ciênciasde Lisboa, Lisboa, Portugal, [2]Departamento de Botanica,Universidade de Coimbra, Coimbra, Portugal.

Cedronella canariensis (L.) Webb & Berth. (= *C. triphylla* Moench, *Dracocephalum canariense* L.) is a sharp-smelling perennial herb which is endemic of Madeira, Azores and Canary Islands, being characteristic of the laurel wood . In this work, the indumentum of the leaves was studied by means of scanning electron and transmission electron microscopy and by histochemical methods. The indumentum possessed both non-glandular and glandular trichomes on both the abaxial and the adaxial surface of the leaves. On the abaxial surface, however, long non-glandular trichomes were present, which contrasted with the short, conic and sparsely distributed trichomes existing on the adaxial surface. Glandular trichomes of two types, capitate and peltate, occurred mainly on the abaxial surface of the leaves. Ultrastructural and histochemical studies of the secretory cells revealed that the secretion is lipophilic in nature, which agrees with our previous chemical study concerning to the isolated essential oils (Antunes et al. 1998).

Antunes T. et al. 1998. III Simpósio Fauna e Flora das Ilhas Atlânticas, Ponta Delgada, Açores.

P0278. Isolation and Identification of Crocetin Aglycons in *Crocus sativus* L. and Some Wild *Crocus* Species Stigmas by Chromatographic and Spectroscopic Methods

T. Radjabian[1], P. Abrishamchi[2], A. Saboora[3], H. Ebrahimzadeh[4];
[1]Shahed University, Tehran, Islamic Republic of Iran, [2]Ferdowsi University, Mashhad, Islamic Republic of Iran, [3]Al Zahra University, Tehran, Islamic Republic of Iran, [4]Tehran University, Tehran, Islamic Republic of Iran.

Crocetin is a dicarboxylic 20-carbon carotenoid that occurs naturally mainly as glycosyl esters (Crocins) in *Crocus sativus* L. stigmas. Crocins are the main biologically active ingredients or the food coloring compounds of *Crocus* species stigmas.They are powerful quenchers of free radicals and could be used as anti-cancer agents.The main aim of the present study was to obtain and characterize of crocetin from commercial and some Iranian wild *Crocus* species stigmas by different available methods.Crocetin aglycons were isolated from dried methanolic extracts of stigma samples in basic and acidic solutions.The crystallized aglycons were dissolved in DMSO and passed through acetate cellulose filters.Finally, crocetins were qualitatively identified using analytical TLC and also an isocratic HPLC method and were characterized using UV-visible and NMR (^{1}H and ^{13}C NMR) spectroscopies.All results and data that were obtained by the different methods confirmed the identity of the isolated aglycons and also showed that crocetin is probably the main aglycon of the carotenoid pigments (Crocins) in different *Crocus* species stigmas.

P0279. Reproductive modifications in *Phaseolus vulgaris* wild and cultivated varieties because of domestication.

N. S. Cajal Gutiérrez[1], A. Delgado Salinas[2], R. Osuna Fernández[1], J. Márquez Guzmán[1];
[1]Facultad de Ciencias UNAM, Mexico, D.F., Mexico, [2]Instituto de Biología, UNAM, Mexico, D.F., Mexico.

Mesoamerican and South American *Phaseolus vulgaris* possesses high potential for genetic improvements. In this investigation we compared some reproductive aspects of wild beans with their cultivated counterparts.

Buds were collected just before the anthesis and fixed with F.A.A. as well pods and seeds; included in JB 4 and finally cut at 2µ.The observation of the four genotypes revealed differences in the curvature angles of the nucellus, in the number of external tegument strata and the shape of the stigma. These include a “cushion” shape in wild types and a “brush” shape in cultivated types. The pollen was tricolporate, anguloaperturate and brevicolpate, as well as being covered by a pseudo operculum, contrary to what has been reported by other authors who describe it as only triporate.

The transverse cut of the pods showed a higher concentration of tannins in the wild varieties in relation to the cultivated ones. The qualitative evaluation of the dominant color resulted in a dark seed for the wild varieties and a light seed for those that were cultivated. The wild varieties had less weight and size in relation to the cultivated varieties.

P0280. Comparative analysis of the sexual phase of nine species in the generus *Argyrochosma, Astrolepis, Cheilanthes* y *Pellaea* (Pteridaceae) in Mexico.

A. Mendoza-Ruiz, B. Pérez-García;
Departamento de Biología, C.B.S. Universidad Autónoma Metropolitana, Iztapalapa, México, D. F., Mexico.

A comparative analysis of the sexual phase of *Argyrochosma formosa, Astrolepis sinuata, Cheilanthes angustifolia, C. bonariensis, C. leucopoda*, *C. myriophylla*, *Pellaea atropurpurea, P. ribae* and *P. ternifolia* is presented. Fertile pinnae of each one of the species were collected in different states of Mexico, and were kept in paper bags until spores were shed. The spores were sown in Petri dishes containing agar supplemented with Thompson’s. In all the species studies, spores are triletes, germination is Vittaria-type and prothallial development is Adiantum-type. The adult gametophytes of *A. formosa* are laminar-branched uniseriate filaments; those of *A. sinuata, C. angustifolia, C. bonariensis, C. leucopoda*, and *P. ternifolia* are laminar-branched to spatulate-cordiform with entire margins; those of *P. atropurpurea* are cordiform-reniform with entire margins, and those of *P. ribae* are cordiform-reniform with wide wings and irregular margins forming a thooted apex. No one of the species present thrichomes. The sporophytes in *C. bonariensis*, *C. leucopoda*, *P. ribae* and *P. ternifolia* are of sexual origin and in the other taxa are of apogamic origin.

P0281. Morpho-histological study in a chilean specie Centaurium cachanlahuen (Mol.) Robinson.

E. Flores, C. Villalobos, M. Lobos;
Valparaiso University, Chile, Valparaiso, Chile.

Morpho-histological study of stem and root of Centaurium cachanlahuen was carried out.Centaurium cachanlahuen belongs to the Gentianaceae.People of Chile has taken concentrate infusions for its hipertensive and sedative properties.Stem and root sectors were selected from several plants of this species. Permanent cross sections by dehydrating in an ethanol battery and preserved material in FAA .(Formalin, Acetic Acid and Etilic Alcohol).Cross sections in Safranin -Fast -Green were stained.Cross sections of stem anatomy shows four wings described for the specie, an uniseriate and rectangular epidermal cells.These cells are isodiametric with convex walls covered by a a thick cuticle, the cortex consists of two-three parenchyma layers with abundant and dense material.The vascular cylinder is enclosed by a sheat with a conspicuous fiber area. The cross section of the root shows irregular parenchyma cells in epidermis and cortex.

The authors wish to thank Proyecto Dipuv 29/2002.

P0282. Cloning and Expression Analysis of Genes Involved in Anthocyanin Biosynthesis from Asiatic Lily.

Y. Adachi[1], A. Kanno[2], N. Chiba[1], S. Nakamura[1];
[1]Miyagi Pref. Agriculture and Horticulture Res.Cent, Sendai, Japan,
[2]Graduate School of Life Sciences,Tohoku University, Sendai, Japan.

Flower color is mainly derived from anthocyanin, one major class of flavonoids. We isolated cDNA clones encoding chalcone synthase (CHS), dihydroflavonol 4-reductase (DFR) and flavanone 3-hidroxylase (F3H), which are involved in anthocyanin biosynthetic pathway, from *Lilium speciosum* var.*rubrum*. The expression of these three genes was analyzed for *L. speciosum* var. *rubrum* (red tepals), *L. formosanum*, *L. x formolongi* (white tepals), and six varieties in Asiatic hybrid (red, white and yellow tepals). RT-PCR analysis showed that CHS, DFR and F3H transcripts were detected in red tepals, while weakly or not detected in white and yellow tepals. This indicates that the accumulation of anthocyanin is correlated with the expression of these three genes in Asiatic lily. We also analyzed the expression of three genes in *L. speciosum* var. *album* (white tepals), which is the variety of *L. speciosum* var. *rubrum* (red tepals). In this variety, CHS and F3H genes were expressed, but DFR transcript was not detected in white tepals, suggesting that lack of red pigments in *L. speciosum* var. *album* (white tepals) was correlated with the absence of the DFR transcript.

P0283. Fruit anatomy of *Amborella*

M. S. Romanov[1,2], P. K. Endress[3], A. V. F. Bobrov[2];
[1]Main Botanical Garden nm. Tcitcin N. V. RAS, Moscow, Russian Federation, [2]M. V. Lomonosov Moscow State University, Moscow, Russian Federation, [3]Institute of Systematic Botany and Botanic Garden, University of Zurich, Zurich, Switzerland.

Amborella trichopoda appeared as the basalmost extant angiosperm in recent molecular phylogenetic analyses. Earlier, based on general morphology, *Amborella* was placed in *Laurales*, thus, far apart from its present position. Also the structure of the fruits (fruitlets) seemed similar in *Amborella* and many *Laurales*. Developmental investigation of pericarp anatomy in *Amborella* showed its differentiation into three histogenetic zones (composed of five histological ones): exocarp (derived from outer epidermis), mesocarp (derived from mesophyll) (three zones: 25-35 layers of parenchymatic cells without idioblasts, 6-18 layers of thick-walled, unlignified, canaliculated sclereids, and 1 layer of thin-walled cells), and endocarp (derived from inner eipdermis) (2-4 layers of small sclereids with thick, unlignified walls). The histological differentiation of histogenetic zones of the pericarp in *Amborella* differs from that in *Lauraceae* and *Monimiaceae* s.l., in which a lignified putamen is formed by 1-2 layers of specialized cells of endocarp. Thus, fruit anatomy of *Amborella* is unique.

P0284. Green plastids, as judged from their chlorophyll auto-fluorescence, and starch distribution in internal stem tissues of three Mediterranean woody species during the year

A. E. Rentzou, G. K. Psaras;
Section of Plant Biology, Patras, Greece.

The occurrence and distribution of green plastids in internal stem tissues, i.e. cortex, wood ray parenchyma and pith cells, was examined with epi-fluorescence microscopy. Green plastids in deep stem tissues are supposed to help toward respiratory CO_2 recycle. Starch accumulation was also investigated. Three species having adopted different life strategies were studied. Pith and wood parenchyma cells of *Euphorbia acanthothamnos*, a drought deciduous species, show chlorophyll fluorescence throughout the year, though during the leafless summer period fluorescence level as well as starch content seem to be relatively low. Chlorophyll auto-fluorescence in internal tissues of the winter deciduous species *Platanus orientalis* increases in summer during leaf bursting, reaching its maximum before leaves drop. In the same period starch content is high. Chlorophyll fluorescence in the evergreen sclerophyll *Nerium oleander* deep stem tissues follows different pattern: it remains high and constant throughout the year. By contrast, starch is accumulated during rainy season.

P0285. Leaf histogenesis in Buxus sempervirens L.

C. Toma, I. Toma;
University Al. I. Cuza, Faculty of Biology, Iasi, Romania.

Immature and mature leaves (from first and second years) of Buxus sempervirens were observed in order to emphasize the histo-anatomical peculiarities related to their persistency. The foliar primordia have a semilunar shape determined by an intense activity of the abaxial meristem in the first stages of development. The marginal growth of the leaves is of median - submarginal type. The mesophyll is compact, dorsiventral, hypostomatic. At the young leaves, the palisade parenchyma consist in 2-3 layers of isodiametric cells which become elongated in mature leaves, especially in the second year. The vascular bundles present a girdle of sclerenchyma obviously more developed in the xylemic pole, contrary with the general case, when it is developed only or especially in the phloemic pole. The 2 years old leaf present isolate strands of sclerenchyma unconnected with the conducting tissue and two thick strands at the leaf edges. The diameter of the xylem vessels is very small. The stomata are localized at the same level with the epidermic cells, but the guard cells exhibit two extended crests which delimit a cavity.

P0286. Microscopic surgeries on meristemic parts and the place of archegonium in prothalli of *Adiantum capillus - veneris*

G. Tajadod, A. Majd;
Azad university , Tehran north branch, Tehran, Islamic Republic of Iran.

Spores of Adiantum capillus -veneris give rise to a heart shaped prothalli after 40 days of their germination.. Microscopic surgeris are done on two parts of prothalli: sexual notch , the place which archegonium are produced. For the first study prothalli with completed notch were collected and their meristemic part and sexual notch were separated.For the second study, 40 days old prothalli were collected and with a very sharp pin the area which archegonium will be differentiated in, were destroyed. The prothalli of first group after starting their growth produce many prothalli on the sides of themselves. These new prothalli grow and become heart shaped with normal sexual organs. After fertilization sporophytes were seen on these prothalli. This is like the growth of lateral buds in advanced plants after removing the apical dominance.

After 10 days the second group of prothalli produces a very huge cellular mass which is very similar to the calluse of advanced plants. On this calluse first protonema and then prothalli are produced .The prothalli become heart shaped and make sexual organs .After fertilization sporophytes can be seen on these prothalli as the usual ones.

P0287. Anatomic structure of Scots pine wood dependending on its geographical origin and temperature factor.

S. R. Kuz'min;
Krasnoyarsk state university, Krasnoyarsk, Russian Federation.

The purpose of the work is the study of anatomic features of tree ring structure of Scots pine. This research was conducted for different climatypes with different geographical origin and climatic characteristics growing in the Boguchany provenance trial. According to climatic data of Boguchany weather station for the research was selected two years with different temperature of vegetation period. The study of the number of cells in row, cell diameter, cell wall thickness was made with the help of Image-system and special computer programs. For each climatype were selected 5 core samples. Climatypes are from north and south taiga and from south Zabaikalie with moisture deficit. The mean cell diameter of cold vegetation period is significantly different from warm for all climatypes. The increase of small cells percentage is in cold vegetation period, for the pine from north taiga the increase is smaller. However, the pine from north taiga has smaller cell diameter and cell wall thickness. The cell wall thickness has a lesser response to vegetation period temperature.

P0288. Pericycle and endodermis in the root, stem and leaf of monocotyledons

V. G. Alves[1], G. Melo-de-Pinna[1], R. C. Arruda[2], E. Scremin-Dias[3], D. C. Silva[4], C. G. Silva[1], N. L. Menezes[1];
[1]Universidade de São Paulo, São Paulo, Brazil, [2]Universidade do Rio de Janeiro, Rio de Janeiro, Brazil, [3]Universidade Federal do Mato Grosso do Sul, Mato Grosso do Sul, Brazil, [4]Universidade Estadual de Santa Cruz, Bahia, Brazil.

Most researchers attribute primary thickening in monocots stems to the PTM (Primary Thickening Meristem). This paper shows that, in species of *Asparagus, Bulbine, Canna, Cephalosthemon, Chlorophytum, Echinodorus, Cipura, Ctenathe, Curcuma, Cyperus*, *Hypoxis, Kaempferia, Lagenocarpus*, *Reineckia, Rhoeo, Ruscus, Sanseviera*, *Scleria* and *Xyris*, the of procambium cells sequence, the pericycle forms vascular tissue and adventitious roots throughout the life of the plant. The endodermis is the innermost layer of the cortex with Casparian strips, starch grains, crystals phenolic compounds or suberin lamellae. The endodermic meristematic activity, observed in the roots of all species examined, gives rise to part of the cortex. In the stem and the leaf, the endodermis may (or may not) have meristematic activity, giving origin to part o the cortex (stem) or part of the mesophyll (leaf). In the shoot apex, the pericycle and the endodermis assemblage seems to be only one meristem, giving origin to the vascular tissues and cortical cells, respectively.

P0289. Morphogenetic Study of *Rhynchostylis coelestis* Rchb.f. ex Veitch In Vitro

S. Chamratpan;
Udonthani Rajabhat University, Udonthani, Thailand.

Green pot seeds of *Rhynchostylis coelestis* (Rchb.f.)Rchb.f. ex Veitch were culture on MS medium supplemented with 20% coconut water and 5% tomato juice for 1,2,3 and 4 months. The protocorm-like bodies and seedlings had been observed by scanning electron microscope. First of all, an oval shape embryo became swollen and released from seed coat within 1-2 months. After that, the embryo had concave top end and the opposite end was sharp. The globular embryo changed to be heart shape and torpedo-like, respectively. The concave end was subsequently convex at the top. After two month of incubation, leaf was formed.No tap root was formed. Adventitious root formation occurred in four months. Rhizoids, root hair- like structures, were seen early on the embryo surfaces and grew up until the adventitious root was formed. Stomatal apparatus was also seen in an early stage of the development of the embryo.

P0290. Effects of Ethanol, Methanol on the Structure and Ultrastructure of the Vegetative Meristem, Formation of Flower Components and Useful Vase Life in *Dianthus Caryophyllus L.*

S. Jafari Marandi, A. Majd;
Islamic Azad University, North Tehran Branch, Tehran, Islamic Republic of Iran.

The one-year-old cuttings of *Dianthus* planted. They were given alcoholic treatments with 3, 6 and 9 percent concentrations
Alcoholic treatments lead to the meristem assumes the features of a generative meristem. The greatest effect of alcohol was in alcoholic treatments with 3%, particularly ethanol. The number of flowering shoots and flowers increased, and accelerated the flowering period.

In the investigations by T.E.M, chromocenters were determined in addition to observation of anticlinal and periclinal divisions in tunica cells, corpus, increase in thickness of cell walls, increase in nucleus volume and density of nucleic substances, as well as expansion of the vacuole system. The study buds flower with same of size and age in control and treated plants were shown that alcohol caused acceleration ontogeny, in flower organs. Ethanol and methanol 3 percent raised number of shoots flowering and flower.

Alcohol treatments on cut flower with the same size of peduncle showed that lower concentration delay aging and drooping in flowers. Increased of useful life in cut flowers were more visible in ethanol.

P0291. Anatomical alterations in pigeon pea roots under soil aluminium toxicity.

A. Marin, **D. M. M. Santos**, F. V. Môro;
Universidade Estadual Paulista,UNESP, Jaboticabal, SP., Brazil.

The objective of this study was to determine the effects of aluminium upon the root anatomy of two pigeon pea cultivars, IAPAR 43-Aratã and IAC Fava Larga, and provide evidence of the differential tolerance to aluminium between these cultivars. Four days after sowing in sand, plants were transplanted to plastic boxes with 0% and 58% soil aluminium saturations, in a growth room under irradiance of 89.5 µmol m^{-2} s^{-1}, photoperiod of 8 hours and temperature of 29°C. A completely randomized design in a factorial scheme 2x2 with four replicates were used. Twenty days later, samples were fixed in FAA, the cross sections taken from paraffin-embedded material, stained with safranina-fast green in toluidine blue, and mounted in Canada balsam. Moreover, samples of living material were cut with freezing microtome and stained after dehydration, and photographed with a photomicroscope. Anatomical alterations in root apical regions of both cultivars evidenced that under soil aluminium toxicity a tissue disorganization takes place. However, since damage effects were similar, it was not possible to distinguish aluminium tolerance between cultivars. (Fapesp 01/03597-0)

P0292. PEACE, a MYB-related tanscription factor, regulating pigmentation in flowering peach, can alter morphological characters of transgenic tobacco

C. Uematsu[1], M. Takashima[1], H. Katayama[2], C. Martin[3];
[1]Osaka City University, Katano-shi, Japan, [2]Kobe University, Kasai-shi, Japan, [3]John Innes Centre, Norwich, United Kingdom.

It is well known that plants use many MYB transcription factors to regulate the secondary metabolism and morphogenesis. One MYB-related gene obtained from pink petals of flowering peach (Prunus persica) can induce anthocyanin biosynthesis in colourless sectors of variegated petals. This gene was named PEACE (peach anthocyanin colouration enhancement). In this study we examined PEACE function by generating transgenic tobacco plants via Agrobacterium mediated transformation. About 40 plants were regenerated. Seventeen plants out of a total of 24 were confirmed as harbouring the PEACE gene by PCR. Divergent morphological changes were observed in transgenic plants expressing PEACE compared to control tobacco plants treated with wild Agrobacterium strain LBA4404 without PEACE, e.g. shorter plant height, paler flower colour, shorter flower length, petals bending outward and small white lesions on the leaves. Also lower seed fertility and higher chlorophyll content was observed occasionally. Genetic analysis of the progeny will reveal the molecular mechanism of morphological and physiological alterations caused by the PEACE gene.

P0293. Pericycle and Endodermis in Monocotyledons

V. G. Alves[1], G. Melo-de-Pinna[1], R. C. Arruda[2], D. C. Silva[3], E. Scremin-Dias[4], C. G. Silva[1], N. L. Menezes[1];
[1]USP, São Paulo, Brazil, [2]Universidade do Rio de Janeiro, Rio de Janeiro, Brazil, [3]Universidade Estadual de Santa Cruz, Bahia, Brazil, [4]Universidade Federal do Mato Grosso do Sul, Mato Grosso do Sul, Brazil.

Most researches attribute primary thickening in monocots stems to the PTM (Primary Thickening Meristem). This paper shows, in species of *Asparagus, Bulbine, Canna, Cephalosthemon, Chlorophyton, Echinodorus, Cipura, Ctenathe, Curcuma, Cyperus*, *Hypoxis, Kaempferia, Lagenocarpus*, *Reineckia, Rheo, Ruscus, Sanseviera*, *Scleria* and *Xyris*, that in the procambium cells sequence, the pericycle forms vascular tissue and adventitious roots throughout the life of the plant. The endodermis is the innermost layer of the cortex with Casparian strips, starch grains (starch sheath), crystals or suberin lamellae. The endodermic meristematic activity was observed in all species examined, which give rise to the innermost layer of the cortex in the root, stem and the innermost layer of the leaf mesophyll. In the shoot apex, the pericycle and the endodermis appear to form a single meristem, giving origin to the vascular tissues and cortical cells, respectively.

P0294. Companion cell and vein type in alfalfa source leaves

N. N. Boughanmi[1], P. Fleurat lessard[2], P. Michonneau[3];
[1]Faculté de Bizerte, Bizerte, Tunisia, [2]Université de Poitiers, Piotiers, France, [3]Métaflore Recherche, Poitiers, France.

In Medicago sativa blade, companion cells present transfer cell features. In source leaves, that support plant growth, structural differences have been observed between minor and main veins that are involved in assimilate loading and unloading respectively. In minor veins, transfer cells are three times larger than sieve tubes and wall ingrowths are finger-like, being always more developed in the old leaves. The presence of transfer cells in these minor veins has been correlated with apoplasmic mineral nutrient cycling, that is closely associated with carbohydrates transport from source to sinks. In the main veins, companion cells and sieve tubes exhibit the same diameter, wall ingrowths are papillate and their area is half to third as that of transfer cells in minor veins. Moreover, early stages of these transfer cell differentiation have been observed in these main veins that contain a procambial area. Structural differences observed in minor and main veins are discussed in relation with mechanisms of assimilate compartmentation.

P0295. Exogenous auxin affects formation of discrete vascular strands in *Arabidopsis* mutant *pin1*

A. S. Banasiak;
Institute of Plant Biology, Wrocğaw University, Wrocğaw, Poland.

Organogenesis and vascular differentiation are interrelated processes controlled by the polar auxin transport (PAT). Mutation of the *PIN1*gene, regulating PAT in a shoot, is supposed to inhibit these processes. However, in *pin1*mutant organ formation is arrested only in early stages of a generative shoot development. Vascular differentiation is not inhibited, although vascular tissues do not form discrete bundles.

Analysis of ontogenetic changes in the mutant vascular pattern shows that initial syphonostelic system changes into eustele and vice versa few times in the same shoot. Eustele formation is correlated with the initiation of bulges and deformed organs.

Eustele formation can be induced in the early ontogenetic stages by exogenous auxin.

At the site of IAA application, primordia are initiated and the vascular system forms quite discrete bundles. Above the primordium initiation level, syphonostelic system returns.

IAA affects then organogenesis and vascular strand separation. In young shoots of *pin1* only exogenous auxin may induce both processes, while in older shoots they occur spontaneously.

P0296. Developmental changes in several isoenzyme systems during somatic embryogenesis of *Petunia x hybrida*

M. E. Carasan, M. M. Antofie, C. R. Voichita, A. Brezeanu;
Institute of Biology, Bucharest, Romania.

The present study reports on the expression of some izoenzymes during somatic embryogenesis process in *Petunia x hybrida* callus cultures. The presence of 2,4-D, the concentration (1mg/l) and the time of cultivation (5 days) had a determinant role in embryonic competence induction. Competent cells expressed this embryonic potential by their subcultivation on culture medium without hormones. The activity of some enzymes as peroxidases (POX), glutamatoxaloacetate transferases (GOT), non-specific esterases (EST) and acid phosphatases (PAC), was monitored during progressive stages of the somatic embryogenesis. Moreover, specific protein and izoenzyme patterns of POX, GOT, EST and PAC in induction and expression phases of embryonic competence were analyzed to identify some embryonic markers. The variations observed in activity and electrophoretic spectra of these enzymes at different stages of culture emphasized the physiological or biochemical changes underlying the process of differentiation and were important for the establishment of the tissue specific biochemical characteristics that were expressed and maintained in cell culture.

P0297. The phenomenon of vivipary in gymnosperms and angiosperms.

E. A. Bragina, N. N. Arnautov, T. B. Batygina, T. B. Batygina;
Komarov Botanical Institute of Russian Academy of Sciences, St.-Petersburg, Russian Federation.

The vivipary is the especial type of propagation, when the generative or vegetative diaspore forms the seedling (propagula) just on the maternal plant without the dormancy period. The place of the vegetative diaspores formation varies (inflorescence, leaf, shoot or root). The vivipary could be either obligate or facultative. As the comparative analysis of vivipary distribution revealed, it is inherent mainly to the angiosperms (173 species of 43 fam.) and ferns (197 species of 8 fam.). The vivipary occurs quite rarely among the gymnosperms. In *Gnetum gnemon* in the greenhouse of BIN RAS the propagulas were found on the leaves of lower part of the crown. The propagulas aroused endogenously on the upper surface of the leaf's apical part (average 2.60±0.68 per leaf), their stage of development varied from the groups of meristematic cells up to the shoot with two pairs of leaves. The leaves bearing the propagulas were in average twice smaller then another ones at the same plant. Probably, the facultative foliar vivipary in *G. gnemon* is the response to the stressing factor (long temperature fall). The ability of plant to the vivipary is the reserve of reproductive systems.

P0298. Ontogenetic transition from protostele to dictyostele in *Ceratopteris richardii*: Cell fate mapping reveals correlations with shoot growth

P. A. Romanov, M. A. Romanova, J. Jernstedt;
University of California, Davis, Davis, CA, United States.

The remarkably regular cell division pattern in juvenile and adult shoot apices of *Ceratopteris richardii* facilitates mapping of cell lineages and cell fates in successive derivative segments of the shoot apical cell (AC), from embryo to mature sporophyte. The developmental transition from protostele to dictyostele is autoapomorphic in ferns. The origin of leaf ACs (LACs), leaf primordia (LPs) initiation and early development, bidirectional procambium differentiation, and the simultaneous origin of LACs and root ACs (RACs) were unaltered during ontogeny. The switch from procambial to parenchymatous fate by the inner cells of the adult shoot apex, which is the basis of changing stelar type, was correlated with alteration in timing of the onset of cell proliferation in incipient LP; it was delayed from the third segment (S_3) to S_{10}. Correlated with this were changes in shoot apical meristem structure, alteration in rhythm of LP development from successive to almost simultaneous development of three successive LPs, and changing leaf shape and leaf trace structure.

P0299. Male flower anther wall development in *Dioscorea nipponica* Makino (Dioscoreaceae)

A. A. Torshilova, T. B. Batygina;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

Some regularities of anther wall formation and their correlations with sporo- and gametophyte processes in *Dioscorea nipponica* (Dioscoreaceae) were revealed. *Dioscorea* species is known to have 4-loculed anther. For the first time it was founded out the succession of laying down the anther wall initials, and wall development from the connective side till the stage of mature pollen grains. The anther wall formation is realized according the centripetal type, but with different variations on the distal and dorsal sides. The tapetum cells occur as the result of parietal cells division. Besides, these parietal cells also are of different origin, different form and moment of origin. The tapetum consists of secretory binuclear cells, without reorganisations. Maximum of its development tapetum cells achieve at the stage of nonvacuolated microspores; its programmed cell death occur in the end of differentiated mitosis in vacuolated microspore. Mature anther wall (distal side) consist of 2 lays: epidermis and endothecium, dorsal side - multilayer endothecium.

P0300. Overexpression of the Arabidopsis thaliana MADS-box gene AGL21 confers leaf-like characteristics to floral organs.

A. Blanco-Jarvio, R. Tapia-Lopez, M. L. Barroso, R. V. Perez-Ruiz, E. Alvarez-Buylla;
Institute of Ecology (IE-UNAM), Mexico D.F., Mexico.

AGL21 is a member of the MADS-box gene family of transcription factors. In order to unravel the function of AGL21 during Arabidopsis thaliana development we characterized loss of function and gain of function lines for AGL21. While the former did not present any obvious phenotypic alterations the overexpression lines (35S:AGL21) showed altered behaviour during flower transition and flower development. The sepals in 35S:AGL21 lines sepals are more elongated than wild type sepals and they have stellate trichomes in both abaxial and adaxial surfaces. The petals of 35S:AGL21 lines are greener and significantly larger than in wild type plants. Carpels of these lines also bear stellate trichomes in contrast to wild type carpels. Under Scanning Electron Microscopy the petal and sepal cells of overexpression lines are flat rather than conical as in wild type and leaf-like respectively. These results suggest that AGL21 ectopic expression interferes with Arabidopsis normal floral development.

P0301. On the so-called “hydrocyte system”

O. A. Churikova, R. P. Barykina;
Moscow State University, Moscow, Russian Federation.

The formation of hydrocyte system is rather often takes place in seed plants, especially in flowering plants. In particular, it is discovered when formation the root shoots from the adventitious buds in the rootstock plants; when natural knitting of roots, and when different methods of shoot grafting. More strikingly is becomes apparent during the regeneration both in vivo and in vitro. The intensity of its development mainly depends on the organ's morphological nature, its functional loading and to an even the lesser degree depends on the taxonomical affiliation of object. More detailed analysis of hydrocyte system both at the light and electronic microscope levels showed its complicated histological structure. It includes the water-conductive elements (hydrocytes-tracheids, rarely - the vessel members), the phloem elements (the sieve cells and the sieve tube members with companion cells) and tracheidal parenchyma cells. The latter accomplish functions of transfering, supporting, accumulation and storing of reserve substances. Therefore, the so-called “hydrocyte system” can be regarded as original variety of seed plant conductive system.

P0302. Structural aspects of the cold and warm stratification effects to embryo development in seeds with complex deep morpho-physiological dormancy

I. M. Kravkina, N. K. Koteyeva;
Komarov Botanical Institute RAS, Saint-Petersburg, Russian Federation.

The structural responses of embryo cells to the conditions of warm and cold stratifications were investigated in Tulipa tarda seeds during embryo development. It was shown that as early as 24 h after imbibition, the structural changes in nucleus, chondriom and plastidom of embryo cotyledon epidermal cells (EC) testified the metabolism activation. After 72 h of stratification the structure of EC in the warm and cold conditions were similar indicated an active metabolic processes related to both transport to cotyledon from embryonal cavity and mobilization of their own reserves. It was concluded that initial stages of T. tarda embryo development has been started after achievement of certain level of water imbibition. The growth of the embryo ceased gradually after 20 d of warm stratification. Only in the cold the embryo development was fully completed after 52-62 d when EC were characterized by strong multiplication of protein synthesizing apparatus. The cells of shoot and root apical meristem had no any structural changes during all stages of embryo development. The mechanisms of low temperature effects to embryo development were discussed. RFBR 03-04-49494.

P0303. The role of smooth endoplasmic reticulum (SER) in regulation of developmental rhythms in early-spring ephemerals

E. A. Miroslavov, K. M. Barmicheva;
Komarov Botanical Institute RAS, Saint-Petersburg, Russian Federation.

The tubular SER structure and surface density of its membranes in ground tissue cells of corm bulb in Scilla sibirica were investigated at different stages of annual growth cycle. In autumn and winter the degree of SER development was low. In early spring the surface density of its membranes per cell increased and SER usually appeared in the form of single tubules. In summer the SER proliferated greatly. In addition to single elements, twisted tubules in the form of compact network were observed. In these case the degree of SER density was similar to that in secretory cells. The

AER is known to be an organelle that is involved in terpenoid biosynthesis including sesquiterpenes. The abscissic acid, growth-inhibiting hormone responsible for seed and bud dormancy, belong to the category of terpenoids. Thus, it appears that summer dormancy of bulbs in Scilla sibirica is closely related to the development of SER in corm that is involved in abscissic acid biosynthesis inhibiting growth processes. The financial support of Russian Foundation Basic Research is acknowledged (project 03-04-49494).

0304. Ultrastructural Aspects Of Oil Gland Initiation And Specialisation In *Citrus limon L.* Ovary

H. Rajaei, M. Rafiei;
Biology Dept., Shiraz University, Shiraz, Islamic Republic of Iran.

Ontogeny of the essential oil glands and ultrastructural features associated with their specialisation have been investigated in *Citrus limon* L..ovary wall during flower and fruit development. Oil glands initiate in young floral buds and attain their maximum number in green fruit peel. Five ontogenic stages are recognized, based on the histological aspect of the secretory structure.Oil glands originate from a pair of meristematic cells which later give rise to a globular main part and a stalk.The young gland consists of a central group of compact polyhedral cells, rich in ribosomes and plasids , and peripheral layers of flattened cells.. After completion of the divisions, a single cell in the center of the gland demonstrates an increase in electron density, degenerated organelles and disintegrated membranes.The cytolysis extends centrifugally until an inner cavity is formed surrounded by cells in active secretion.Terpenoids seem to be synthesized in plastid matrix, transported through ER elements, and pourred into the central cavity after fusion of the latter with the plasmalemma. Peripheral cells are modified into a protective sheath

P0305. Regulation of the V-ATPase

J. Dettmer[1], A. Hermesdorf[1], G. Grüber[2], **K. Schumacher**[1];
[1]ZMBP, Tübingen, Germany, [2]Universität des Saarlandes, Homburg, Germany.

V-ATPases are universal energizers of eukaryotic membrane systems and belong to the most fundamental enzymes in nature. Their primary function, the acidification of endomembrane compartments, makes them essential for a variety of cellular processes including secondary active transport, protein targeting, vesicle trafficking and membrane fusion. Because of their essential and complex functions it is important to determine the mechanisms that regulate the activity of these proton pumps. The genome of Arabidopsis contains 27 VHA-genes encoding the 13 different subunits necessary to form active V-ATPase complexes, thus offering an enomous potential to form different V-ATPase isoforms. Using reporter genes, we have identified tissue-, organell- and stress-specific isoforms and will present our approaches to dissect their biological functions. Furthermore we show that VHA-C is phosphorylated by a novel protein kinase and contains a nucleotide-binding site and will present our attempts to characterize the in vivo function of these regulatory mechanisms.

P0306. The autophagy-associated Atg8 gene family operates both under favourable growth conditions and under starvation stresses in arabidopsis plants

S. Slavikova, G. Shy, Y. Yao, R. Glozman, H. Levanony, Z. Elazar, G. Galili;
Weizmann Institute of Science, Rehovot, Israel.

Arabidopsis plants possess family of nine *AtAtg8* gene homologues of the yeast autophagy associated *Atg8* gene. To gain insight into these genes functions in plants, we transformed *Arabidopsis* plants with chimeric genes encoding two Atg8 proteins fused to N-terminal GFP and C-terminal HA (hemagglutinin) epitope tags. Analysis of these plants showed that under favourable growth conditions, the Atg8 proteins are efficiently processed and subsequently degraded. These proteins were localized to autophagosome-resembling structures both in the cytosol and in the central vacuole in a similar manner to their processing and localization under starvation stresses. Treatment with a cocktail of proteasome inhibitors did not prevent the degradation of these proteins, implying that their degradation takes place in the vacuoles as is occurring in yeast. Our results suggest that in plants the cellular processes involving the *Atg8* genes function efficiently in young, non-senescing tissues both under favourable growth conditions and under starvation stresses.

P0307. Gravisensitivity of plant meristematic cells under clinorotation

N. I. Adamchuk, M. A. Sobol, O. A. Artemenko, G. V. Shevchenko, D. P. Chernyshov;
Institute of Botany of NASU, Kyiv, Ukraine.

Data of clinorotation influence on mitotic index and DNA content in meristem root cells of 3-5-7 day pea seedlings were occurred. Structural-functional organization as well localization of cytoskeleton actin filaments in root and marginal meristem cells under clinorotation demonstrated the primary mechanisms of meristem cell gravisensitivity. Destruction degree of meristem organization depended from clinorotation period. Under clinorotation, the nucleolus functional activity as well mitotic index was inhibited in the early stages of seedling development. Contradictory, the growth of marginal and root meristem cells intensified. The stress influence of clinorotation on the early stages of plant development was determined as a level of summary protein synthesis and hsp70 presence in pea seedlings. The results allow to necessary information for future investigation on molecular basis of cell cycle regulation. Determination of meristem cell changes furthers both the prognosis of experimental plant cell specialization and to work out methods for correction of the alterations in space plant technologies.

P0308. Effects of hypergravity environment on lignin formation in Arabidopsis

D. Tamaoki[1], I. Karahara[1], L. Schreiber[2], T. Wakasugi[1], K. Yamada[1], S. Kamisaka[1];
[1]Department of Biology, Faculty of Science, Toyama University, Toyama, Japan, [2]IZMB, University of Bonn, Bonn, Germany.

Lignin, forming an important chemical modification of secondary cell walls, imparts mechanical strength to plant bodies. Deposition of lignin to secondary walls was essential during evolution of land plants. In this study, effects of hypergravity environment on lignin deposition in shoots of Arabidopsis thaliana was examined. In seedlings grown for 3 days after a hypergravity treatment for 24 hours, xylem vessels in the basal region of the shoots showed intense staining with phloroglucinol-HCl and pronounced autofluorescence under UV light. Lignin contents, quantified by acetylbromide, were slightly increased in secondary walls of shoots exposed to hypergravity.The effect of hypergravity on lignin deposition in secondary walls of shoots was partially reduced in the presence of gadolinium, which is a blocker of mechanoreceptors. Our results suggest that lignin formation is positively regulated under hypergravity, and mechanoreceptors were partially involved in the positive regulation of lignin formation under hypergravity.

P0309. Expression of *CsPIN* auxin efflux carrier genes during gravity-regulated peg formation of cucumber seedlings

N. Fujii[1], H. Takuya[1], D. Kim[2], M. Kamada[1], Y. Miyazawa[1], K. Kim[3], H. Takahashi[1];
[1]1, Sendai, Japan, [2]2, Kyungpook, Republic of Korea, [3]3, Kyungpook, Republic of Korea.

When cucumber seeds germinate in a horizontal position, seedlings form a peg on the lower side of the transition zone. We have shown that a threshold level of auxin is required for peg formation. We have also shown that cucumber seedlings in microgravity develop a peg on each side of the transition zone, suggesting that gravistimulation decreases auxin and suppresses peg formation on the upper side of the transition zone on the ground. It is hypothesized that modification of auxin transport due to gravity causes the reduction of auxin on the peg-suppressed side of the transition zone. To verify this hypothesis, we isolated 6 cucumber cDNAs of *PIN* auxin efflux carrier genes and investigated their mRNA accumulation in the transition zone by *in situ* hybridization. Our results show that mRNA of *CsPIN1* and *CsPIN6* accumulates in several tissues including endodermal cells that are predicted to sense gravity. Furthermore, clinorotated seedlings of cucumber increase mRNA of *CsPIN1* and *CsPIN6*. These results suggest that CsPIN1 and CsPIN6 could play a role in gravity-response to regulate peg formation of cucumber seedlings.

P0310. PnSCR, a gene responsible for shoot circumnutation in Pharbitis nil

D. Kitazawa[1], Y. Hatakeda[1], M. Kamada[2], N. Fujii[1], Y. Miyazawa[1], A. Hoshino[3], S. Iida[3], H. Fukaki[4], M. Tasaka[4], H. Takahashi[1];

[1]Graduate School of Life Sciences, Tohoku University, Sendai, Japan, [2]Japan Aerospace Exploration Agency, Tsukuba, Japan, [3]National Institute for Basic Biology, Okazaki, Japan, [4]Graduate School of Biological Sciences, Nara Institute of Science and Technology, Nara, Japan.

An agravitropic mutant of morning glory (*Pharbitis nil*), *weeping*, has defect in shoot gravitropism. Our previous results showed that *weeping* were also defective in proper endodermis development and in shoot circumnutation. Such defects in circumnutation were also observed in endodermis-less *Arabidopsis* mutant, *scarecrow* (*scr*). In search of the mutated gene of *weeping*, cDNAs for *SCR* homolog from morning glory (*PnSCR*) were cloned from both wild type and *weeping*. We found three nucleotides insertion in *PnSCR* obtained from *weeping*. To investigate whether this mutation causes a loss of function of PnSCR, we performed complementation test by introducing either wild type *PnSCR* or *weeping* type *PnSCR*, respectively, into *Arabidopsis scr* mutants. As a result, none of the defects were rescued by *weeping* type *PnSCR*, whereas wild type *PnSCR* rescued them. This result indicates that defects in gravitropism, proper endodermis development, and circumnutation observed in *weeping* are attributable to the loss of function of PnSCR.

P0311. The role of auxin and ethylene for gravitropic differential growth of coleoptiles and roots of rye- and maize seedlings

A. Hahn[1], U. Roth[2], **H. G. Edelmann**[1];
[1]Botanisches Institut, 50931 Köln, Germany, [2]Zentrum für Molekulare Medizin Köln, 50931 Köln, Germany.

According to the Cholodny-Went hypothesis differential growth is brought about by the redistribution of auxin (indolyl-3-acetic acid, IAA). We studied the relevance of auxin and ethylene for gravitropic differential growth in shoots and roots of rye- and maize seedlings. As earlier demonstrated, incubation of coleoptiles in dichlorophenoxy acetic acid (2,4-D) resulted in a two- to threefold length increase compared to water controls. In spite of this effect on growth, gravi-curvature was similar to water controls. In contrast, inhibition of ethylene synthesis prevented differential growth of coleoptiles and of roots. Inhibition of ethylene perception in horizontally stimulated maize roots growing on surfaces inhibited the roots to adapt growth to the surface, resulting in a vertical orientation of the root tips. This effect is accompanied by up- and down-regulation of a number of proteins as detected with the 2D-MALDI-TOF. Together the data challenge the regulatory relevance of IAA-redistribution for gravitropic differential growth. They corroborate the crucial regulatory relevance of ethylene for gravitropic growth, in both roots and coleoptiles.

P0312. Microgravity-specific changes in gene expression after short-term exposure of Arabidopsis thaliana cell cultures

M. Martzivanou[1], **M. Babbick**[1], M. Cogoli-Greuter[2], R. Hampp[1];
[1]Physiological Ecology of Plants, Tübingen, Germany, [2]ETH-Space Biology Group, Zürich, Switzerland.

Cell cultures of Arabidopsis thaliana (cv. Columbia) were used to screen for early alterations in gene expression as a response to altered gravitational fields. Genes of interest were selected from a larger group, the expression of which was altered under hypergravity (microarray study; Martzivanou and Hampp, Physiologia Plantarum 118, 221-231, 2003). Transcriptional changes of these genes were studied within a time frame of up to ten minutes of exposure to microgravity in a sounding rocket experiment (TEXUS), to clinorotation (random positioning machine), and to hypergravity (8 g). We could identify a set of six genes (mainly components of signalling chains) with increased transcript levels after about six minutes of exposure to microgravity. As clinorotation and hyper-g treatment did not alter the respective transcript amounts, we assume that the identified genes could be involved in a microgravity-related response.

P0313. Transcriptional regulation by CsARF2 and CsIAA1 for the gravity-regulated morphogenesis of cucumber seedlings

Y. Saito, D. Kitazawa, Y. Miyazawa, N. Fujii, H. Takahashi;
Graduate School of Life Sciences, Tohoku University, Sendai, Japan.

Cucumber (*Cucumis sativus* L.) seedlings develop a peg on the concave side of the gravitropically bending transition zone between the hypocotyl and the root. Peg initiation occurs due to auxin accumulated in the concave side of the transition zone through gravireponse. Auxin and mRNA of auxin-responsible genes accumulated more abundantly in the lower side of the transition zone in a horizontal position, compared to those in the upper side. Also, mRNAs of *CsARF2* and *CsIAA1* that encode transcriptional regulators of auxin-responsible genes, concomitantly accumulated in the transition zone at the stage of peg initiation. Tobacco BY-2 protoplast transient assay showed that CsARF2 activated the transcription of auxin-responsible promotor, DR5 and IR3, in the presence of auxin. These results suggest that CsARF2 is a transcriptional activator for the auxin response required for peg formation. We will discuss the role of CsIAA1 in the transcriptional activation of CsARF2.

P0314. Functioning of rye seedlings adenilatcyclase system under the microgravity influence.

I. V. Dragovoz, V. K. Yavorska;
Institute of plant physiology and genetics NAS of Ukraine, Kyiv, Ukraine.

Role of adenilatcyclase system (AC) in resistance formation to various stress factors is well known. We have studied cAMP content, phosporodiesterase (PDE) characteristics in rye seedlings under the microgravity influence caused by klinostating (4 turns per minute).

3-day seedlings exposition to microgrogravity have decreased vegetative and root mass, changed their spatial orientation. Short-term klinostating have increased cAMP level. Retrieving seedlings to steady-state conditions have decreased this index to control values. At this, PDE cAMP activity has decreased almost by three times resulting in increase of cAMP level and enzyme sensitiveness to Ca2+ and Ca2+-calmodulin.

Enzyme was found to be sensitive to phytohormones - cytokinins and ABA. It was inhibited by zeatin and stimulated by ABA.

Role of AC both in the mechanism of ABA action and the importance of phytohormone in regulation of AC cascade reactions was indicated. Initial increase of cAMP level acts as signal for the adaptation processes initiation and is reversible. Change of its characteristics cause increase of cAMP level and initiation of adaptation to stress action of microgravity.

P0315. MADS about moss

N. W. Ashton[1], S. D. Singer[1], N. T. Krogan[2];
[1]University of Regina, Regina, SK, Canada, [2]University of Toronto, Toronto, ON, Canada.

Classic *MIKC*-type (*MIKC*^{c}) MADS-box genes are indispensable elements in genetic programming of pattern formation, including segmental organisation of angiosperm flowers, in seed plants. Since little is known about functions of *MIKC*^{c} genes in non-seed plants, functional analysis of moss *MIKC*^{c} homologues was performed with the genetically amenable species, *Physcomitrella patens*.

Expression of moss homologues was knocked down by antisense RNA or abolished by single and multiple targeted gene knockouts.

Knocked down (antisense) transformants displayed a multifaceted mutant phenotype comprising abnormal leaf morphogenesis, delayed gametangia formation and abnormal sporophyte development. Most knocked out transformants were phenotypically normal. A single exception possessed the complex mutant phenotype that characterised the antisense strains.

MIKC^{c} genes play significant roles in morphogenetic programming of the moss. Functional redundancy characterises some members of the gene group. Our findings provide clues concerning the ancestral roles of at least some *MIKC*^{c} genes that may be represented in the genomes of diverse extant plant taxa.

P0316. Functional analysis of class 2 KNOX gene in Physcomitrella patens

K. Sakakibara, H. Deguchi;
Department of Biological Science, Graduate School of Science, Hiroshima University, Higashi-Hiroshima, Japan.

KNOX homeobox genes have an important role in initiation and maintenance of shoot apical meristem and they are divided into two subfamilies, class 1 and 2. The functions of class 1 genes have been characterized by mutant analyses and overexpression experiments, while the functions of class 2 genes are still unknown, because loss-of-function mutants have not been reported and any phenotype has not been reported in its over-producing transformants.

Physcomitrella patens Bruch & Schimp subsp. patens is a suitable model plant to analyze genes with unknown function, since gene targeting techniques have been established in this moss. We are investigating the function of a KNOX class 2 gene, *MKN1* (Champagne and Ashton 2001). The expression pattern of *MKN1* was analyzed by RT-PCR. *MKN1* mRNA was expressed in gametophores with gametangia and embryonic sporophytes, but not in protonemata nor gametophores without gametangia. Detailed expression pattern is unraveled by transformants, in which *uidA* (GUS gene) is inserted at the end of *MKN1* coding sequence. Phenotypic analyses of *MKN1* disruptants are presented.

P0317. Plant homologs of bacterial peptidoglycan biosynthesis genes in moss

H. Takano[1], M. Machida[1], S. Takio[2], K. Takechi[1], M. Hasebe[3];
[1]Grad. Sch. Sci. Tech., Kumamoto Univ., Kumamoto, Japan, [2]Center for Mar. Environ. Stud., Kumamoto Univ., Kumamoto, Japan, [3]National Institute for Basic Biology, Okazaki, Japan.

It is now widely agreed that all plastids in red and green algae, land plants and glaucocystophytes originated from a single cyanobacterial ancestor. Therefore, the evolution from endocytobiont into a wall-less, photosynthetic organelle involved a loss of the cyanobacterial cell wall. The peptidoglycan synthesis pathway is a major target for antibiotics. In the moss *Physcomitrella patens*, treatments with ß-lactam antibiotics including ampicillin and penicillin, D-cycloserine and fosfomycin, which inhibit peptidoglycan synthesis at different steps, resulted in giant chloroplasts. Moreover, ampicillin inhibited plastid division in the liverwort *Marchantia polymorpha* and Pteridophyta *Selaginella nipponica*. We isolated 9 genes that were related to peptidoglycan synthesis from *P. patens*. Seven of them were predicted to have plastid-targeting sequences by the TargetP program. These findings suggest that a relic of the bacterial peptidoglycan synthesis pathway is retained in moss plastids.

P0318. Role of the PpPOK protein, an homolog of the yeast Vps52p protein involved in vesicle trafficking, in the protonema growth of Physcomitrella patens.

H. Guermonprez, F. Charlot, A. Guyon, F. Nogué, S. Bonhomme;
INRA, Versailles cedex, France.

The Vps52p protein of Saccharomyces cerevisiae, has been shown to be essential in retrograde vesicular transport to the late Golgi in a complex with other proteins, Vps53p, Vps54p, and Vps51p (Conibear et al., 2003). Vps52p is highly conserved from lower to higher eukaryotes. The Arabidopsis homolog of Vps52p, named POK (poky pollen tube), is essential for normal pollen tube growth and the mutation is lethal when homozygous (Lobstein et al., 2004). These phenotypes and the POK gene expression in most plant tissues suggest a general role for POK in polar growth processes. In order to precise the function of the Vps52p homolog in plants, we extended its study to mosses, which protonema represent, as pollen tube, excellent unicellular tip-growing cells experimental systems. Moreover, the high levels of homologous recombination in Physcomitrella allow specific genes to be targeted and their functions thereby studied. We have identifed the Physcomitrella POK homolog, designed PpPOK. The PpPOK protein shows 94% identity with the Arabidopsis POK protein. Knockout transformants for PpPOK have been generated and their phenotypical characterisation is in progress.

P0319. What makes leafy gametophytes turning

M. Turzanska, B. Zagórska-Marek;
Institute of Plant Biology, Wroclaw University, Wroclaw, Poland.

Chiral aspects of phyllotaxis in leafy gametophytes of true mosses have been much less studied than in sporophytic shoots of other plants. The direction of leaf initiation in the gametophyte i.e. the configuration of phyllotaxis, reflects the order of divisions of its single apical cell because leaves are clonally related to merophytes. When divisions are parallel to the sides of the base of the apical cell, as it is in *Fontinalis antipyretica*, every 4-th merophyte rises exactly in the same circumferential position of a shoot. As a result tristichous phyllotactic pattern develops with three vertical ortostichies. When divisions are oblique, as in *Polytrichum commune*, every 4-th merophyte is circumferentially displaced - presumed ortostichies become bias. As expected, both chiral configurations occur in the two species. However, branching system of *Fontinalis* shows a peculiar, hard to explain dependence of the configuration of the lateral stems on that of the supporting ones. In *Polytrichum* the ortostichy deviation from the vertical course is concordant with the direction of leaf initiation although, theoretically, the opposite relationship is possible.

P0320. Spore ultrastructure in five Canarian species of pleurocarpous mosses.

C. Alfayate[1], B. Estébanez[2], E. Ron[3];
[1]Dpto. Microbiología y Biología Celular, Fac. Biología, Univ. La Laguna, La Laguna, S/C Tenerife, Canary Islands, [2]Dpto. Biología Vegetal (Unidad de Botánica), Fac. Ciencias, Univ. Autónoma, Univ. Autónoma de Madrid, Spain, [3]Dpto. Biología Vegetal, Fac. Biología, Univ. Complutense, Univ. Complutense Madrid, Spain.

Ultrastructural researches in moss spores have yielded interesting results, although it is still difficult to assess their systematic or adaptative meaning.

We selected five species from the Canarian laurisilva forest: *Leucodon canariensis* (Leucodontaceae); *Leptodon longisetus, Neckera cephalonica*, and *Neckera intermedia* (Neckeraceae), and *Isothecium myosuroides* (Brachytheciaceae). They all coexist in this very special habitat and share similar ecological requirements.

Mature spores were studied using SEM and TEM. Spore size frequencies were also analyzed. This research is carried out for the first time in these families.

All five species are distinct according to spore characters. The spore of *Leucodon canariensis* stands apart due to its bigger size, pluricellularity, and presence of an aperture. A bimodal distribution of the spore size indicates anisospory in both *L. canariensis* and *L. longisetum*. In the latter species, we discuss the spore features supporting its placement into a new family, Leptodontaceae, as recently suggested.

P0321. Changes in cortical microtubule organization in scale cells of *Narcissus tazetta* entering dormancy stage

S. Zaffryar[1], M. Abu-Abied[1], B. Zimerman[1], E. Belausov[1], A. Vainstein[2], G. Luria[3], R. Kamenetsky[1], E. Sadot[1];
[1]Volcani Center, Bet-Dagan, Israel, [2]Plant Sciences and Genetics in Agriculture, Rehovot, Israel, [3]Agricultural Extension Service, Ministry of Agriculture,, Bet-Dagan, Israel.

Dormancy induction and completion can not be determined visually in geophytes and is defined as the time where no visible changes of the bulbs are observed. The annual life cycle of *Narcissus tazetta* represents a classic example of the "Mediterranean" type of bulb where dormancy initiates at spring, last all summer and the mild drop of temperatures to 8-17°C in the winter fulfill the requirements for flowering. In this research we use molecular cell biology techniques to characterize intra-cellular changes delineating different stages of dormancy in cells of *Narcissus tazetta* bulbs. We found that amyloplasts increase in size gradually from November (10-15 µm) till May (25µm in diameter). During this time the organization of cortical microtubules changes from parallel arrays to a net encircling the big amyloplasts. This unique organization changes back into parallel arrays towards the months of June-July. We continue to characterize this phenomenon, both *in-vivo* and *in-vitro* in order to verify a possible cross talk between microtubules and amyloplasts membranes in cells of scales of *Narcissus tazetta*.

P0322. Phospholipase D activation is involved in the macrotubule-dependent protoplast volume regulatory mechanism in plasmolyzed root-tip cells of *Triticum turgidum*.

G. C. Komis[1], H. Quader[2], B. Galatis[1], P. Apostolakos[1];
[1]Department of Botany, Athens, Greece, [2]Biocenter Klein Flottbek, Hamburg, Germany.

The involvement of phospholipase D (PLD)-produced phosphatidic acid (PA) in the macrotubule-dependent protoplast volume regulation [*Plant Cell Physiol*. (2002) 43: 911] was studied in plasmolyzed wheat root cells. In these cells, the effects of butanol-1, NAE and PA were assessed on the hyperosmotic response and the macrotubule organization. Butanol-1 and NAE, which inhibit PA production, induce a marked reduction in the plasmolyzed protoplast volume and inhibit the hyperosmotically-induced macrotubule formation. By contrast, PA potentiated the hyperosmotic response of root cells while inducing supernumerary macrotubules. Results from western blot analysis suggest that the PLD/PA system acts upstream of a MAPK pathway as treatment with the above inhibitors modulated the accumulation of a 46 kDa phosphorylated p38 MAPK-like protein in plasmolyzed roots. This protein was previously shown to interfere with macrotubule formation [*FEBS Lett*. (2004) 573: 168].

P0323. Effect of red and blue light on the orientation of cortical microtubules in epidermis of sunflower hypocotyl

A. Burian, Z. Hejnowicz;
Department of Biophysics and Cell Biology, University of Silesia, Katowice, Poland.

The effects of red and blue light and auxin on the orientation of cortical microtubules (cMTs) under the outer epidermal walls of sunflower hypocotyls were investigated. The strips of epidermis were isolated, then incubated for 12 hours in Murashige & Shoog medium with or without auxin and irradiated with blue or red light for 1 hour.

The orientation of cMTs was transverse or oblique with respect to the cell axis, independently of the auxin's presence or irradiation. Many histograms showing frequencies of parallel cMTs versus orientation angle exhibited asymmetrical distribution with prevailing of right-handed cMT arrays. The irradiation with red light caused increase in the amount of asymmetrical histograms in which right-handed arrays of cMTs were dominated. Taking into consideration that the autonomous reorientation of cMTs is rotational (Hejnowicz, Protoplasma 2005, in press) we propose that the red light influences chirality of the cMTs by modulating the velocity of autonomous reorientations of the cMTs in the rotational cycle.

P0324. Polyglutamylation effects on the spatial structure and molecular dynamics of plant tubulin

A. Y. Nyporko, A. I. Yemets, O. N. Demchuk, Y. B. Blume;
Institute of Cell Biology and Genetic Engineering Natl. Acad. of Sci. of Ukraine, Kiev, Ukraine.

Polyglutamylation has been detected as post-translational modification of animal Ŭ- and ɓ-tubulins. This modification is typical for stable microtubule populations, and can be involved in microtubule-MAP interaction. Polyglutamate side chains of various lengths can be attached to multiple neighboring glutamate residues on C-terminus of tubulin molecules. Using specific GT335 antibody we found polyglutamylation of Ŭ- and ɓ-tubulins in *Daucus carota*. To study influence of this modification on tubulin molecular dynamics, the 3-D models of *D. carota* polyglutamylated tubulins were reconstructed. (Glu)$_n$ were attached to Glu445 of Ŭ- and to Glu432 of ɓ-tubulin. Molecular dynamics was calculated during 1 nsec using GROMACS software. It was found, that addition of (Glu)$_2$ and (Glu)$_4$ reduced levels of molecular oscillations of Ŭ-tubulin, but does not influence on ɓ-tubulin dynamics. Addition of (Glu)$_6$ resulted in increasing of Ŭ-tubulin molecular dynamics, but does not modify ɓ-tubulin behavior. Thus, reduction of tubulin molecule oscillation by adding glutamate residues results, in fact, in increasing of its stability was confirmed by *in silico* methods.

P0325. Mechanisms of plant resistance to dinitroanilines and phosphoroamidates based on ɓ-tubulin mutations

A. I. Yemets[1], A. Y. Nyporko[2], G. Swire-Clark[3], W. V. Baird[3], Y. B. Blume[4];
[1]Lab. Cell Biology and Biotechnology, Institute of Cell Biology and Genetic Engineering, Kiev, Ukraine, [2]Lab. Structural Biology and Bioinformatics, Institute of Cell Biology and Genetic Engineering, Kiev, Ukraine, [3]Dept. of Horticulture and Genetics, Clemson University, Clemson, SC, United States, [4]Dept. Genomics and Biotechnology, Institute of Cell Biology and Genetic Engineering, Kiev, Ukraine.

Early we produced *Nicotiana plumbaginifolia* ɓ-tubulin mutants resistant to amiprophosmethyl (APM), a phosphoroamidate herbicide (PAH), with cross-resistance to trifluralin, dinitroaniline herbicide (DNH). Altered tubulin formed APM-resistant microtubules after transfer of this trait to another species by somatic hybridization.ɓ-Tubulin genes from control and mutant lines were sequenced, and replacement of Ser248 to Pro in one of beta-tubulin gene from mutant was established. Comparative analysis of 3-D structures of sensitive and resistant ɓ-tubulins identified location of this residue in zone of tubulin intradimeric interaction. Ser248 as well as Lys252 and Lys350 participates in cavity formation, which can be identified as PAH/DNH interactive site, and in creation the microenvironment for ligand-tubulin interaction. Substitution of Ser248 to Pro results in the blocking of interactive cavity. These results coincide with our data on reconstruction of spatial structure of *Chlamydomonas* mutant ɓ-tubulin, obtained by Schibler and Huang (1991), where crucial role of missense mutation of Lys350 in colchicine- and PAH/DNH-resistance was found.

P0326. Expression of the *Nicotiana tabacum* pollen-specific gene NTP303 is required for pollen tube growth and fertilization.

P. F. M. de Groot, J. Derksen, F. Wittink, G. Wullems;
Faculty of Science, Nijmegen, The Netherlands.

We isolated a pollen-specific gene from tobacco, NTP303 with four other family members. NTP303 transcripts accumulate in pollen, but the protein is only found at germination and during pollen tube growth. Presently, we analyzed the effect of NTP303 gene silencing on pollen function. The kanamycin resistance trait linked to the NTP303-silencing gene was not transmitted through the male gametophyte. Since we could not find a readily distinguishable phenotype in pollen from the hemizygous plants, we produced double-haploid plants homozygous for the NTP303 anti-sense gene. In pollen from these plants, transcript levels of all NTP303 family members were strongly reduced. Pollen and pollen tubes grown *in vitro* appeared completely normal. However, the pollen tubes *in planta* showed lower growth rates and their growth became arrested in the style, so that fertilization failed. These data indicate that NTP303 and its family members are essential for pollen tube growth *in planta*. Together with the localization of the NTP303 protein in the wall and at the plasma membrane of the pollen tubes, the present results suggest a function in cross talk between pollen tube and pistil.

P0327. A role for the exocyst complex during plant development.

M. Quentin[1], L. Synek[1,2], V. Zarsky[1,2];
[1]Institute of Experimental Botany, Academy of Sciences of the Czech Republic, Prague, Czech Republic, [2]Department of Plant Physiology, Faculty of Sciences, Charles University, Prague, Czech Republic.

The exocyst is a eight subunits protein complex conserved among eukaryotes. Characterised in yeast and mammals, it was shown to participate in the spatial regulation of exocytosis. Acting as a tether, the exocyst physically links secretory vesicles with localised plasma membrane subdomains before fusion. Homologues of each exocyst subunit were identified in the Arabidopsis thaliana genome [1]. And a putative exocyst-like complex involved in vesicles tethering was recently described in Arabidopsis [2].

In this study, we describe Arabidopsis RNAi lines in which we were able to suppress the expression of Sec3 and Sec5 exocyst subunits. A mutant phenotype was observed in early plant development under stress conditions. We used antisense oligonucleotides to analyse the exocyst function in tobacco pollen development. The exocyst appeared to be involved in pollen tube elongation. These results indicate the exocyst complex may have a role to play in different processes of plant development.

P0328. Localization of the exocyst complex in plant cells

L. Synek[1,2], M. Quentin[1], M. Elias[2], V. Zarsky[1,2];
[1]Institute of Experimental Botany, Academy of Sciences of the Czech Republic, Prague, Czech Republic, [2]Faculty of Sciences, Charles University, Prague, Czech Republic.

Highly conserved protein complex called the exocyst is thought to participate in tethering of secretory vesicles to the plasma membrane. The exocyst has been described in mammalian and yeast cells. However analysis of plant genome sequences revealed the presence of homologues to all eight exocyst subunits (Elias et al. 2003), indicating that the exocyst complex is present also in the plant cell. Most of exocyst subunits are encoded by more than one gene.

Our analysis of public expression data based on the Affymetrix DNA chip revealed that some genes are tissue specific. We have focused on highly expressed or unique genes and constructed several GFP fusions. Using the method of transient expression in tobacco leaves and an immunolabeling of pollen tubes, we observed predominantly cortical and perinuclear localization of these fusion proteins. The localization to cell invaginations and tips of pollen tubes suggests the role of the exocyst in the spatially localized exocytotic pathway.

This work is supported by the GAAV CR grant A6038410 and EU-HPRN-CT-2002-00265 TIPNET.

P0329. Crosstalk between different signaling pathways in pollen tube growth and reorientation

C. Rodrigues[1,2], **C. Rato**[1], E. Sousa[1], P. Castanho Coelho[1], R. Malhó[1];
[1]Faculdade de Ciências de Lisboa, ICAT, Lisboa, Portugal, [2]ICBL, Dept. of Biomedical and Biological Sciences, University of Durham, Durham, United Kingdom.

Pollen tube growth and re-orientation are dynamic cellular processes important for a successful fertilization. Understanding the guidance mechanisms involved has been our main research focus and important insights into the biochemical and physiological aspects of these events have been reported. Nevertheless, much is still unknown. Here we describe recent findings of our laboratory on the regulation of endo/exocytosis as a motor for pollen tube growth and how the secretory machinery depends on the modulation of intracellular Ca^{2+} levels. Ion pumps and channels, Ca^{2+}-dependent protein kinases, phosphoinositides and phospholipids, all seem to play an active role in this process. To study the cross talk between these different signalling pathways is thus the thrive of our work. Here we show new data on the intracellular perception of guidance cues and how this affects endo-exocytosis. The results support a model where directioning is dictated by the combined action of several molecules and not by a simple cascade of events.

P0330. Phospholipase D signaling cascade regulates polar cell expansion

R. Bezvoda[1], M. Potocký[1,2], L. Synek[1,2], M. Oveļ ka[3,4], I. Lichtscheidl[3], O. Valentová[5], V. árský[1,2];
[1]Department of Plant Physiology, Charles University, Prague, Czech Republic, [2]Institute of Experimental Botany, Academy of Sciences of the Czech Republic, Prague, Czech Republic, [3]Institute of Ecology, University of Vienna, Vienna, Austria, [4]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia, [5]Department of Biochemistry and Microbiology, Institute of Chemical Technology, Prague, Czech Republic.

Phospholipase D (PLD) is an important regulating enzyme involved in many processes in animal cells while its role in plants remains largely unknown. PLD cleaves phospholipids producing phosphatidic acid (PA), an emerging second messenger in plant cells.

We studied PLD roles in regulation of vesicle trafficking within plant cell employing tobacco pollen tubes as a model system. Application of 1-butanol, the inhibitor of PLD signaling, rapidly affected pollen tube cytoarchitecture and vesicle dynamics as visualized by video-enhanced microscopy. Conversely, exogenous PA was able to stimulate pollen tube growth and trafficking dynamics.

To characterize distinct PLD isoforms, we used gene specific knock-down mediated by antisense oligos. The suppression of selected PLDs lead to lower pollen tube growth rates, confirming the importance of PLD signaling for polar growth and raising the question of downstream targets of PA. We suggest that different PLDs regulate cytoskeletal dynamics and production of reactive oxygen species generated by NADPH oxidase.

This work is supported by the MSMT CR grant LN00A081-SIDROS and EU-HPRN-CT-2002-00265 TIPNET.

P0331. Disturbance of endomembrane trafficking by Brefeldin A and Calyculin A reorganizes the actin cytoskeleton of *Lilium* pollen tubes

K. Hörmannseder[1], **G. Obermeyer**[1], I. Foissner[2];
[1]Molecular Plant Physiology, Div. Allergy & Immunology, Dept. Molecular Biology, 5020 Salzburg, Austria, [2]Plant Physiology, Dept. Cell Biology, 5020 Salzburg, Austria.

We investigated the effect of Brefeldin A (BFA) on the actin cytoskeleton of pollen tubes of *Lilium longiflorum*. The formation of a subapical BFA-induced membrane aggregation (BIA) was associated with the formation of an actin basket from which filaments extended towards the tip. Their orientation correlated with the trajectories of FM-stained membrane material suggesting that the BIA-associated actin filaments are used as tracks for retrograde transport. These tracks (actin filaments) were either stationary or glided towards the BIA together with the attached membranes. Treatment with Cytochalasin or Latrunculin caused arrest of membrane trafficking, dissipation of the BIA and the actin basket. Our observations suggest that BFA causes ectopic activation of actin nucleating proteins at the BIA resulting in retrograde movement of membranes not only along but also together with actin filaments. We show further, that subapical membrane aggregations and actin baskets supporting retrograde membrane flow can also be induced by Calyculin A, indicating that dephosphorylation by type 2 protein phosphatases is required for proper formation of membrane coats.

P0332. Phospholipid signaling in pollen tubes of Nicotiana tabacum

D. Helling, U. Klahre, B. Kost;
Developmental Biology, Heidelberg Institute of Plant Sciences, University of Heidelberg, Heidelberg, Germany.

Pollen tube growth is essential for plant fertilization and reproductive success. Pollen tubes expand by extremely polarized and rapid growth. Multiple signal transduction cascades are controlling fast organelle movements, targeted secretion and a tip-focused Ca2+ gradient, which are required for pollen tube growth. Phosphoinositide-specific phospholipases C are enzymes that hydrolyze phosphatidyl-inositol-4,5-bisphosphate (PIP2) and play key roles in diverse signal transduction processes in all organisms. Five PI-PLC isoforms have been identified in mammalian cells. The enzymatic activities of each of these types of PI-PLC isoforms are regulated by distinct mechanisms. The functions and regulation of plant PI-PLCs are not well understood to date. A number of plant PI-PLCs have been cloned so far, e.g. from Arabidopsis, tomato, pea and soybean. They all are most similar to the mammalian class of PI-PLCs delta and/or zeta. We identified two pollen-specific PI-PLCs from Nicotiana tabacum. The Ca2+-dependent enzymatic activities of wild type and various mutant forms of NtPLC4 have been determined and in vivo functional analysis has shown that PI-PLCs are key regulators of polar pollen tube growth.

P0333. Oscillations in pH anticipate growth in lily pollen tubes; a role for actin

A. Lovy-Wheeler, J. G. Kunkel, P. K. Hepler;
University of Massachusetts, Amherst, MA, United States.

Lily pollen tubes exhibit oscillations in their rate of growth (100-600 nm/sec), which are accompanied by oscillations in calcium and protons in the apical domain. We have compared these oscillatory events (e.g., growth vs. protons) using cross-correlation analysis to determine if a process precedes or follows growth. Our results show that increases in alkalinity anticipate growth by 100 degrees, suggesting that pH is a possible regulator of growth. Exploring the relationship between pH and actin polymerization, we show the following: 1) The oscillating alkaline band colocalizes with the cortical actin fringe. 2) ADF, an actin binding protein, which stains the actin fringe, is pH sensitive; at elevated pH it enhances the turnover of actin. 3) The culture of pollen tubes in sodium acetate causes acidification of the apex, and a rapid decay of the actin fringe. Since actin polymerization is essential for pollen tube growth we suggest that proton pumps extrude protons creating an intracellular alkaline band. The elevated pH activates ADF, which then fragments F-actin. The actin fragments stimulate polymerization and facilitate growth of the pollen tube.

P0334. Molecular identification of 14-3-3 isoforms of lily pollen and their possible role in activation of the plasma membrane H^+ ATPase

S. Rittmann, H. Pertl, G. Obermeyer;
Molecular Plant Physiology, Div. Allergy & Immunology, Dept. Molecular Biology, 5020 Salzburg, Austria.

Members of the highly conserved 14-3-3 protein family were detected in virtually all eukaryotic cells. They are involved in essential cellular processes including plant defence and stress responses, plant development, signal transduction, and modulation of enzyme activities. The role of 14-3-3 proteins depends on their intracellular localisation and on the interaction of specific 14-3-3 isoforms with phosphorylated target proteins. In lily pollen grains and tubes 14-3-3 proteins are associated with all organelle membranes and show a fusicoccin-dependent binding to plasma membranes activating the PM H^+ ATPase (Pertl et al. 2001, 2005). In order to investigate the isoform specificity of this interaction, cDNA libraries obtained from pollen grains and tubes, respectively, were screened with a degenerated digoxigenin-labelled probe. So far, 4 different 14-3-3 isoforms were identified and partially sequenced. The interaction of the various isoforms with the PM H^+ ATPase will be tested by immunodetection in an overlay blot using a plasma membrane-enriched fraction and native as well as recombinant 14-3-3 proteins obtained from lily pollen.

P0335. Molecular identification of a putative K$^+$ inward channel in lily pollen

R. Hude, R. Gehwolf, G. Obermeyer;
Molecular Plant Physiology, Div. Allergy & Immunology, Dept. Molecular Biology, 5020 Salzburg, Austria.

An influx of potassium ions is necessary for the germination of pollen grains on compatible stigmas as well as in *in-vitro* pollen cultures. The plasma membrane H$^+$ ATPase hyperpolarizes the plasma membrane more negative than the K$^+$ equilibrium potential and thus energises the K$^+$ influx mediated by K$^+$ inward channels. During germination of pollen grains and growth of pollen tubes different types of K$^+$ inward currents were detected and characterised in *Lilium longiflorum* pollen grain, pollen tube, and pollen tube tip protoplasts using the whole-cell configuration of the patch-clamp technique. The identification of the responsible K$^+$ channel genes was performed by by RT-PCR using K$^+$ channel-specific primer, by screening cDNA libraries obtained from lily pollen grain and tubes with a digoxigenin-labelled probe, and by SMART-PACE-PCRs, respectively. In this study we present the first results on K$^+$ inward channel sequences expressed in lily pollen grains and pollen tubes.

P0336. Ammonium: A major nitrogen source for plant nutrition in ectomycorrhizal symbiosis?

A. Selle[1], A. Gessler[2], S. Schwager[1], M. Willmann[1], U. Nehls[1];
[1]Institute of Botany, Pysiological Ecology of Plants, Tübingen, Germany, [2]Institut für Forstbotanik und Baumphysiologie, Freiburg, Germany.

In ectomycorrhizal symbiosis, plant fine roots are isolated from soil by a fungal sheath, making plant nutrition dependent on the fungal partner.

To understand plant nitrogen nutrition in symbiosis, a total of 7 putative high affinity ammonium importer genes were identified within the Populus trichocarpa genome. One gene (PoptrAMT1.1) was expressed only in roots, and 4 genes were detectable to a different extent in all poplar organs.

Ectomycorrhiza formation resulted in a strongly increased (5- to 9-fold) transcript level for those 3 genes (including PoptrAMT1.1), that are most prominent in fine roots.

The transport properties of the root-specific transporter were investigated by heterologous expression in a yeast mutant, revealing a KM value of about 52 µM, and thus indicating the protein as high affinity ammonium uptake system.

The enhanced expression of 3 poplar genes encoding putative ammonium uptake systems in mycorrhizas indicates a strongly increased ammonium uptake capacity of tree roots in symbiosis. This result is a first hint that ammonium could be a major nitrogen source that is delivered from the fungus to the plant in ectomycorrhizas.

P0337. Tree roots and underground infrastructure - a problematic relationship

M. Streckenbach, T. StÃ¼tzel;
Special Botany, Ruhr-University, Bochum, Germany.

Tree roots intrusing sewer pipes and drains lead to blockages. The real causes for the roots to find and enter the pipes are still unknown. In the past, leaking joints were supposed to cause these damages. Analysing excavated joints we could reject this theory. Furthermore, our investigations have shown that neither the water inside the pipes nor the nutrients carried with the water represent the leading causes for the roots to penetrate the pipe-joints. Instead we could set up the density-trap-model. Empty space in the joint, outside the sealing ring, leads to a density gradient which is followed by the growing root. Mechanical measurements of forces exerted by growing roots showed forces from 5 bar (Pisum sativum) up to 12 bar (Quercus robur). This indicates clearly, that resistance to inside overpressure of 0,5 bar as defined by industrial norms does not guarantee root-proof joints.

P0338. Shoot and root length are controlled by separate genes in barley mutants

M. Nawrot, A. Janiak, J. Guzy-Wrobelska, A. Braszewska, I. Szarejko, M. Maluszynski;
Department of Genetics, University of Silesia, Katowice, Poland.

Nine barley mutants with seminal roots significantly shorter than roots of parent varieties have been identified in the collection of dwarf and semi-dwarf forms of the Department of Genetics, University of Silesia. Genetic analysis performed at seedling and spike emergence/maturity stage indicated that a single recessive gene was responsible for root and shoot shortening in each of analysed mutants. The presence of recombinants with short root, long shoot (or opposite) in F2 generation of the crosses 'mutant x parent' proved that root and shoot length were controlled by independent loci. Reciprocal crosses between four mutants revealed that they were non allelic. In two mutants (225DV from cv.'Diva'; 035AR from cv. 'Aramir'), the linkage between genes responsible for root and shoot length was revealed. Molecular mapping with AFLP and SSR markers indicated that genes responsible for root and shoot lenght in mutant 225DV were located in the centromere region of chromosome 5H. Genes controlling root and shoot phenotype of mutant 035AR were localized in the distal part of chromosome 7H.

P0339. Structural and functional traits of scion-rootstock interactions in cherry tree (*Prunus avium* L.) under drip-irrigation

B. M. C. Gonçalves[1], J. Moutinho-Pereira[1], A. P. Silva[2], C. Correia[1], E. A. Bacelar[1], A. Santos[2], E. Rosa[2];
[1]UTAD - CETAV, Vila Real, Portugal, [2]UTAD - CECEA, Vila Real, Portugal.

Anatomical and functional traits of cvs Burlat and Summit grafted on Gisela 5 (dwarfing rootstock) and on *Prunus avium* (invigorating) were studied during 2003. Leaf gas exchange, photosynthetic pigments, carbohydrates and total phenols concentrations and anatomical parameters (by Scanning Electron Microscopy) were measured on each scion-rootstock combination. Higher values of net CO_2 assimilation rate, stomatal conductance, transpiration rate and internal CO_2 concentration were always observed in trees grafted on *Prunus avium*. In opposition, higher concentrations of total chlorophyll and carotenoids were presented by trees on Gisela 5. Higher starch and total phenols concentrations were determined in Burlat. In addition, Burlat presented higher stomatal density, particularly when grafted on the dwarfing Gisela 5. Summit on Gisela 5 exhibited a thicker mesophyll tissue (palisade and spongy parenchyma) and a thicker lower epidermis, traduced in a higher total lamina thickness. The relationship between physiological and morphological parameters is discussed by scion-rootstock combination.

P0340. Physiological functions of ammonium transporters of the AMT family in plants

N. von Wirén, Y. Lixing, D. Loqué, S. Kojima;
Institut für Pflanzenernährung, Stuttgart, Germany.

Proteins of the AMT family are believed to represent the major transporter class for the membrane transport of ammonium in plants. So far, correlations between transcript levels and ammonium influx have been used to attribute putative physiological roles to AtAMTs, but the contribution of individual AMT homologs to ammonium uptake remained unclear.

To investigate the physiological role of AtAMTs, our group isolated a number of Arabidopsis lines carrying transposon or T-DNA insertions in *AtAMT1;1*, *AtAMT1;2*, and *AtAMT1;3*. These lines were tested for influx of ^{15}N-labelled ammonium into roots and subjected to a phenotypical analysis under different growth conditions. Furthermore, tissue-specific gene expression and membrane localization were determined besides the posttranscriptional regulation of AMT-dependent ammonium transport using specific antibodies and overexpression lines. A summary of the actual results will be given and a model will be presented for the proposed physiological functions of individual AMTs in roots.

P0341. A new approach to analyze morphological heterogeneity within grass root systems

F. A. Lattanzi[1], L. A. Dawson[2], B. Thornton[2], A. Cuesta[2], H. Schnyder[1];
[1]Lehrstuhl für Gründlandlehre, Technische Universität München, Freising-Weihenstephan, Germany, [2]Soil Plant Microbial Interactions Group, The Macaulay Institute, Craigiebuckler, Aberdeen, United Kingdom.

Uniform activity among all roots is a common assumption in most studies of root physiology. It is almost certainly grossly inaccurate, but little information exists with which to formulate a description of the heterogeneity within root systems. Here, a new approach, based on the segmental morphology of grasses, was used to categorise root ages and analyze the effect of defoliation on the relationships between root age and morphology in *Lolium perenne*.

Defoliation strongly reduced total root length. This was mainly due to a drastic effect on root elongation at phytomers which were branching at the time of defoliation. Defoliation also reduced total root mass. However, specific root length (SRL, mm mg^{-1}) was only slightly affected. This was due to two contrasting responses: on one hand, new root tissue had higher SRL, and on the other, this was counter-balanced by concomitant decreases in branching, and therefore in SRL (branches are thinner than main axes and have higher SRL). These results emphasise that responses of whole-root system should be carefully interpreted for they are integrated by quite contrasting responses of mature compared to actively growing roots.

P0342. How similar are the tuberous roots between Pterocactus and Peniocereus?

R. Kiesling[1], T. Terrazas S.[2];
[1]Instituto de Botánica Darwinion, San Isidro, Argentina, [2]Colegio de Postgraduados, Montecillo. Edo. de México, 56230, Mexico.

We document structural modifications of tuberous roots in Pterocactus (7 species) and Peniocereus (18 species) that belong to Opuntioideae and Cactoideae subfamilies to support the hypothesis that storage roots arose independently in Cactaceae. The species of Peniocereus are distinctive by their napiform large tuberous root or fasciculated roots, but no adventicious storage roots or subterranean stems were observed, while in the Pterocactus species, there is a large tuberous root that acquires an irregular shape depending on plant age, but additional storage roots having a caulinar origin and subterraneous stems were common. Among the distinctive root anatomical differences between Pterocactus and Peniocereus species are: widening of parenchyma cells in the root central core, secondary xylem with wide band tracheids and druses or absent in Peniocereus, secondary phloem near the periderm in Pterocactus or separated by an extensive parenchymatous region, lack of sclerenchyma in tuberous roots or present in Peniocereus. Anatomical differences suggest that tuberous roots in Cactaceae have an independent origin.

P0343. Characteristics of Root Structure in Tea Plants

T. Homma[1], E. Tanimoto[2], A. Lux[3];
[1]Chiba Institute of Science, Choshi, Japan, [2]Nagoya City University, Nagoya, Japan, [3]Comenius University, Bratislava, Slovakia.

Tea plants (Camellia sinensis L.) are evergreen and long-living shrubs. Because the knowledge of tea root anatomy is quite limited, we have studied the structure of seminal and adventitious roots under different conditions. Seeds of tea cultivar Yabukita were grown in perlite in greenhouse. Cuttings of the same cultivar were planted in the field, hydroponic-cultured in the greenhouse and grown in the mist chamber. Roots of those plants were stained with berberine - toluidine blue and fluorol yellow in order to visualize Casparian bands and suberin lamellae, respectively. Casparian bands were developed both in exodermis and endodermis close to the apex. Endodermal Casparian bands were formed at 0.1, 0.2, 0.5 cm from the root tip in soil, mist and hydroponic culture respectively. Exdodermal Casparian bands were developed at 0.1 cm in soil, 0.1 cm in mist culture and 0.2 cm in hydroponic culture. Such development of functional exodermis sooner than endodermis in tea roots is quite exceptional. This early development of apoplastic barrier close to the root tip is suggested to play an important role in regulation of radial transport of water and minerals in tea roots.

P0344. Competitive ability of the root systems of beech and spruce: a space-related cost-benefit analysis

K. Häberle[1], P. Nikolova[1], H. Blaschke[1], S. Raidl[2], R. Agerer[2], R. Matyssek[1];
[1]Ecophysiology of Plants, Freising, Germany, [2]Systematic Mycology, München, Germany.

In a 60-year-old mixed forest of *Fagus sylvatica* and *Picea abies* structure and function of the roots of both species have been analysed and compared. To determine their competitive ability, the space occupied per unit of root biomass, the amount of water extracted by the roots per unit of occupied space, and the space-related ‘running costs’ of respired carbon were quantified. Although the coarse-root systems as evaluated through ground-penetrating radar were similar in both species regarding rooting depth and total biomass, substantial differences existed in physiological traits, when dividing the fine roots into functional classes. The latter were characterised by lignification and mycorrhization rather than root diameter. By identifying types of ectomycorrhizae which distinctly differ by the radii explored around the root tips, the effectively occupied space could be approximated. The exceptionally dry summer of 2003 was used as a test scenario which showed beech roots to be less affected by prolonged water shortage and to have competitive advantages over spruce.

P0345. Fast alterations in root cell patterning precede the changes in root architecture induced by aluminium stress.

M. Amenós, S. Doncheva, **C. Poschenrieder**, J. Barceló;
Universidad Autonoma de Barcelona, E-08193 Bellaterra, Spain.

Inhibition of root cell elongation has been made responsible for the fast Al-induced decreased of root growth. However, inhibition of cell elongation alone may not explain the subsequent alterations in the entire root architecture of Al stressed plants. Here the influence of short-term Al exposure on cell division in roots of maize was investigated using fluorescence confocal microscopy detection of immunolabeled S-phase nuclei. A 5 minutes Al exposure was enough to inhibit cell division in the meristem (250-800 µm from tip). After 10 or 30 min with Al only a few S-phase nuclei were found in the cortical initials. In contrast, cell division was stimulated in the distal elongation zone (2.5 to 3.1 mm). After 3 h the protrusion of lateral root was observed in this zone. Similar changes were induced by a local supply of NPA. This suggests that inhibition of auxin transport plays a role in the fast Al-induced alteration of root cell patterning that underlies the drastic change in root architecture. *.Acknowledgement: Supported by DGICYT (BFU2004-02237CO$_2$-01) and Plà Recerca Catalunya 2001 (SGR00200).*

P0346. Comparative study of cellular structures implicated in gravisensing in the statocytes of primary and lateral roots of Vigna angularis

N. Kuya, M. Kato, M. Ishida, S. Sato;
Ehime University, Matsuyama, Japan.

The lateral roots already had the statocytes with small amyloplasts sedimented in their lower end immediately after they emerged from a primary root. Neverthless, they showed plagiogravitropism in an early growth stage. Both in primary and lateral roots, all the statocytes had cortical microtubules which showed various arrays and actin filaments appeared as cables or bundles in the root-cap peripheral cells, whereas they did not clearly seen in mature statocytes with sedimented amyloplasts. Noteworthily, the endoplasmic reticulum (ER) developed much better in primary roots than in lateral roots. The tubular ER cisternae were suggested to form a large complex in the lower part of the statocytes of primary roots and the amyloplasts appeared to settle on the upper surface of this complex. Whereas, only a few cisternae were seen in the statocytes of lateral roots. Thus, it is suggested that the differential developmental level of the amyloplasts-ER complex system strongly correlates with differential gravitropism of the two types of roots.

P0347. Root system morphogenesis and comparative anatomy of Fabaceae species in relation to the environment

T. A. Kraus[1], C. A. Bianco[1], S. C. Basconsuelo[1], F. Weberling[2];
[1]UNRC, Río Cuarto, Argentina, [2]University of Ulm, Ulm, Germany.

The anatomy, dimension, and distribution of the root system of **Fabaceae** species seem to be related to the exploration and efficacy of the exploitation of resources. These factors vary under different environmental conditions and according to the different genotypes. The morphogenesis and anatomy of the root system of the species indigenous to Argentina of *Adesmia*, *Aeschynomene*, *Chamaecrista*, *Coursetia*, *Desmanthus*, *Hoffmannseggia, Indigofera*, *Lathyrus*, *Poiretia,* and *Rhynchosia* were studied particularly in relation to the environment. The development of the root system was observed through glass-sided containers. Serial transversal cuts of the roots were performed. The histological traits that determine the seven structural root models found, are the following: xylematic/phloematic relationship, presence and dimension of radii, quantity of cambia, cells produced by the cambium, presence and distribution of reserve substances. Adaptation strategies were also inferred.

P0348. Endocytosis and vesicle trafficking in root hairs

M. Ovecka[1,2], I. Lang[1], F. Baluska[3,2], A. Ismail[1], I. K. Lichtscheidl[1];
[1]Institution of Cell imaging and Ultrastructure Research, University of Vienna, Vienna, Austria, [2]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia, [3]Institute of Cellular and Molecular Botany, University of Bonn, Bonn, Germany.

Tip growth of root hairs depends on regulated vesicular trafficking; vesicles supply new cell wall and membrane components to the tip by exocytosis and they mediate the recycling of the material from the tip by endocytosis. So far, however, little is known about the dynamics of endocytosis in living root hairs.

We analyzed endocytosis and the behaviour of vesicles in living root hairs of *Arabidopsis* and of *Triticum* using fluorescent endocytosis marker dyes FM1-43 and FM4-64. We showed active endocytosis at the tip and further trafficking of the endocytosed membranes through highly dynamic early endosomes, late endosomal compartments and the tonoplast. We found that rapid endocytosis of the plasma membrane needed the actin cytoskeleton, and that vesicle trafficking but not rapid endocytosis was interrupted by Brefeldin A. Moreover, complexation of structural sterols in the plasma membrane of root hairs altered the physiological properties in the tip and compromised regulated endocytosis.

Results describe specific endomembrane compartments of the endocytotic pathway during the tip growth of root hairs.

Support: EU TIPNET HPRN-CT-2002-00265, VEGA 2/5085/25

P0349. Measuring aquaporin activity in a protoplast swell assay: contribution of the non-osmotic volume

A. Sommer, G. Obermeyer;
Molecular Plant Physiology, Div. Allergy and Immunology, Dept. Molecular Biology, Univ. Salzburg, Salzburg, Austria.

Due to the growing interest in the contribution of aquaporins (AQP) to water transport in plant cells, protoplast swell assays are performed routinely to test for the physiological functionality of AQPs. Usually, the water permeability coefficient (P_{os}) is determined according to a method used for *Xenopus* oocytes, in which the water uptake is monitored by a time-dependent volume change upon a hypoosmotic shock. Although it is commonly known that a certain fraction of the cell content does not participate in the osmotic process (fractional non-osmotic volume ß), it was neglected in osmotic swelling experiments on plant cells. In this context, we developed an analysis method to determine the non-osmotic volume from the time-dependent volume changes of single-cell measurements and tested this method on protoplasts of different origins (lily pollen and mesophyll tissue from *N. tabacum* and *A. thaliana).* Average ß-values around 30% were obtained. We compared these results with ß-values calculated using the "classical" Boyle-van´t Hoff plot and analysed the impact of ß on calculating P_{os}.

P0350. Reactions of growing root hairs to hypertonic media

M. Volgger, I. Lang, I. K. Lichtscheidl;
Institution of Cell Imaging and Ultrastructure Research, Vienna, Austria.

Root hairs are a plant's contact site with the environment and the first to sense changes in the soil. In order to test their reactions to osmotic stress, we observed root hairs of 3 day old seedlings of *Triticum aestivum*. Plants were exposed to iso- and hypertonic solutions of glucose, mannitol and polyethylenglycol (PEG) in concentrations of 100 - 500 mOsm.

Roots and root hairs adapted to hypertonic solutions of glucose by taking up considerable amounts which increased their osmotic value. Contrary to established opinion, also mannitol was taken up, thus allowing for initiation and growth of new root hairs in hypertonic solutions. In PEG, however, new root hairs were formed only up to isotonic concentration, it was not taken in. During plasmolysis, the polar organisation of the cytoplasm persisted and cell wall formation continued.

Endocytosis of the plasma membrane was tested with membrane-impermeable fluorescent dyes like FM1-43. We compared membrane recycling during tip growth with the behaviour of the plasma membrane during plasmolysis

P0351. Intrusive growth of the cambial initials between periclinal walls and its influence on the arrangement of wood cells: a critical evaluation

W. Wğoch[1,2], J. Jura[1,2], M. Iqbal[3], P. Kojs[2,4], A. Wilczek[2];
[1]Department of Biophysics and Cell Biology, Silesian University, Katowice, Poland, [2]Botanical Garden - Center for Biological Diversity Conservation of the Polish Academy of Sciences, Warsaw, Poland, [3]Jamia Hamdard, New Delhi-110062, India, [4]International School of Education and Culture, Silesian University, Cieszyn, Poland.

The mechanism of change in the orientation of cells in dicotyledonous wood, like fibres, parenchyma and vessel elements, is poorly understood. Observations suggest that the degree of inclination and the rate of changes in orientation of the axial wood elements, creating curly waves or interlocked grain in the wood, depend on the unidirectional intrusive growth of the fusiform cambial initials between tangential walls of the neighbouring cambial cells. Changes in the location of the initials, as estimated from the arrangement of the confluent parenchyma cells forming interlocked grain in the wood of tropical rainforest trees, have shown that unidirectional intrusive growth of cambial cells between periclinal walls is responsible for changes in vessel orientation to the same extent. The aim of this study is a critical evaluation of assumptions being applied to cambial anatomy and a reinterpretation of the facts in the context of hypothesis that intrusive growth of the initials takes place between periclinal walls of the contiguous cells.

P0352. Phytoecological investigation of the sweet chestnut coenosis (Castanea sativa Mill.) in Belasitza Mountain - Bulgaria

S. V. Bratanova-Doncheva[1], M. Lubenovʘ[2], V. Dimitrova[1];
[1]Central Laboratory of General Ecology - BAS, Sofia, Bulgaria, [2]Sofia University , Faculty of Biology, Sofia, Bulgaria.

Progressivly worsening of the health status of the chestnut phytocoenosis - drying - up, defoliation, development of semiparasites, parasites and diseases impose evolution of the degree of degradation prosesses and the factors responsible for this state.

In this investigation the plant species composition, structure of coenosis and intensity of cycling of some bioelements in chestnut coenosis in Belasitza mountain are present. They were used to evoluate the state of two types of model chestnut coenosis - century old seed chestnut stands and young sprout stands with different sylvicultural management .

A total of 150 species of vascular plants were described. The structure of the studied phytocoenosis based on biological type, life form by Raunkier and floristic elements by Asov was determined. The assessments were made by the scales of Braun - Blanquet for abundance, coverage and sociability and by Ponjatovskaja for frequency.

The stores of mulch and litterfall are established and intensity of nutrient cycling of 8 elements were calculated.

P0353. The polymer network of wood cell walls - an examination of chemically degraded wood by X-ray scattering

K. Jungnikl, O. Paris, I. Burgert, P. Fratzl;
MPI-KGF, Potsdam / Golm, Germany.

Wood cell walls are composed of complex interconnected polymer networks. The three structurally relevant groups of polymers are cellulose, hemicelluloses and lignin, of which cellulose is the one, whose function has been investigated most thoroughly. Our aim is to gain some more insight into the function of the matrix polymers, hemicellulose and lignin. For the present study, slices of Spruce wood (Picea abies [L.] Karst.) were degraded by three different chemical treatments: maceration by hydrogenperoxide, lignin removal by sodiumclorite and swelling by sodiumhydroxide. Those treatments each produce a different effect on the condition of the individual cell wall polymers and on their composition. The corresponding structural changes of the cell wall were observed by small-angle scattering (SAXS) and wide-angle diffraction (WAXS), in the wet state and after drying.

P0354. The development of cell walls during wood formation in Larix sibirica Ldb. stems

G. F. Antonova, I. A. Chaplygina;
VN Sukachev Institute of forest, Siberian Branch of Russian Academy of Sciences, Krasnoyarsk, Russian Federation.

The changes in growth rates of primary and secondary walls and the accumulation of hemicelluloses in the course of wood formation in Larix sibirica Ldb. stems were studied. To study the growth rate the samples were isolated from tree stems in the course of season. The growth rates of primary and secondary walls in the zones has been shown to decrease during tracheid development. To investigate the accumulation of hemicelluloses in tracheid walls at different differentiation stages xylem cell layers from cambium zone, radial cell expansion zone, secondary wall development before lignification and two consecutive layers of lignifying cells of early-wood and three consecutive ones of lignifying latewood tracheids as well as mature xylem cells have been obtained from the stem cuttings of 20-year-old larch trees. The amounts of polymer carbohydrates, deposited at each of development stages were calculated per dry weight and per cell. Pectin, arabinogalactan, arabinigalactan-proteins, A and B hemicelluloses have been found to have own dynamics at the each of differentiation stages according to them functional role in the creation of wall structure and growth cell.

P0355. Comparative Wood Anatomy of Nepalese Ulmaceae

L. Joshi;
Department of Plant Resources, National Herbarium and Plant Laboratory, Godawari, Nepal.

Eleven wood samples of Nepalese Ulmus, Celtis and Trema belonging to the family Ulmaceae are collected from different localities and described their wood structure. Wood is ring porous, semi-ring porous or diffuse porous. Transition from early wood to late wood is abrupt. Early wood pores are one to three layered, tangentially arranged. Late wood pores are arranged in dendritic or ulmiform pattern. Perforation plate is simple. Inter-vessel pit is alternate. Fiber tracheids, tracheids and libriform fibers are the non perforated tracheal elements. Wood parenchymatous cell is apotracheal, marginal and paratracheal. Rays are homo or heterogeneous. *Ulmus* differs from Celtis in ray structure and crystal location. A tentative key is prepared to identify the species based on wood character.

P0356. Molecular changes during deformation of wood studied by Raman Microscopy

N. Gierlinger, I. Burgert;
Max-Planck Institute of Colloids and Interfaces, Potsdam, Germany.

To meet the natural demands of a tree, wood tissues are formed in various ways with different anatomical, chemical and physical characteristics. As a result the mechanical properties of wood differ widely. To gain insights into the stress-strain behaviour at a molecular level, Raman spectra were acquired during tensile testing. Molecular changes were monitored by following changes in Raman bands attributed to vibrational modes of characteristic functional groups of cellulose and lignin. In normal spruce wood the band at 1095 cm^{-1}, corresponding to the stretching of cellulose (C-O-C), was shifted towards shorter wavenumbers, demonstrating that the cellulose molecule was subjected to a uniform stress deformation. No shift occurred for the 1600 cm^{-1} band, assigned to the aromatic C=C stretching in lignin. Investigating wood tissues, differing in chemical composition as well as orientation of the microfibril angle (e.g. reaction wood), will help to understand their stress-strain behaviour and the micromechanics behind.

P0357. Deformation behavior of wood under stress relaxation as cellular solids

K. Ando[1], Y. Kubojima[2];
[1]Graduate School of Bioagricultural Sciences, Nagoya University, Nagoya, Japan, [2]Forestry and Forest Products Research Institute, Tsukuba, Japan.

When compressive load is applied to wood in a transverse direction, the wood has high deformation capacity (low stiffness) and a superior ability to absorb the elastic energy. These characteristics of the wood subjected to transverse compression are important when wood is used as a construction material. Those characteristics are mainly due to the elaborate geometrical arrangements of various macro-structural and micro-structural units that constitute wood. In this study, the stress relaxation properties of coniferous wood in a radial direction were investigated to clarify the relationships between the various structures and the deformation behavior of wood. In the research on the macro-structure, that is, the annual rings unit, we elucidated that every annual ring is deformed individually and that when the strain of one annual ring becomes large, the strains of the others are recovered. In the research on the micro-structure, that is, the single cell unit, we elucidated that the shape of cells changes every moment at the early stage under stress relaxation. These behaviors are considered to be due to the viscoelasticity of wood as honeycomb cellular solids.

P0358. From cell wall architecture to wall modeling and back: a systems biology approach

A. Emons;
Laboratory of Plant Cell biology, Wageningen University, The Netherlands.

Plants produce 180 billion tons of cellulose per year, which has enormous commercial value in, for instance, wood. Cellulose microfibrils are crystalline aggregates of linear polymers of D-glucopyranosyl residues, linked in the ɓ-(1Ÿ 4) conformation. The architecture of microfibrils is cell type and developmental stage specific, and a determinant of mechanical wall properties. Using a systems biology approach, we have formulated a theory explaining how cells can determine microfibril angle. This fully mathematical developmental model quantitatively relates the deposition angle of CMFs to (1) the density of active synthases in the plasma membrane (N), (2) the distance between individual microfibrils within a wall lamella (d) and (3) the geometry of the cell (D). The model constructs all textures and predicts them, if [N], [d], and [D] are known. By predicting texture when a parameter is altered, the model is a design tool for production of plants with desirable traits.

P0359. Role of Cellulases in the Wood Formation

J. Takahashi[1], E. R. Master[2,3], U. J. Rudsander[2], T. T. Teeri[2], B. Sundberg[1], E. J. Mellerowicz[1];
[1]Umea Plant Science Centre (UPSC), Umea, Sweden, [2]Dep. of Biotechnology, Royal Institute of Technology (KTH), Stockholm, Sweden, [3]Centre for Structural and Functional Genomics, Montreal, PQ, Canada.

Cellulases are the enzymes hydrolyzing internal 1, 4-ß-glucosidic bonds such as found in cellulose and hemicelluloses. Plant cellulases form a multigene family composed of nine subfamilies that differ in enzyme structure and expression. Since no *in vivo* substrates of plant cellulases are known, the role of these enzymes in plant tissues is not understood.

In this work, we investigate the function of two cellulase genes, *PttCel9A1-1* and *PttCel9B*, that have been found in wood forming tissues in *Populus*.

Sequence analysis placed *PttCel9A1-1* in the subfamily of KORRIGAN, which has a membrane-anchored domain and is essential for cellulose biosynthesis. 36 cellulase genes have been so far identified in poplar genome, including a closely related gene *PttCel9A1-2. PttCel9B* was associated with subfamily V containing cell wall residing cellulases.

We have studied the expression of *PttCel9A1-1/2* and *PttCel9B* in 13 different tissues of hybrid aspen and analysed phenotype of *Arabidopsis* lines overexpressing *PttCel9A1-1* and *PttCel9B.* The data obtained indicate that the genes play distinct roles in the wood formation.

P0360. Enzymatic modification of primary and secondary cell walls - a tool for better insights into the mechanical functions of cell wall polymers

W. P. Abasolo[1], K. Yamauchi[1], N. Obel[2], L. Goswami[1], M. Pauly[2], I. Burgert[1];
[1]Max Planck Institute of Colloids and Interfaces, Potsdam, Germany, [2]Max-Planck Institute for Molecular Plant Physiology, Potsdam, Germany.

The unique mechanical performance of (ligno)cellulosic materials are based on nature's strategy in designing plant cells with an assembly of stiff cellulose microfibrils and soft matrix polymers. From a materials science point of view it is mainly the unique combination of stiffness and toughness of the cell wall that made plants to widely used biomaterials and inspires new biomimetic fibre composites. Knowledge of the mechanical relevance of each of the cell wall polymers separately is fundamental and imperative for the understanding of plant tissue properties. However, to date this knowledge is only rudimentary without input about the interaction of the cell wall components.

On one hand, Arabidopsis hypocotyls were enzymatically modified in vitro to investigate the polymer interaction in primary walls. On the other hand, mechanically isolated softwood tracheids were treated with enzymes to suppress the mechanical function of specific cell wall polymers in secondary walls. Micromechanical tests on hypocotyls and individual tracheids reveal the relevance of polymer interaction for the mechanical behavior of the entire primary and secondary cell wall.

P0361. Wood resin formation in slash pine trees of subtropical Australia: Genetic and environmental influences as revealed by tree ring ^{13}C and solid state ^{13}C NMR spectra

Z. Xu[1,2], N. M. Mathers[3], N. V. Prasolova[1,2], K. Harding[4], T. Copley[4], P. Keay[5], T. Smith[6];
[1]Griffith Centre for Forestry and Horticultural Research, Nathan, Brisbane, Australia, [2]Australian School of Environmental Studies, Griffith University, Nathan, Brisbane, Austria, [3]Department of Natural Resources & Mines, Indooroopilly, Brisbane, Australia, [4]Department of Primary Industries & Fisheries, Indooroopilly, Brisbane, Australia, [5]Department of Primary Industries - Forestry, Gympie, Queensland, Australia, [6]Department of Primary Industries & Fisheries, Gympie, Queensland, Australia.

There is little information about genetic and environmental determinants of wood resin formation for tropical tree species. The objective of this study was to quantify the genetic and environmental influences on wood resin formation in tree rings of a slash pine plantation in subtropical Australia, using both stable isotope and ^{13}C NMR techniques. This has highlighted the exciting potential and opportunities to use tree ring ŭ^{13}C and solid state ^{13}C NMR spectra for examining the genetic and environmental influences on wood resin formation. Tree ring ŭ^{13}C proved to be an effective, non-destructive tool to differentiate between good and healthy trees without wood resin defects, and those bad trees with a lot of wood resin defects. Both water and nutrient stresses and their interactions have been implicated in the wood resin formation. The wood resin formation appears to occur in the very dry growing season, where both water deficit and nutrient deficiency might be experienced.

P0362. Variation and relationship of tracheid length and S2 layer microfibril angle in *Cupressus arizonica* compression wood and opposite wood.

R. Oladi[1], D. Parsapajouh[2];
[1]State University of Tehran, Karaj, Islamic Republic of Iran,
[2]Department of Wood Science and Technology, Tehran University, Tehran, Islamic Republic of Iran.

In this study, variation of tracheid length and microfibril angle of S_2 layer (MFA) from pith to bark in compression and opposite wood of *Cupressus arizonica* was investigated and it was tried to determine the relationship between these two factors, quantitatively. Hence, four leaned stands were selected from the cypress plantation of Tehran University. After sampling and deteminig tracheid length ,MFA was measured by two methods; namely "inducing cracks in the secondary wall" and "Orientation of pit aperture" .There was a good agreement between these two methods which is described in the following equation:
$Y = 7.3 + 0.87 X$
X is the value of MFA obtained by the second method and Y is probable value which will be obtained by the first method.
Obtained results showed that tracheids are shorter and mean MFA is bigger in compression wood than opposite wood. Besides, in both tissues tracheid length has increased from pith to bark while MFA has decreased in the same direction. There was an intensive and negative correlation between these factors in both tissues. The best equation describing this correlation is:
L = 0.09 + 1.97 Cot Ŭ
L is the mean tracheid length and Ŭ is the mean MFA.

P0363. Contact and Non-contact Wood Fibers in Some Hardwoods

C. Zhang[1,2], M. Fujita[1], K. Takabe[1];
[1]Laboratory of Tree Cell Biology, Division of Forest and Biomaterials Science, Graduate School of Agriculture, Kyoto University, Kyoto, Japan, [2]Wood Anatomy and Quality Laboratory, Department of Wood Properties, Forestry and Forest Products Research Institute, Tsukuba, Japan.

Contact and non-contact wood fibers of *Pterocymbium beccarii, Paulownia tomentosa* and *Albizia julibrissin* were investigated. In the Mäule color reaction, wood fibers with small diameters (tips) appeared much darker in color than those with larger diameters (bodies), but there were no significant differences in the depth of color between the contact and non-contact wood fibers with similar diameters. This observation indicates that the tips of the wood fibers tend to be richer in syringyl lignin than the bodies, but there is no positive correlation between the content of lignin and the distance of the wood fiber from the ray. In the immunogold labeling with anti-xylan mouse antiserum, no essential difference was found in labeling distribution and density between two types of the wood fibers. In *Albizia julibrissin*, moreover, almost all wood fibers regardless of contact or non-contact with the ray contained starch grains in the outer portion of the outermost annual ring. These findings suggest that even the non-contact wood fibers might be supplied with almost the same amount of photosynthetic products, which are a source of raw materials for cell wall biosynthesis.

P0364. Rope-controlled design

C. Mattheck, R. Kappel, I. Tesari, O. Kraft;
Forschungszentrum Karlsruhe GmbH, Eggenstein-Leopoldshafen, Germany.

Moving biological structures are highly optimized in terms of mechanical strength and minimum weight. Due to their materials strength properties, tension-loaded components are therefore often highly qualified for material-efficient and lightweight structures. Humans, for example, have about 650 muscles (ropes!) and only about 225 bones. We are a rope-controlled biological design. In the past, lightweight design was achieved in engineering by using the SKO method (Soft Kill Option), which simulates the merciless work of osteoclasts. Non-load-bearing members of a mechanical component are nibbled away in a computer simulation. However, leasing rates of FEM software (Finite Element Method) are expensive. For this reason, a computer-free method was developed which learns from the mammal skeleton and from tensile belts in plants. In the cases tested so far, this method yielded results similar to those of the SKO, but with much less effort. The poster shows “hidden tension ropes” in nature and how the “thinking in ropes” method can be used for designing lightweight technical components.

P0365. Plasticity of single wood fibres - Basic research on cold forming of wood

L. Goswami, M. Eder, **I. Burgert**;
Max-Planck-Institute of Colloids and Interfaces, Department of Biomaterials, 14476 Golm, Germany.

At the molecular level of wood the cell wall polymers e.g. cellulose, lignin and hemicelluloses are the basic components influencing the mechanical behaviour of the tissue. However, only little is known about the mechanical interaction of the constituents. It was shown recently, that wood with a high cellulose microfibril angle in the S2-layer shows permanent plastic deformation without significant mechanical damage of the matrix, such as usually only observed in metals. The gliding of dislocations is replaced by a molecular stick-slip mechanism operated by some sort of "velcro" connection. To better understand the mechanical interaction of the cell wall components, individual polymers were suppressed in their functioning. Single fibres were isolated mechanically and the cell wall assembly was modified using specific enzymes. Micromechanical tests were carried out to characterize the mechanical behavior of the modified material without the missing component and thus, to learn more about the mechanical relevance of the eliminated polymer. In the long-term our objective is to modify wood, making it suitable for cold forming processes.

P0366. Development of biomimetically optimised pultruded composite profiles with high levels of dynamic load capacity and high vibration damping

M. Milwich[1,2], C. Linti[1], H. Planck[1,2], H. Spatz[2,3], T. Speck[2,3], O. Speck[2,3];
[1]Institut für Textil- und Verfahrenstechnik Denkendorf, Denkendorf, Germany, [2]Kompetenznetz Biomimetik, Albert-Ludwigs-Universität, Freiburg, Germany, [3]Plant Biomechanics Group, Albert-Ludwigs-Universität, Freiburg, Germany.

The aim of the project is to transfer findings about fibre orientation of plants into technical composite profiles with optimised weight related bending stiffness and strength combined with high dynamic load capacity and damping.
Like in plant stems the fibres embedded into a foam-like matrix, will be thinned out in regions of the cross section with less stress. Furthermore, structural collapse caused by of high bending and

shear stresses between flexible matrix and stiff fibres will be avoided by gradual transitions of stiffness.

Additionally, a distinctive circular spacer structure will provide excellent bending and buckling stability. Furthermore T-shaped fibre bundles along the longitudinal axis contribute to high stability and vibration damping.

An optimal technical realisation of these principles could be achieved by means of the braid-pultrusion process. Specially designed braid-pultrusion can generate spacer fabrics, and produces ,,technical plant stems“ with the features described above, reproducing the principal optimisations of plant paradigms.

P0367. Microcapsules prepared from pollen grains are promising tools in biotechnology

H. Woehlecke[1], K. Lerche[1], T. Gasperazzo[2], R. Ehwald[2];
[1]Dr. Lerche KG, Berlin, Germany, [2]Humboldt-University, Berlin, Germany.

Several angiosperms and gymnosperms produce large amounts of pollen grains that are covered by a sporopollenin envelope with fascinating properties. Microcapsules representing isolated exines of different species are rigid and nearly monodisperse particles with excellent packing properties for high performance liquid chromatography. They have unique properties for their application as filtrable support particles in biocatalysis and bioanalytics. The exremely high resistance of sporopollenin to heat as well as to harsh acid and alkaline treatments allows simple sterilisation, purification and regeneration.

Sporopollenin microcapsules from pine, birch and walnut have been designed for a new type of size exclusion chromatography that enables rapid and efficient isolation of extremely large polymers from a polydisperse colloidal mixture. Based on this principle, there has been developed a system for DNA isolation. The miniaturised columns or column arrays enable rapid and complete separation of genomic DNA from the proteins of fresh crude cell-free extracts obtained from plant tissues, yeast or bacteria.

P0368. Biomimetic application of plant gaseous exchange

T. Stegmaier[1], A. Roth-Nebelsick[2];
[1]ITV, Denkendorf, Germany, [2]Institute for Geosciences, Tübingen, Germany.

Plant gaseous exchange by stomatal diffusion represents a tightly controlled process. The details of stomatal regulation are very complex and still not yet fully understood. Since the stomatal pore opens under high turgor pressure of the guard cells and closes if the turgor decreases, it is, however, possible to apply this basic mechanism to humidity-sensitive textiles. Biomimetical mimicking of stomatal regulation is therefore achievable by various structural concepts by combining different fibres and materials. Furthermore, there are many variations of the stomatal architecture which probably represent additional structural optimizations of stomatal diffusion. For example, it can be shown that a sunken stomatal position and cutinization of the stomatal channel can decrease stomatal conductance significantly. Detailed analyses of the biophysical effects of the various stomatal fine structures will increase 1) the biomimetic potential of this biological mechanism, and 2) our understanding of ecophysiological adaptations of stomatal architecture.

P0369. A microfluidic system based on Münchs theory

R. Ehwald[1], H. Adleff[1], M. Ehwald[1], P. Geggier[2];
[1]Humboldt-University, Berlin, Germany, [2]Saarland University, St. Ingbert, Germany.

The osmoregulatory principles of phloem transport first formulated by Ernst Münch are of high interest for microfluidics. A micropump has been constructed on this background. As in the plant, volume flow is driven by a stationary osmotic gradient created by continuous regeneration of the solute (upstream) and its dilution within a membrane-boarded micro-channel (downstream). The prototype uses dissolution of NaCl for solute regeneration and a vapour-permeable hydrophobic capillary membrane on the dilution path. It enables pulse-free flow in the range of 2 to 30 nl per second for several days. The volume delivered by the pump with an adjustable flow rate is about twenty times larger than that of the osmotic working cell. An increase of the back pressure by 1 bar reduces the flow rate by less than 2 %. The pump contains a mobile separation element between the salt solution leaving the working cell and the pumped liquid. Osmotic micropumps of the described type and arrays of such pumps may be useful for labs on a chip, micro-electrophoresis, micro-injection and other applications, where small volume fluxes have to be manipulated.

P0370. Biomimetic Hydrophobic Surfaces generated by Self-Assembly of Plant Waxes

K. Koch, A. Dommisse, S. Koch, W. Barthlott;
Nees Institut für Biodiversität der Pflanzen, 53115 Bonn, Germany.

On plant surfaces a great diversity of micro- and nanostructures exist. These structures are often built up by crystalline and self-assembled waxes, which form hydrophobic microstructured surfaces. A surface template effect of artificial surfaces (HOPG = Highly ordered pyrolytic graphite) was used to generate highly ordered biomimetic surfaces by re-crystallisation of wax tubules from Lotus (*Nelumbo nucifera*) and wax platelets, extracted from wheat (*Triticum aestivum*) leaves. These in-vitro systems of substrate and adsorbates give a well defined biomimetic interface for studying a wide range of surface interactions at the micro- and nanometre scale. The dynamic process of wax tubule crystallisation on HOPG was observed in real time by Atomic Force Microscopy (AFM), and the mechanism of tubule formation documented. The in vitro formation of wax platelets was analysed by scanning tunnelling microscopy (STM), AFM and scanning electron microscopy (SEM), and the organisation form the molecular level up to the three dimensional crystal is documented.

P0371. *CYCLOIDEA* and flower head development in Aster family

M. KIM[1], P. Cubas[2], M. Cui[1], A. Gillies[3], R. Abbott[3], E. Coen[1];
[1]John Innes Centre, Norwich, United Kingdom, [2]Centro National de Biotecnologia, Madrid, Spain, [3]Institute of Environmental and Evolutionary Biology, University of St. Andrews, St. Andrews, United Kingdom.

Flowers of the aster family are arranged in a compressed inflorescence called a flower head (capitulum), which resembles a solitary flower. Most common flower head forms are radiate or discoid. Radiate heads contain disc florets in the centre, surrounded by marginal ray florets, whereas discoid heads have only disc florets. In *Senecio vulgaris*, the radiate and discoid head forms are controlled by a single locus, *RAY*. Linkage analysis reveals that two *Senecio CYCLOIDEA* genes (*sCYCs*) are linked to the *RAY* locus. These two genes are expressed only in ray florets, suggesting that *sCYCs* are involved in ray floret development. This suggests that *sCYC* is involved in generating dorso-ventral symmetry in a novel way that is different from *Antirrhinum CYC*. Generating transgenic *Senecio* plants with higher or lower levels of *sCYC* expression is underway to confirm the function of *sCYCs* in flower head development.

P0372. Study on floral biology and fruit setting in Pointed Gourd (*Trichosanthes dioica* Roxb.)

T. K. Maity, S. K. Sakar;
Bidhan Chandra Krishi Viswavidyalay, Mohanpur741252, west bengal, India.

The knowledge of floral biology helps a great deal in formulation of breeding strategy in any crop plant as it helps in crossing programme. With a view to studying the floral biology, Pointed gourd (*Trichosanthes dioica* Roxb.) of Cucurbitaceae, was taken as the experimental material. Characters like flower form, pollen shape and size, anthesis time, anther dehiscence, pollen viability, germinability, stigma receptivity and fruit setting under controlled pollination were taken into consideration. The opening of flowers and dehiscence of anthers tend to go together. Opening of female flowers almost synchronised with those of male flowers. Temperature had an effective role in development of buds, anthesis and dehiscence of anthers. Fruit setting percentage reduced with the aging of pollen. Staminate flowers developed earlier than the pistillate flowers. The average interval between the opening of the first and last flower within a same plant ranged from 2-6 hours.

P0373. Molecular evolution of floral dorsoventral asymmetry

M. M. R. Costa, S. Fox, C. Baxter, E. Coen;
John Innes Centre, Norwich, United Kingdom.

A key problem in evolutionary biology is the understanding of how genetic pathways diversify to give rise to a new morphology. Flower dorsoventral asymmetry has evolved multiple times independently. In Antirrhinum, flower dorsoventral asymmetry requires the combined activity of four key transcription factors: *CYC*, *DICH*, *RAD* and *DIV*. CYC promotes dorsal petal and stamen identity through directly binding to *RAD* promoter. RAD antagonises the activity of DIVcell and non-cell autonomously restricting its activity to the most ventral part of the flower. In Arabidopsis, a species with radial symmetrical flowers, *TCP1* (*CYC* orthologue) does not interact with any of the six *RAD*-like genes. In contrast to *CYC*, *TCP1* expression is transient and cannot be detected in floral primordia older than stage 2. Persistent expression of CYC in 35S:CYC:GR Arabidopsis plants promoted petal growth. The network of genes regulated by CYC is being analysed. Our results suggest that the persistent asymmetric expression of *CYC* and the recruitment of *RAD* expression in the dorsal domain of Antirrhinum floral primordia were important for generating a flower with dorsoventral asymmetry.

P0374. Genes and functions activated by the homeotic gene *AGAMOUS* during floral organ initiation in Arabidopsis

C. Gomez-Mena[1], S. de Folter[2], M. M. Costa[1], T. Lawrenson[1], G. C. Angenent[2], R. Sablowski[1];
[1]John Innes Centre, Norwich, United Kingdom, [2]Plant Research International, Wageningen, The Netherlands.

In Arabidopsis, the homeotic gene *AGAMOUS* (*AG*) terminates meristem activity and promotes development of stamens and carpels. To understand the program of gene expression activated by AG, we followed genome-wide expression during early stamen and carpel development. The AG target genes identified include most genes for which mutant screens revealed a function downstream of AG. Novel targets were identified and a core of genes that showed sustained activation is currently under study. The pattern of expression of these genes was analysed using in situ hybridisation confirming their expression in early reproductive organ primordia. The promoters of these genes are enriched for AG binding sequences and binding of AG was confirmed *in vitro*. We confirmed interaction with AG *in vivo* using chromatin immunoprecipitation for most of the other regulators of stamen and carpel identity (AG, AP3, SEP3 and CRC) and for GA4 (which suggested a role of AG in promoting gibberellin biosynthesis). These results suggest firstly a co-ordinated regulation of floral organ identity genes and secondly a role for gibberellins in floral organ initiation, which is currently under study.

P0375. Cellular and molecular mechanisms that lead to the unisexuality in flowers of Opuntia stenopetala (Cactaceae)

G. Orozco Arroyo[1], L. Flores Rentería[1], J. Márquez-Guzmán[1], F. Cruz-García[2], **S. Vázquez-Santana**[1];
[1]Facultad de Ciencias, Mexico distrito federal, Mexico, [2]Facultad de Química, Mexico distrito federal, Mexico.

The unisexuality is a mechanism that promotes the cross pollination. Some dioecious species never develop one of the sexual organs or its development is arrested. However, the cellular and molecular mechanisms that lead to the unisexuality are not well understood.

Our work is focused on the study of the dioecious cactus Opuntia stenopetala. We have found that male flowers show several defects in the ovary such as poor ovule development; lack of ovules and in some plants a total absence of the ovary cavity. Additionally, all the male flowers lost the stigmatic surface; instead, the style end is forming a sharp pointed structure. In order to understand the molecular defect associated to defective stigma phenotype, we have cloned from O. stenopetala, the partial cDNAs of Tousled and Stylish, two genes associated to this phenotype in A. thaliana. This analysis is in progress.

On the other hand, we have found male sterility in female flowers, since these plants do not produce pollen grains because during the anther development the microspore mother cells (MMC) do not go to or finish the meiosis, instead it we have evidence that MMC go to programmed cell death.

DGAPA IN216105-3

P0376. Switching sex along the spike: synchronised monoecy in Ecdeiocoleaceae, sister of Poaceae.

B. G. Briggs;
Royal Botanic Gardens, Sydney, Australia.

Ecdeiocoleaceae includes only two species, *Ecdeiocolea monostachya* and *Georgeantha hexandra*. Both are wind pollinated and monoecious; spikes produce zones of female and male flowers, with several switches of sex in an acropetal succession. *Ecdeiocolea* commonly shows a sequence up the spike: female/male/female/male/female, with high fruit set in both of the lower female zones. *Georgeantha,* with fewer flowers per spike, shows fewer switches. Through most of the flowering season, all spikes on a plant flower synchronously, either all in a female or all in a male phase. Fruits are nuts in *Ecdeiocolea*; capsular in *Georgeantha*.The two species are found in semi-arid habitats in southwest Australia. Both are highly xeromorphic with leaves reduced to few sheaths and with stomates in deep grooves. Ecdeiocoleaceae floral morphology may assist in interpreting the morphology of grass flowers, but the monoecy and xeromorphy are presumably autapomorphic. There is robust support from DNA sequence data for the clade (Poaceae, Ecdeiocoleaceae, Joinvilleaceae) and some support for Ecdeiocoleaceae as the closest extant sister to the Poaceae.

P0377. Environmental control of sepalness and petalness in waterlilies

K. A. Warner[1], P. J. Rudall[2], M. W. Frohlich[1];
[1]The Natural History Museum, London, United Kingdom, [2]The Royal Botanical Gardens, Kew, London, United Kingdom.

The conventional concept of an "undifferentiated perianth" obscures the fact that individual perianth organs may be differentiated into sepaloid (sepal like) and petaloid (petal like) regions. We have observed such differentiation in genera from several families including the basal angiosperms *Nuphar* and *Nymphaea* (Nymphaeaceae). In *Nuphar* the perianth organs traditionally called sepals exhibit both yellow petaloid and green sepaloid patches that show anatomical distinctions in addition to color differences. In *Nymphaea* the perianth organs near the boundary between "sepals" and "petals" are often subdivided into sepaloid and petaloid regions, rather than being intermediate in morphology over their entire surfaces. Our data suggest that the environment of a perianth organ helps specify these regions. The traditional concept of "sepal" and "petal" includes a hidden assumption that we believe is false: that sepalness and petalness must refer to whole perianth organs. We suggest a novel theory of perianth evolution, in which differentiation of the perianth into sepals and petals was predated by the evolution of sepalness and petalness.

P0378. Assessing adaptive evolution in homeotic B MADS-Box genes. Implications in the evolutionary history of petal development.

T. Hernandez-Hernandez[1], S. Magallon-Puebla[2], E. R. Alvarez-Buylla[1], L. P. Martinez-Castilla[1];
[1]Instituto de Ecologia, Ciudad Universitaria, DF, Mexico, [2]Instituto de BiologÃa, Ciudad Universitaria, DF, Mexico.

We investigate the evolution of petals at the molecular level by performing statistical tests to detect adaptation in the coding sequences of B MADS-Box genes, determinant in the molecular mechanisms of petal and stamen specification.

We use likelihood methods to evaluate the role of positive selection (PS) at specific moments during the evolution of B genes and at specific regions of the codified proteins, correlating our findings with crucial events in the evolutionary history of flowering plants. Our analyses focus on the AP3-PI duplication given its role in the evolution of heterodimerization and B function, and the euAP3-TM6 duplication and its possible role in the diversification of core eudicots.

We present phylogenetic hypotheses on which PS analyses were based, and report a complete description of substitution rates, divergence dates and sites under PS, particularly within the C-terminus of the amino acid sequences of core eudicots. Our results contribute to a better understanding of the evolutionary forces driving the functional diversification of B proteins, and provide a framework to explain petal evolution and core eudicots radiation.

P0379. Gene expression in homeotic flowers of carrot CMS plants

B. Linke[1], T. Nothnagel[2], T. Börner[1];
[1]Department of Biology, Humboldt University Berlin, Germany, [2]Federal Centre of Breeding Research on Cultivated Plants, Quedlinburg, Germany.

Flower formation is predominantly controlled by the nuclear genome. As known from the maternally inherited trait of ‘cytoplasmic male sterility’ (CMS), extranuclear genetic information also takes part in flower development. CMS flower defects are attributed to a perturbed interaction between specific nuclear (restorer/maintainer) genes and aberrant mitochondrial genes.

The homeotic florets of the 'carpeloid' CMS-type of carrots (*Daucus carota*) resemble nuclear organ identity mutants impaired in function of certain MADS transcription factors. We observed a reduced expression of the B-class MADS genes during early organ differentiation of 'carpeloid' carrot CMS flowers. CMS flower alterations are presumed to be an effect of reduced respiratory efficiency or another mitochondrial dysfunction. To detect a stage-specific correlation to an impaired mitochondrial function, we have analysed the expression of mitochondrial genes including also putative small regulatory RNAs in normal fertile and homeotic CMS florets of carrot plants by RT-PCR and *in-situ* hybridisation.

P0380. Xylan deposition on secondary wall of fiber and tracheid

T. Awano, T. Watanabe, K. Takabe, M. Fujita;
Division of Forest and Biomaterials Science, Graduate School of Agriculture, Kyoto University, Kyoto, Japan.

Xylans, including glucuronoxylans and glucuronoarabinoxylans, are abundant hemicelluloses in the secondary cell walls of xylem tissue.

Immuno-EM study showed that xylan localizes exclusively in secondary wall layer of xylem cells. Labeling increased in deep cell wall layers when the layer close to plasmalemma was being formed, which was observed in both fiber of woody dicotyledonous species and tracheids of conifer. This result suggests that xylan continues to be deposited after cellulose microfibril deposition. FESEM observation coupled with chemical extraction also showed that xylan penetrated into cell wall and continuously accumulated on microfibrils.

Xylanase treatment after delignification caused extensive swelling of secondary wall. A transverse view of fiber cell wall showed rounded shape after xylanase while angular shape was observed in non-treated and delignified sections. Xylan might act as a cementing material for lamellated structure of cellulose microfibrils.

P0381. Structural analysis of linear hydroxyproline-bound glycosides in *Chlamydomonas reinhardtii*

K. Bollig, J. Warnau, S. Waffenschmidt;
Universität zu Köln, Köln, Germany.

Extracellular hydroxyproline-rich glycoproteins (HRGPs) in *Chlamydomonas* and higher plants are posttranslationally modified by sugars O-glycosidically linked to hydroxyproline. While higher plant HRGPs of the extensin family are decorated by a simple mixture of tri- and tetraarabinosides, *Chlamydomonas* employs a broad variety of mixed, linear and branched sugar side-chains. As *Chlamydomonas* HRGPs are considered to be evolutionary ancestors of higher plant extensins, we were interested in the comparison of the respective glycosylation strategy based on anomeric conformation and linkage position of the sugars involved. We thus purified hydroxyproline-glycans isolated from *C. reinhardtii* HRGPs to homogeneity and analyzed the most abundant linear species by NMR and GC-MS after deuteromethylation. Our data proof that the *C. reinhardtii* linear hyp-glycans exclusively consist of arabinose and galactose, partly methylated in characteristic positions. Furthermore, we found that the first two arabinoses linked to hydroxyproline have the same anomeric conformation and linkage to each other as the arabinosides analyzed in higher plants.

P0382. Interaction analysis of outer wall HRGPs of *C. reinhardtii* and *C. incerta*

D. Wirth[1], C. Tschesche[1], U. W. Goodenough[2], S. Waffenschmidt[1];
[1]Universität zu Köln, Köln, Germany, [2]Washington University, St. Louis, MO, United States.

The cell wall of the unicellular green alga *Chlamydomonas reinhardtii* exclusively consists of hydroxyproline-rich glycoproteins (HRGPs), some of which are crosslinked to form the inner wall onto which perchlorate-soluble outer wall HRGPs assemble, a process which is called nucleated assembly. A nucleated assembly was observed as well, when *C. reinhardtii* outer walls were assembled onto perchlorate extracted cells of *Volvox carteri.* Isolated perchlorate extracted outer wall HRGPs of *C. reinhardtii* self-assemble *in vitro*, a process that was shown to produce the same lattice organization as *in vivo*. In a recent study, we have used isolated outer wall GPs of *C. reinhardtii* and *C. incerta*, which are capable to nucleated assembly and analyzed the interactions of their respective outer wall HRGPs under equilibrium and real time conditions. Interaction data of the respective species and chimera will be presented.

P0383. Nectar resorption in flowers of *Sinapis alba* L., Brassicaceae and *Platanthera chlorantha* Custer (Rchb.), Orchidaceae

M. L. Masierowska, M. StpiczyŒska;
Agricultural University in Lublin, Lublin, Poland.

In the flowers of *Sinapis alba* nectar is secreted by two pairs of nectaries and accumulated as drops between filaments and in the cavity of sepals whereas in *Platanthera chlorantha* nectar is produced and accumulated within a spur. Previous studies of these species revealed that after a period of secretion and cessation, rapid nectar resorption occurs. The aim of this study was the observation of nectar resorption by the nectaries using radiolabelled sucrose. During the peak of secretion the nectar accumulated in unpollinated flowers was replaced with the same volume of labelled sucrose and after 12-48 hrs of incubation, at the resorption phase, parts of *S. alba* flowers with nectaries as well as fragments of *P. chlorantha* spur were sampled and fixed for microautoradiographic studies. In *S. alba* the presence of [^{14}C(U)] sucrose was detected at the base of nectaries, in phloem elements of main vascular strands supplying glands, whereas both epidermis and nectary parenchyma showed no traces of radiolabelled sugars. In *P. chlorantha* the presence of labelled sucrose was stated mainly in the walls of nectary cells, which indicate an apoplastic route of reabsorbed nectar.

P0384. K+ channels regulate wood production

P. Ache[1], K. Langer[1], A. Stinzing[1], J. Fromm[2], R. Hedrich[1];
[1]Julius-von-Sachs-Institut für Biowissenschaften, Würzburg, Germany, [2]FG Holzbiologie, München, Germany.

Poplar cambial K^+ content increases during growth period in a K^+ supply-dependent manner. Upon K^+ starvation or application of TEA^+, a K^+ channel blocker, the average vessel lumen and expansion zone area were reduced. Expression of three K^+ channel types was analyzed. PTORK (release) and PTK2 (bidirectional) transcripts followed annual K^+ variations in poplar branches. During dormancy both channels were low expressed but up-regulated during the wood producing season. KPT1 (uptake) was expressed in guard cells and buds, strongly correlated with bud break. PtKUP1 (a K^+ transporter) was low-level expressed throughout the year, suggesting a housekeeping function. *Arabidopsis* petioles expressing PTORK- or the PTK2-promotor-GUS showed signals in vascular tissues only. In poplar, PTORK protein was detectable in young fibres, rays and phloem. Patch-clamp measurements identified PTORK like K^+ release channels as the major K^+ conductance of fibre cell protoplasts. A distinct K^+ channel might be required for K^+-dependent wood production and we now extend our analyses towards all poplar K^+ channels. New findings regarding salt stress and ABA will also be presented.

P0385. Biometric study of charcoalified softwood cross-field pitting

t. /. Gerards;
Services of Palaeobotany, Liege, Belgium.

Cross-field pitting is an important character for softwood identification. During charcoalification, qualitative and quantitative modifications occur in cross-field pitting. These modifications may hamper the safe identification of some taxa. This work is a systematic biometric study of a wide range of gymnosperm cross-field pitting after experimental charcoalification. We focused on the fenestrate, piceoid, taxodioid, cupressoid, araucarioid and podocarpoid cross-field pitting types. Our main results are the following. (1) Cross-field pits of wood specimens dried out before charcoalification are hidden by a thin closing wall; in this case, it is often impossible to discriminate the various types of cross-field pitting. (2) Piceoid cross-field pitting becomes taxodioid-like after charcoalification. (3) Biometric study of charred softwood cross-field pitting dimensions shows that the ratios between height and width of pit aperture and border can be used to characterise four types of pitting (fenestrate, piceoid, taxodioid, cupressoid+araucarioid+podocarpoid [= CAP]). The discrimination of the CAP type requires further investigation.

P0386. The Effect of Calcium on Wood Formation in Poplar

S. Lautner, E. Windeisen, J. Fromm;
Wood Biology, TUM, Munich, Germany.

Populus tremula L. *x populus tremuloides* Michx. clones were grown in hydroponics, supplied with Hoagland nutrition solution which was modified in its calcium contents. Energy dispersive X-ray analysis (EDXA) revealed an increase of calcium in the phloem, the cambium as well as in the xylem elongation zone with increasing Ca-supply in the nutrient solution. By using light microscopy a strongly reduced cambial zone of only a few cell layers in radial direction was shown under calcium starvation, accompanied with a limited elongation zone and early start of secondary cell wall formation. In addition, upon Ca^{2+} starvation transmission electron microscopy revealed significant changes in the cambial ultrastructure. Using FTIR technique on xylem cells formed under calcium starvation, we were able to detect a reduction of all absorptions, i.a. carbon-oxygen groups and of methoxy groups from S-lignin. On macerated fibres we found a significant reduction in the fibre length with decreasing calcium supply in the nutrient solution.
In conclusion, our results showed a significant influence of calcium on the structure and chemistry of young xylem cells.

P0387. The application of molecular markers for the identification of wood from different origins in the tropical tree familiy Dipterocarpaceae

Y. Rachmayanti, R. Finkeldey, L. Leinemann, O. Gailing;
Institute of Forest Genetics and Forest Tree Breeding, Göttingen, Germany.

Dipterocarpaceae dominate low land rainforests and comprise the most important timber species in Southeast Asia. Illegal loggin is a major cause of forest degradation in tropical rainforests. In order to develop tools for wood certification of dipterocarps, 200 wood probes will be collected from natural populations as well as from wood enterprises covering 20 geographic origins in 5 countries of Southeast Asia. DNA extraction methods will be adapted for marker analysis from wood. Different marker techniques - chloroplast and nuclear markers - that in former studies showed a strong differentiation between geographic origins will be applied. Specific PCR primers will be developed in order to amplify very short polymorphic regions also in degraded DNA probes from wood samples.These markers will be used for the certification (falsification) of the origin of wood from dipterocarps.

P0388. Aspects of the seasonal development of the secondary phloem in two Brazilian semi-ring porous trees

V. Angyalossy[1], C. R. Marcati[2], R. F. Evert[3];
[1]Universidade de São Paulo, São Paulo, Brazil, [2]Unesp, Botucatu, Brazil, [3]University of Wisconsin-Madison, Madison, WI, United States.

The structure of the secondary phloem of *Cedrela fissilis* Vell. (Meliaceae) and *Citharexylum myrianthum* Camb. (Verbenaceae) was studied in specimens collected from a semi-decidous seasonal forest in southeastern Brazil. Periodic collections were carried out from 1996 to 2000. Annual growth increments in the secondary phloem of these two species can be distinguished. In *Cedrela fissilis* early and late phloem are evident with one fiber band delimitating them. There is no distinct boundary between the early and the late phloem in *Citharexylum myrianthum*, but a gradual decrease in the diameter of sieve elements can be detected along each increment. The two species present very narrow sieve tube elements associated with their companion cells and phloem parenchyma cells, scattered along the outer surface of the cambial zone. The very narrow sieve elements mature just before the cambium dormancy that coincides with the dry season when the trees lose their leaves. These groups of very narrow sieve elements can be recognized as terminal phloem growth ring markers. The active cambium period begins with the wet season when trees leaf-out with the production of new phloem.

P0389. The International Association of Wood Anatomists

S. J. L. Jansen[1], P. Gasson[1], R. Miller[2];
[1]Royal Botanic Gardens, Kew, Richmond, United Kingdom, [2]Forest Products Laboratory, USDA Forest Service, Madison, WI, United States.

Despite our modern, hi-tech world and a long history of the study of wood structure, there is a great demand for wood products and research focusing on the anatomy of wood. The International Association of Wood Anatomists was founded in 1931 and has about 600 members in over 60 countries. The major aim of this association is to promote contacts between scientists from such diverse fields as wood development and ultrastructure, molecular developmental genetics of wood, archaeology, palaeobotany (including palaeoecology, palaeoclimatology), biomechanics, xylem physiology, systematic and ecological wood anatomy, dendrochronology, forestry, forest products, and wood technology. Other objectives are to exchange ideas, research material and information, to facilitate wood collecting, to promote the consistent use of terminology, and to stimulate research and publications in wood anatomy and related fields. The IAWA Journal is published quarterly and is the only international periodical entirely devoted to all aspects of fundamental and applied wood and bark structure. Further information is available from the IAWA website (http://www.iawa-web.org).

P0390. A novel biological rhythm of cell inclination change in cambium of *Cinnamomum camphora* T.Nees & Eberm.

M. Fujita[1], B. M. Zagorska-Marek[2];
[1]Graduate School of Agriculture, Kyoto, Japan, [2]Institute of Plant Biology, Wroclaw, Poland.

Figured wood in trees originates from cambium, in which the initial cells periodically change inclination. These oscillations represent the longest of known biological rhythms. Their period usually approximates 20 years. Here we introduce a short-term cycle discovered recently in a young cambium of camphor tree. We also give the first full description of its properties *in planta*. An analysis of young stems has showed that at the beginning of the ontogeny cambium produces remarkably straight-grained wood. However, in the 2-nd or 3-d year of cambial activity, in the middle of growing season, cambial cells start deviating to the right. Next spring they tilt to the left and, in a second half of the season, again to the right. No exception has been found from this sequence, although, theoretically, a mirror-like image od such annual cycle is possible. Two phases of the cycle are remarkably synchronised both cimcuferentially and longitudinally. A hypothesis has been put forward that the factor responsible for altering the direction of cell tilting in young stems is a peculiar, second flush of shoot apical meristem activity in the middle of growing season.

P0391. Climate sensitivity of tracheid wall thickness and ring width in intertropical trees and their relationship with cambial activity

S. Bernal-Salazar[1], T. Terrazas[2];
[1]Universidad Autónoma del Carmen, Cd. Del Carmen, Campeche, Mexico, [2]Colegio de Postgraduados, Montecillo, Edo de México, Mexico.

Two chronologies based on tracheid latewood wall thickness and ring width were obtained from *Abies religiosa* trees growing in the intertropical region of Mexico and their climatic sensitivity investigated by dendroclimatological techniques. In addition, samples of vascular cambium were removed over a two-years period to gain insight in cambial activity and seasonal wood development. Cambial activity is initiated at the end of January, reaching two peaks; one from March to April and the other during August; then activity slows down and ceases in mid-November. Two transition large periods, dormancy-activity and activity-dormancy, were observed within cambial activity cycle. Earlywood accumulation takes place from March to September and latewood from late September to mid-November. Tracheid wall thickness chronology shows low sensitivity whereas ring width chronology is positively correlated with precipitation in January and negatively with temperature in the May. The results suggest that rainfall in the transition period dormancy-activity and temperature after the first activity peak influence strongly wood accumulation.

P0392. The cambium activity in pernambuco-wood (*Caesalpinia echinata* Lam., Leguminosae)

E. Amano, V. Angyalossy;
Universidade de São Paulo, São Paulo, Brazil.

Caesalpinia echinata is a Brazilian endangered species. At first this species occurred throughout the Atlantic coast, but nowadays only a few populations remain left. We analyzed specimens planted in the state of São Paulo outside their natural environment as well as specimens planted in the state of Bahia in a natural area of occurrence. The periodic collections were carried out from 2000 to 2004. The cambium activity is different between the specimens of the two different areas. In the specimens of Bahia, the cambium activity is continuous along the year. The activity period is evidenced by the presence of fragmoplasts, recently formed tangential walls and xylem cells under differentiation adjacent to the cambium zone. On the other hand, the specimens collected in São Paulo present an active and an inactive period characterized by a sudden transition between the cambium zone cells and differentiated xylem cells. The cambium inactive period is related to a dry season which is, in general, five months long. In the specimens from Bahia, the cambium activity is continuous probably due to a shorter dry season.

P0393. Variability in cork oak wood anatomy in relation to water stress

S. Leal, V. B. Sousa, H. Pereira;
Centro de Estudos Florestais, Lisboa, Portugal.

The variability in libriform fibers and rays (multi- and uniseriate) dimensions, and vessel size and distribution was studied in the wood of *Quercus suber* L. young trees, never submitted to cork harvesting, and growing in very extreme conditions.

Fiber and ray biometry was studied at three radial positions. Fiber dimensions presented an increasing radial trend, already reported for other *Quercus* species. Ray variables remained rather constant along the radius. Since ray dimensions in general decline with age, the observed stability was interpreted as an adaptation to improve water storage.

Vessels were measured continuously along the radial direction by image analysis, on transverse surfaces. Cork oak trees have smaller vessel sizes in comparison with ring-porous oak species. This feature was interpreted as an adaptation to the harsh edaphoclimatic conditions, resulting in lower rates of water conduction and lower probability of cavitation occurrence, therefore contributing to the species tolerance to water stress. The radial constancy of vessel density, not usual in other tree species, was also interpreted as a strategy to survive to water stress.

P0394. Wood anatomy of some Brazilian species, based on charcoal analysis. II. Compositae

R. Scheel-Ybert, M. B. Zborowski;
Museu Nacional / UFRJ, Rio de Janeiro, Brazil.

Application of wood anatomy is the foundation of palaeobotanical research, specially charcoal analysis (anthracology), which allows the reconstruction of past vegetation and climate, as well as palaeoethnological studies. Prior to the development of anthracological studies, it was imperative to improve our knowledge of wood anatomy, especially on charred samples. Wood structure is very well preserved after charring, even if some quantitative anatomical parameters may change. Charcoal identification is more effective, and methodologically easier, when ancient samples are compared to charred modern equivalents. Charcoal pieces were manually broken and the three fundamental wood sections examined under a reflected light microscope. Descriptions followed the IAWA list of microscopic features for hardwood identification. This paper presents descriptions of 17 species from 10 genera of Brazilian Compositae. Tribe Astereae: *Baccharis* (2 species); tribe Mutisieae: *Dasyphyllum* (1), *Gochnatia* (2), *Stifftia* (1); tribe Vernonieae: *Eremanthus* (1), *Moquinia* (1), *Piptocarpha* (3), *Vanillosmopsis* (1), *Vernonia* (2); tribe Eupatorieae: *Eupatorium* (3).

P0395. Specialization of vessel elements in root, stem, and leaves of *Syagrus flexuosa* (Mart.) Becc. and of *Syagrus petraea* (Mart.) Becc. (Arecaceae)

M. R. Pace, M. P. Botânico, V. Angyalossy;
Instituto de Biociências, São Paulo, Brazil.

We examined root, stem and leaves of the suckering palm *Syagrus flexuosa* and of *Syagrus petraea*, a palm with subterranean trunk, which grow in the Brazilian *cerrado*. The *cerrado* (arboreal savanna) is characterized by a seasonal tropical climate, with poor and acidic soil. Cross-sections and macerations were used to analyze the material. Both species presented vessel elements whose width and type of perforation plate dimorphism corroborated what we know about the evolution of vessel elements in monocots. In relation to their length, we found that the vessel elements in the roots were much longer than those from the stem, differently from what the literature shows for monocots. Such differences bring to question the potential ecological and functional roles of the specialization of vessel elements. It is possible that long and wide vessel elements at the roots would be related to the increase of water transport efficiency to the leaves. This would, in turn, replace the loss with transpiration and would avoid cavitation, common phenomenon in dry environments. Furthermore, we suggest that apart from avoiding embolism, these roots might also play a role in water storage.

P0396. The vertical migration of rays in cambium of *Aesculus turbinata*

E. MyŜkow, B. Zagórska-Marek;
Institute of Plant Biology, Wrocǧaw University, Wrocǧaw, Poland.

Storied pattern of ray distribution, called double storied pattern, in case of *Aesculus turbinata* cambium, develops very slowly and becomes visible as late as in 32-years old secondary xylem. In a young, nonstoried cambium, expanding rapidly, the total number of rays increases mainly in a result of splitting of already existing rays, which seems to act against the rising order. After such an event, however, the daughter rays vertically migrate on the cambial surface, with distances between their middle points increasing. This is facilitated by highly controlled, polar additions or (and) eliminations of ray initial cells on the opposite margins of each ray. The rays repetitively split and migrate until they reach a suitable position within the forming storeys of fusiform initials and this is how the double storied pattern is ultimately formed. Tracing the offspring of one ray often led to locations not in one or two but even three neighbouring storeys. The displacement of rays was also noted in older, 50-years old storied cambium indicating highly dynamic maintenance of the storied pattern.

P0397. Embolism potential of embryonic gas bubbles in conduits of vascular plants

W. Konrad, A. Roth-Nebelsick;
Institute for Geosciences, Tübingen, Germany.

We analyze the final states (including embolism) of embryonic gas bubbles filled with water vapour, air, or both. They are created by air seeding or spontaneous vapourization. Their final states evolve from an interplay of surface tension, gas pressures in the bubble and xylem water pressure. The final states are calculated in terms of the initial values of bubble radius, xylem water pressure and number of air molecules.

The results are as follows:

(i) Pure water vapour bubble:

(a) If the initial radius exceeds a critical value the bubble bursts (causing embolism).

(b) If the initial radius falls below a critical value the bubble dissolves immediately after creation.

(ii) Air/water vapour bubble:

(a) If the number of air molecules exceeds a critical number (depending inversely on the xylem water pressure) the bubble bursts (causing embolism).

(b) If the number of air molecules falls below a critical value and the initial radius exceeds a critical value the bubble bursts (causing embolism).

(c) If both the number of air molecules and the initial radius fall below critical values the bubble attains a stable radius. In this case, the bubble can disappear by diffusion.

P0398. Fossil woods related with Malvales and Fagaceae from the Olmos Formation (Maastrichtian), Coahuila, México

E. Estrada-Ruiz[1], H. I. Martínez-Cabrera[2], S. R. S. Cevallos-Ferriz[3];
[1]Posgrado en Ciencias de la Tierra, UNAM, Del. Coyoacan, Mexico D.F., Mexico, [2]Posgrado en Ciencias Biológicas, UNAM, Del. Coyoacan, Mexico D.F., Mexico, [3]Instituto de Geología, UNAM, Del. Coyoacan, Mexico D.F., Mexico.

The Olmos Formation, in northern Mexico, bears a diverse biota with more than 80 plant taxa based on leaf and flower/frut impression /compression fossils, and tons of permineralized wood waiting detailed study. Here, we introduce two wood types resembling the xylem of Malvales and Fagaceae. *Javelinoxylon*, previously described from the Cretaceous of Southern Texas, has storied axial and radial elements, septate fibers and scanty paratracheal parenchyma. The second wood type has heterocellular aggregated rays, diffuse in aggregates axial parenchyma (forming one cell wide bands) and vasicentric tracheids, suggesting resemblance with Fagaceae, specially with *Quercus* and *Lithocarpus*; however, the dominance of scalariform perforation plates, infrequent in Fagaceae, suggest the presence of a new taxon. These woods document the earliest occurrence of storied structure, and what appears to be a member of Fagaceae with a major anatomical deviation when compared with its extant relatives.

P0399. Bark anatomy of *Meryta* (Araliaceae)

E. L. Kotina, A. A. Oskolski;
Komarov Botanical Institute, St.Petersburg, Russian Federation.

Meryta comprises ca. 30 species distributed among the islands of Southwest Pacific, with highest diversity in New Caledonia. Bark structure was studied in 7 New Caledonian spp. (*M. coriacea*, *M. denhamii*, *M. lecardii*, *M. oxylaena*, *M. schizolaena* and an undescribed species), 2 from Samoa (*M. capitata* and *M. mauluulu*) and 1 each from New Zealand (*M. sinclairii*), Fiji (*M. tenuifolia*). The secondary phloem of all the species studied has axial secretory canals associated the aliform sheaths of the axial phloem parenchyma sometimes confluent into tangential bands. Two species, *M. sinclairii* and *M. tenuifolia*, differ distinctly by the total absence of sclerified cells in the collapsed secondary phloem (a condition never before noted in Araliaceae). This finding agrees with results from molecular phylogeny. Several features are of diagnostic value, incl. the presence and type of crystals in the phelloderm and cortex, the type of secondary phloem rays, the occurrence of crystaliferous cells in collapsed secondary phloem, and the presence of radial secretory canals.

P0400. Wide-band tracheids in brazilian cacti

G. F. Melo-Pinna, E. Arruda, D. D. Abreu, T. Valvassoura;
Universidade de São Paulo, São Paulo, Brazil.

Wide-band tracheids were present in species that had dimorphic and monomorphic wood. In all dimorphic woods in wich WBTs were involved, the phase that contained WBTs was produced initially. In seedlings of *Cipocereus minensis* the first phase consisted of vessels and parenchyma in a matrix of wide-band tracheids and the second phase consisted of a fibrous matrix with vessels and parenchyma. In adults plants of *Opuntia leptocaulis*, *O. articulata* and *Nopolea cochenillifera* the first phase consisted of WBTs wood and the second phase of parenchyma matrix with solitary vessels. In the WBT wood of adults plants of *Discocactus placentiformis* and *Melocactus ernestii* the axial cells differentiated into parenchyma that was distributed as small clusters between the vessels and wide-band tracheids (monophorphic WBT wood). In *Opuntia leptocaulis* and *Nopalea cochenillifera* the WBTs were sporadic, being detected in one or two vascular bundles of the same set of sections. In all species examined the bandlike secondary wall was present as annular rings or as a helix, but we observed “mixed” type or double-helix.

P0401. Presence of storeyed cambium in trees of the tropical rain forests: an adaptive strategy

M. Iqbal[1], P. Kojs[2,3], W. Włoch[4,2], W. Szendera[5,2], J. Jura[4,2];
[1]Jamia Hamdard, New Delhi - 110062, India, [2]Botanical Garden - Center for Biological Diversity Conservation of the Polish Academy of Sciences, Warsaw, Poland, [3]Faculty of Ethnology and Education, Silesian University, Cieszyn, Poland, [4]Department of Biophysics and Cell Biology, Silesian University, Katowice, Poland, [5]Department of Plant Systematics, Silesian University, Katowice, Poland.

In a given environment, organisms capable of optimizing utilization of the resource available as a limiting factor, dominate. In tropical rainforests, light limits tree growth, during the first few years. The individuals that reach the canopy layer first, win the struggle for light. However, height of trees is limited by the mechanical properties of the trunk which depend mainly on its wood anatomy, which in turn depends on structure and activity of vascular cambium. Interlocked grain of wood provides high mechanical strength to the tree. Formation of interlocked grain is based on a fast cyclic change in orientation of the fusiform cambial initials, which is possible only in the storeyed cambium. It has been hypothesized that the presence of the storeyed cambium has an adaptative value for the fast-growing trees and forms an important evolutionary achievement which facilitates rapid cell rearrangement in the cambium without excessive expenditure of energy on events like elaborate apical intrusive cell growth, frequent oblique anticlinal cell divisions, and loss of the fusiform initials.

P0402. Floral development and presumed mycetomyiophily in *Tacca chantrieri*

R. Claßen-Bockhoff, I. Kreis, V. Aretz, S. Hirsch;
Institut für Spezielle Botanik, Universität Mainz, Germany.

Flowers in *Tacca chantrieri* are bisexual, actinomorphic and self-fertile. Dull colours, filiform bracts, window-effects, a significantly higher temperature inside the flowers and a musty smell suggest the syndrome of mycetomyiophily. However, no pollinators were ever reported. Fungiform structures originate from both stamens and stigmatic lobes. Each of the six stamens has a hood-like shape resulting from connective and filament broadening and incurving. They form separate chambers with small lateral entrances hiding the pollen-sacs. The gynoeceum is epigynous. The free tips of the three carpels postgenitally fuse and completely fill the flower centre forming a large six-lobed structure. Diverse epidermal surfaces, furrows and projections are present in the flower, which are interpreted as guiding structures for pollinators. Contrary to previous interpretations we argue that the 5 mm large pollinators enter the flower by creeping below the stigmatic lobes. They first transfer pollen to the stigma and are then guided into the staminal hoods where they get dusted with pollen. Finally they leave the flowers through the lateral openings of the hoods.

P0403. Evaluating constrasting interpretations of reproductive axes in Pandanales using cladistic analyses of developmental gene sequences

F. Vergara-Silva[1], P. Rudall[2], M. Frohlich[1];
[1]The Natural History Museum, London SW7 5BD, United Kingdom,
[2]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey TW9 3AB, United Kingdom.

The newly-recircumscribed monocot order Pandanales now comprises five families: Cyclanthaceae, Pandanaceae, Stemonaceae, Triuridaceae and Velloziaceae; their precise relationships are uncertain because placement of the mycoheterotrophic Triuridaceae has hitherto proved problematic. As part of an ongoing developmental-genetic approach to resolving contrasting interpretations of the nature of reproductive axes in Triuridaceae (either as "true" flowers, or as highly condensed inflorescences, i.e., pseudanthia), we present a cladistic analysis of sequences homologous to selected transcription factor-encoding genes important in the mechanistic aspects of floral development (namely, LEAFY and APETALA3/PISTILLATA). The rationale for expecting incongruent cladograms from morphological, molecular non-developmental ('process-neutral') or molecular developmental ('process-laden') data sets, separately or in combination, will be discussed.

P0404. Embryology and seed development of *Lachnocaulon* Kunth (Eriocaulaceae)

A. I. Coan[1], V. L. Scatena[1], M. M. Unwin[2];
[1]Instituto de Biociências - UNESP, Rio Claro/SP, Brazil, [2]Miami University, Oxford, OH, United States.

The embryology and seed structure of *Lachnocaulon* species were studied in order to describe the embryology of this north american genus and supply data for Eriocaulaceae´s phylogeny. The anther in *Lachnocaulon* is bisporangiate and the 4-layered wall present a conspicuous and fibrous endothecium, and a secretory tapetum with uninucleate cells. Microsporogenesis is successive with isobilateral microspore tetrads; pollen is spiroaperturate and bicellular at release. The ovule is orthotropous, inverted, bitegmic and tenuinucellate, with a micropyle formed by the inner integument. The megagametophyte is of the *Polygonum* type, with a conspicuous antipodal cyst. The seed is endotestal, with a tanniniferous endotegmen, and the seed coat is derived from the two ovule integuments. These embryological features agree closely with that known for Eriocaulaceae, and demonstrate the uniformity of the family. This investigation also indicates, as for several embryological aspects, the proximity of Eriocaulaceae to Xyridaceae, Mayacaceae, Rapateaceae, and Hydatellaceae (Poales), and they may be used to complement new databases in commelinids.

P0405. Sexual reproduction in a Mexican Caribbean seagrass: Description of fruits and seeds, and their potential distance of dispersión

K. Jiménez[1], B. Van Tussenbroek[2], A. Novelo[3], J. Márquez[1];
[1]Facultad de Ciencias, Universida Nacional Autónoma de México,

Mexico City, Mexico, [2]Unidad Académica Puerto Morelos, Instituto de Ciencias del Mar y Limnología, Universidad Nacional Autónoma de México, Quintana Roo, Mexico, [3]Instituto de Biología , Universidad Nacional Autónoma de México, Mexico City, Mexico.

Seagrasses are angiosperms which complete life cycle in the sea. We studied Thalassia testudinum a dioic plant that occurs throughout the shallow coasts of the Western Atlantic. It mainly spreads through extension of horizontal rhizomes, but also high densities of flowers are reported. Not much is known concerning the role of sexual reproduction in population maintenance of this species. Development of the fruits and seeds was followed through histological techniques. In all cases the embryos developed from a fertilized zygote. The seed wall is thin and the endosperm is helobial. Early embryogenesis belongs to the Caryophyllad type, with a new variant Thalassia type. No radicle formation were detected instead a pair of adventitious roots were developed. The seeds presented cryptovivipary. During 2002, 92% of the fruits opened in situ, and the seeds dispersed on average 30 cm. The remainder of the fruits detached, and floated to the surface where they remained afloat for max. 10 d. and the distance of dispersal could be up to 100 km. In this population the sexual reproduction assure a mechanism for genetic variability and the connectivity between population.

P0406. Evolution of developmental genes and flower form in orchid diversification

M. Mondragon-Palomino, K. Kaufmann, G. Theissen;
Friedrich-Schiller University of Jena, Jena, Germany.

The objective of this project is to investigate how changes in the spatial and temporal expression of developmental control genes bring about new structures that are subject to natural selection and evolutionary fixation. In particular we are interested to find out how these morphological changes influence species diversification. Understanding species diversity is an issue of high priority, but not much is known about how it initially emerges. By investigating these problems in orchids, the largest family in the plant kingdom, we will provide novel insights into the relationship between the evolution of genes and morphological structures. MADS-box genes, encoding transcription factors, are the best understood plant developmental regulators. The results here presented are part of a experimental project to isolate and characterize the function and regulation of MADS-box genes in orchid flower development. We investigate the relationship between the phylogeny and functional divergence of these genes during evolution and the emergence of key floral features associated with reproduction and species diversification in the orchid subfamilies.

P0407. Floral structure in the basal grass genus *Pharus*

G. M. Sajo[1], H. M. Longhi-Wagner[2], P. J. Rudall[3];
[1]Depto de Botânica, UNESP, IB, C. Postal, 199, 13506-900, Rio Claro, SP, Brazil, [2]Depto de Botânica, UFRS, Av. Bto Gonçalves 9500, 91501-970, Porto Alegre, Brazil, [3]Royal Botanic Gardens, Kew, Richmond, Surrey, TW9 3AB, United Kingdom.

Detailed knowledge of the reproductive structures of basal grasses is critical for understanding the homologies of grass reproductive structures, which are frequently anomalous with respect to other monocots. The tropical New World genus *Pharus* (5 species; subfamily Pharoideae) represents one of these basal grass lineages. Here we investigate floral structure in *Pharus* as part of ongoing comparative work on basal grasses. Most species have the classic monocot complement of six stamens (in male flowers) or staminodes (in female flowers), but in some representatives of two species (*P. latifolius* and *P. lappulaceus*) only four or five stamens or staminodes are present, reminiscent of another basal grass, *Anomochloa*. Examination of the vasculature associated with these reduced numbers reveals loss of the adaxial stamen of the inner whorl (5-staminate condition) and fusion of the two lateral adaxial bundles related to stamens of the outer whorl (4-staminate condition). Reduction in stamen number is correlated with adaxial compression of the flowers.

P0408. Diversity of climbers and lianas in North Andaman, India

P. K. Mukherjee, **A. Ghosh**;
University of Calcutta, Calcutta, India.

The climbers and lianas of North Andaman, India, are represented by 236 species under 127 genera and 53 families, including 3 species of ferns and 1 of *Gnetum* and monocotyledons with 30 species in 11 genera and 7 families. The most speciose families are Leguminosae (27), Convolvulaceae (21), Asclepiadaceae (16), Vitaceae (14), Menispermaceae (11), Dioscoreaceae (9), Arecaceae (8), and Smilacaceae (7). While 24 species are endemic, 89 are shared with mainland India and 123 have wider distribution in S.E. Asia. In the general pattern of species richness, 44 in the evergreen type, 38 in moist deciduous, 32 in mixed evergreen and 13 in littoral forests follow the semi-evergreen forest with 54 species. Bamboo thickets have 13 species and mangroves with only 7 species. Herbaceous climbers represent 71.61% of the total. Twiners and branch climbers are largest group (64.8%) followed by the tendril climbers (14.8%), sprawlers and scramblers (13.13%) and root climbers (7.2%). IVI ranged from 1.4 to 20.4 in the different forest types. Fruit is the most (60%) prevalent dispersal unit though anemochory (63.2%) supersedes zoochory (22.9%) and other dispersal means.

P0409. Fine-scale spatial variation in plant performance in a grassland: species-specific effects and neighbor root mass matter

T. Herben[1,2], S. BŚezina[1], V. Hadincová[1], H. Skálová[1], F. Krahulec[1];
[1]Institute of Botany, Pruhonice, Czech Republic, [2]Dept. of Botany, Charles University, Benátská 2, Praha 2, Czech Republic.

Many studies have shown that crowding intensity is an important predictor of plant performance in plant communities. Still in herbaceous communities aboveground plant biomass in the neighborhood is often a poor predictor of plant performance. We examine the hypothesis that belowground interactions and species composition of neighbors are more important for plant performance in such communities. We implanted phytometers of two species, *Anthoxanthum alpinum* and *Festuca rubra* into a mountain grassland, and examined their response to local variation in (i) aboveground biomass (ii) root mass in the soil, and (iii) abundance of individual species. The results show that neighbor root mass and by species composition were the the major determinants of phytometer performance. This suggests that interactions in the mountain grassland take place primarily belowground and that biomass-independent species-specific effects are important. This may be common in communities where maximum size of individuals is constrained.

P0410. Analysis of Aerenchyma Patterns in Aquatic Vascular Plants

S. Lee, H. Choi;
Ajou University, Suwon, Republic of Korea.

The existence of aerenchyma is considered as a important factor to distinguish aquatic vascular plants from other wetland species. We collected about 30 species of aquatic plants, *Potamogeton, Hydrilla, Vallisneria, Ottelia, Hydrocharis, Acorus, Sagittaria, Monochoria, Typha, Phragmites, Zizania, Scirpus, Eleocharis, Ceratophyllum, Myriophyllum, Oenanthe, Euryale, Nuphar, Nelumbo, Nymphoides, Polygonum, Persicaria, Trapa, Utricularia,* and *Limnophila*, from south Korea, and performed anatomical analysis to elucidate the characteristics of aerenchyma in aquatic vascular plants. As a result, aerenchyma patterns are divided into two groups. One is schizogenous aerenchyma that is a honeycomb-type or wide circular form, and the other is lysigenous aerenchyma that have cortical cells which are collapsed radially or tangentially. Especially in *Trapa*, aerenchyma is significantly enlarged in the petiole to give buoyancy to foliage, as well as to survive in flooding environments. Besides, we have cloned ADH gene of *Phragmites australis* and PRL gene of *Trapa japonica* to search genes associated with aerenchyma development in aquatic environmnets.

P0411. Determination mechanisms of matured plant construction in embryogenesis and germination in three species of *Araceae* Juss. family

I. V. Rudskiy, T. B. Batygina, G. E. Titova;
Komarov Botanical Institute RAS, Saint-Petersburg, Russian Federation.

Development of the axial and lateral organs (phyllotaxis (P) formation, leaf (L) construction, branching (B)) during embryonic (EP), pregenerative (PP) and generative periods (GP) in species of genera *Anubias* (*An*), *Calla* (*C*) and *Amorphophallus* (*Am*) is studied. Starting from PP all the species has a regular B and either distichous (*C*, *Am*) or spiral (*An*) P. However the initiation of some first L after the cotyledon is not coordinated, resulted both in irregular in divergence angle P (*C*, *An*) and B without any order, accompanied with death of buds (*Am*) and L tissue (*An*). By late EP or the seedling has rooted this processes put in order and L with blade similar to L in GP appeared. There is a partly repeating of this scenery as the adult plant B occurred. Analysis of the cell layers dynamic and structure using SAM and cytohistology methods has shown that determination of L and L part space position in EP lies in the establishment of species-specific space coordination between them without any respect to their rank. Such a coordination system is a topological invariant under following plant development. B and L complication conform to the increasing of this system fracture rank.

P0412. Ecomorphology and anatomy in *Sedum* species

V. Morawetz[1,2], M. A. Fischer[1], G. Draxler[2], J. Greimler[1], A. Kästner[1];
[1]Institut für Botanik, Vienna, Austria, [2]Institut für Ökologie und Naturschutz, Vienna, Austria.

Growth-form and lateral growth was monitored in *Sedum album, S. rupestre, S. thartii, S. acre, S. sexangulare, S. maximum (=Hylotelephium maximum)* and *S. spurium* during one season. The 6 chamaephytic Sedum species show a mainly vegetative propagation. *S. maximum*, being a geophyte, is far less propagative. Within the first week of growing the primary root dies and is replaced by adventitious roots. Approximately after 12 weeks the stems of the young plants become prostrate and lateral shoots start growing. In *S. maximum* seedlings the older root-parts begin thickening after ca. 8 weeks. These root parts consist of a starch enriched storage parenchyma, which contains concentric fascicles with a central xylem. All species develop one or more libriform fibre rings during secondary stem thickening. Leaves are isobilateral. Mesophyll consists of peripheral rounded chlorophyll cells and inner isodiametric water-storing cells surrounding the fascicles. A distinct palisade parenchyma is not developed. All species increase their phytomass largely during spring.

P0413. Phenology and radial growth of trees in a subtropical rainforest of Mexico

L. Yáñez-Espinosa[1,2], T. Terrazas[2], L. López-Mata[2];
[1]Instituto de Ecología, A.C., Xalapa, 91070 Veracruz, Mexico, [2]Colegio de Postgraduados, Montecillo, 56230 Estado de México, Mexico.

Association of *Aphananthe monoica*, *Pleuranthodendron lindenii* and *Psychotria costivenia* radial growth and phenology variables with environmental factors (local climate, vertical strata microclimate, and soil physical and chemical variables) was collectively evaluated. The generalized canonical correlation analysis (GCCA) revealed a strong influence of climate in phenology and radial growth. Leaf initiation and cambial activity periods were associated with maximum temperature and day length, and vascular tissue differentiation with soil moisture and rainfall. The first environmental canonical variable explained more than 84% of variance in the phenology and radial growth data in the species. The GCCA also allowed stating a general model of relationships among tree phenology and radial growth with climate, microclimate, and soil factors. However, after the individual species analysis, it was detected different relationships magnitude for each species, suggesting that each one take advantage in a different way of the environment in which they are growing, distributed throughout the different vertical stratum, and allowing them to coexist.

P0414. Leaf structure in *Chlorogalum* and its allies - Hyacinthaceae or Agavaceae?

A. H. Lynch, P. J. Rudall, D. F. Cutler;
Royal Botanic Gardens, Kew, Surrey, United Kingdom.

The North American genera *Chlorogalum*, *Camassia*, *Hastingsia* and *Schoenolirion* have traditionally been placed in Hyacinthaceae-Chlorogaloideae, but recent analyses of molecular sequence data have indicated closer affinity with Agavaceae. Here we investigate comparative leaf anatomy of Hyacinthaceae and Agavaceae as part of the *Anatomy of the Monocotyledons* series. Leaf morphology is frequently xeromorphic in these families, with some exceptions. Many Agavaceae have thick fleshy leaves, a character that was formerly used to group them with other xeromorphic Asparagales. Raised 'pustules' or dark-coloured spots are a feature of leaves of some Hyacinthaceae, which typically possess relatively little sclerenchyma and copious mucilage derived from large, 'rhexigenetic' lacunae that are formed by the breakdown of large central mesophyll cells between the leaf vascular bundles. Such lacunae are an unusual feature that is also present in Chlorogaloideae; they may allow rapid leaf expansion in deciduous-leafed species from xeric habitats. On the other hand, Chlorogaloideae share some features with Agavaceae, including the presence of styloid crystals.

P0415. Population Biology of an annual psammophytes of the South Russia

M. J. Kondakova, V. V. Fedyaeva;
Biology faculty, Rostov-on-Don, Russian Federation.

Different species of plant, which followed to the determined ecological group and grew into similar ecological-coenotic conditions, are distinguished current models of shoot-forming. Some aspects of plant population biology are considered: 1) analysis of features of the morphological constructions of shoot (architectural models) and 2) correlation between morphological construction, ecology and phytocoenology of certain plant species.
Some species of annual psammophytes of the Rostov region were investigated by methods of population biology. Researched populations of annual psammophytes had different architectural models of shoot-forming and grew on diverse sand areas. Classification of different species, comparison populations of one species growing in different sand areas were implemented, and diversity of architectural models within current taxon were investigated.

P0416. Floral correlations in two distylous *Primula* species

K. Kálmán, A. Medvegy;
University of Szeged, Szeged, Hungary.

An important question in pollination biology is that the sizes of flower parts are developmentally or functionally related to each other. Five floral traits (corolla tube length, anther and stigma height, stigma-anther separation, and anther length) were measured in long-styled and short-styled flowers of Primula vulgaris and P. veris in order to test these two hypotheses. The strong positive correlation between anther height and corolla tube length can partly be explained by developmental constraints, since anthers are fixed directly onto the corolla tube. According to the selective correlation hypothesis, stigma height is expected to be related to corolla tube length strongly in long-styled and weakly in short-styled flowers, but our results demonstrated weak correlation in both morphs. The two mating types varied considerably in the correlation between stigma-anther separation and corolla tube length: strong positive correlation was detected in short-styled, and weak negative correlation was detected in long-styled flowers. This phenomenon could be a possible explanation for the longer corolla tube in short-styled than in long-styled flowers.

P0417. Anatomical Studies in tribe Cereeae (Cactoideae, Cactaceae)

P. Soffiatti, V. Angyalossy, R. Yoshikawa;
Institute of Bioscience, São Paulo, Brazil.

The anatomy of species of *Arrojadoa*, *Brasilicereus*, *Melocactus* and *Stephanocereus* is here presented. These genera belong to tribe Cereeae and occur in the "campos rupestres", "caatingas" and cerrados (Brazilian savannah) of the Espinhaço range in the Northeastern region of Brazil, which represents the tribe centre of diversity. The anatomy of the dermal, fundamental and vascular tissue systems were studied in the genera, aiming to discover potential phylogenetic characters in an anatomically poorly studied group. The stems were transversal and longitudinally sectioned. Potential phylogenetic characters regard presence of crystals in the epidermis and hypodermis; shape of the lignified cork cells; type of hypodermis; occurrence of mucilage cells and sclereids in the cortex; lignification of the vascular cylinder; fibrous and non fibrous wood; presence of non lignified parenchyma; type of axial parenchyma; and presence of vascular tracheids in the secondary xylem.

P0418. A Survey of Root and Shoot Adaptations of Aquatic and Amphibious Angiosperms

W. B. Eyres[1], J. Seago[1], K. Mohamed[1], D. Fernando[2];
[1]SUNY Oswego, Oswego, NY, United States, [2]SUNY ESF, Syracuse, NY, United States.

Roots and shoots of a wide spectrum of species of aquatic and amphibious wetland flowering plants were surveyed to determine the range of structural adaptations to aquatic and wetland conditions. The majority of the wetland adaptations usually included the presence of aerenchymatous tissues, an endodermis and a secondarily lignified hypodermis, which also included an exodermis. These modifications are possible factors in internal ventilation, the exclusion of soil toxins from the roots and rhizomes, and structural support for either emergent or floating plants. We include representative members from orders such as the Nymphaeales, Acorales, Alismatales, Poales, Asparagales, Commelinales, Zingiberales, Caryophyllales, Lamiales, Ranunculales, Myrtales, Proteales, and Asterales to illustrate these adaptations, which included cell types and arrangements in the cortex, methods of producing aerenchyma, and the barrier layers.

P0419. Stomatal Architecture And Evolution in Basal Angiosperms

K. J. Carpenter;
University of California, Davis, Davis, CA, United States.

Stomatal architecture_the number, form, and arrangement of specialized epidermal cells associated with stomatal guard cells_of 46 species of basal angiosperms representing all ANITA grade families and Chloranthaceae was investigated. A sample of 100 stomata from each specimen was coded for stomatal type and five other characters contributing to stomatal architecture. New stomatal types are defined, and many species are examined and illustrated for the first time. Character evolution examined in light of the ANITA hypothesis and evidence from the literature on fossil angiosperms and other seed plant lineages suggest that the ancestral condition of angiosperms can be described as anomo-stephanocytic, a system in which complexes lacking subdidiaries intergrade with those having weakly differentiated subsidiaries forming a rosette. Tangential divisions of these cells led to the profusion of different types in early fossil angiosperms and Amborellaceae, Austrobaileyales, and Chloranthaceae, while the state in Nymphaeales is little modified. Formation of new, derived types by tangential division appears to be a recurrent theme in seed plant evolution.

P0420. Rhizophore in Angiosperms

N. L. Menezes;
Universidade de São Paulo, São Paulo, Brazil.

Roots, stem and leaves are present in all vascular plants: pteridophytes, gymnosperms and angiosperms. Rhizophore are shoots that grow downwards with roots in the apex and that occur in living *Selaginella* and Carboniferous *Lepidodendrales*. More recently, rhizophores were also observed in angiosperms. This organ is a stem with positive geotropism and is the sole organ that gives rise to roots in the plant. It can be composed of nodes, internodes, and cataphylls protecting lateral buds (*Vernonia* L., *Cordyline* Comm., *Smilax* L. and *Curcuma* L.) or it can lack nodes and only present adventitious buds (*Rhizophora mangle* L. and *Dioscorea* L.). The rhizophores grow by apex expansion, without terminal buds. In *R. mangle*, there is a periderm similar to a root cap in the apex. In all species mentioned above, the rhizophore has exogenous origin, wide pith, polyarch stele, vascular tissues making up collateral bundles, endarch protoxylem and branching sympodially.

P0421. Architecture of blackberry (Rubus hirtus Waldst. & Kit. agg.) and the structure of chosen populations of this species.

A. Gazda;
Agricultural University of Cracow, Cracow, Poland.

In forest there are periodic changes in resource availability. The blackberry, a common forest understory species, proved to be very sensitive to changes in environmental conditions. It can occur as a very common species forming a dense shrub layer or can survive for several years under deep shade, though often as stunted individuals The expansion of blackberry in the first year after a gap creation is mainly by increase in cane length, and in the next years by the increase in density of population. Changes in cane length and changes in population density are very tightly interrelated. The most important factor of blackberry population dynamic is the probability of creating a long primocane (longer than 50 cm) by an individual. Most (usually more than 70%) of long primocanes are able to multiply by tip-rooting. This probability is modified by environmental conditions. This process seems to be a reaction to the regeneration cycle of natural forest.

P0422. Effects of the structural importance of roots of tropical trees on their conductive physiology.

K. K. Christensen - Dalsgaard[1,2], M. Fournier[3], P. Imbert[3], R. Ennos[1];
[1]University of Manchester, School of Biological Sciences, Manchester, United Kingdom, [2]University of Aarhus, Aarhus, Denmark, [3]UMR EcoFoG – CIRAD CNRS ENGREF INRA, Kourou, French Guiana.

Previous studies have shown that roots have a high area specific conductivity compared to e.g. the stem. Tropical trees can develop an efficient conductive system with fewer large vessels and thus thin roots. Since these will have little mechanical strength, however, one might expect mechanically important areas of the root system to produce relatively more fibres or more and smaller vessels, and so have a lower area specific conductivity.
We measured the conductivity and studied the anatomy of different types of roots from four species of tropical trees, two with and two without buttresses. In buttressed trees the distal, superficial roots had a significantly higher area specific conductivity that the structurally important sinker and buttress roots. This was reflected in differences in vessel frequency as well as size. The superficial roots of non-buttressed trees, which also have a mechanical role, had a low conductivity. These and structural roots had a lower area specific conductivity than the stem. Hence the relative conductive physiology of different sections of the tree is more complex than previously thought and may depend on their mechanical functions.

P0423. Patchy nitrate availability alone contributes to heterogeneity in structure and functions in plants with contrasting vascular architecture

V. Gloser[1], C. M. Orians[2];
[1]Masaryk University, Department of Plant Physiology, Brno, Czech Republic, [2]Tufts University, Department of Biology, Medford, MA, United States.

Previous research has shown that patchy nutrient availability will generate aboveground heterogeneity in plant growth and chemistry, especially in plants where the movement of solutes from root to shoot is restricted by their vasculature. However, it is unclear whether nitrate itself generates this response when interactions with other nutrients are minimized. Using two broadleaf tree species, *Acer rubrum* and *Betula papyrifera*, grown in split-root hydroponics chambers, we examined the effects of patchy nitrate availability on morphological and functional traits of the plants. A comparison of plant parts with and without direct access to nitrate reveals that a higher nitrate supply can lead to larger leaf area, greater root proliferation, longer leaf lifespan and higher chlorophyll content. Data suggest that patchy nitrate availability can be responsible for heterogeneity in plant development and chemical composition, and is especially pronounced in plants with strong vascular restrictions in the movement of xylem sap.

P0424. Variation in the stomatal limitation of photosynthesis during vegetative phase change in *Metrosideros excelsa*

D. S. Kubien[1], J. Clemens[2];
[1]Massey University, Palmerston North, New Zealand, [2]Canterbury University, Christchurch, New Zealand.

Ontogenetic changes in leaf anatomy are a common feature of many higher plants, but the functional significance of this vegetative phase change is unclear. In *Metrosideros excelsa* (Myrtaceae) phase change is characterised by a progressive increase in leaf pubescence from juvenile to adult leaf forms. We measured stem hydraulic conductance and leaf gas-exchange in juvenile and adult leaves of *M. excelsa*. The stomatal limitation of photosynthesis (*l*) is 1-*A/A'*, where *A* is the rate of net photosynthesis at an ambient CO_2 of 38 Pa, and *A'* is the rate that would occur if the concentration of CO_2 in the intercellular airspace (Ci) was 38 Pa (i.e. if stomatal conductance was infinite). In juvenile (glabrous) leaves of *M. excelsa* the stomatal limitation of photosynthesis is approximately 0.5, while in the pubescent adult leaf *l* is 0.27. This change in *l* is accompanied by a decline in stomatal density and an increase in leaf specific hydraulic conductivity. We suggest that in *M. excelsa*, leaf vegetative phase change reflects an increase in the capacity of the stem and roots to supply water to the aerial parts of the plant.

P0425. Rhizophore in Angiosperms

N. Menezes;
USP, São paulo, Brazil.

Roots, stem and leaves are present, with some exception, in all vascular plants: pteridophytes, gymnosperms and angiosperms. Rhizophore are vegetative organs which grows downwards putting out roots, occurring in the genus *Selaginella* and *Carboniferous Lepidodendrales*. All the characteristics considered exceptions in roots define rhizophore as a stem system: sympodial branching of exogenous origin, wide pith, polyarch stele, endarch protoxylem and vascular tissues making up collateral bundles. In Angiosperms was observed shoots growing with positive geotropism, which can store nutritive material. These organs are formed by nodes, internodes and cataphylls protecting buds and can originate adventitious roots. Comparative analyses were made in species of *Vernonia* L., *Dioscorea* L., *Smilax* L., *Cordyline* Comm., *Curcuma* L. and *Rhizophora mangle* L. In *R. mangle* the rhizophores grow downwards and it's apex is protected by a periderm similar to the root cap.

P0426. Procambium distribution and anisotomous branching in *Selaginella*

E. M. Gola[1], J. Jernstedt[2];
[1]Institute of Plant Biology, Wroclaw University, Wroclaw, Poland, [2]Department of Plant Sciences, University of California, Davis, CA, United States.

Factors controlling the interrelationships of phyllotaxis, stelar type, and shoot branching are especially poorly known in the lycophyte lineage. The vascular systems of *Selaginella kraussiana* and *S. martensii* consist of two parallel steles (meristeles), which are supported in an air chamber by trabeculae with Casparian strips on radial and transverse walls. This results in potential physiological isolation of each meristele. Experiments with dye microinjection into and dye diffusion throughout the vascular system show differences in supply to microphylls lying in lateral parts of the shoot, and to alternating individual anisotomous branches. The regular pattern of procambium distribution during dichotomous branching and the discrete nature of the two meristeles may be associated with sectorial transmision of morphogenetic signals. Anisotropy of morphogen distribution is a hypothetical mechanism to control anisotomous branching in *Selaginella*.

P0427. Dependence between the degree of changes in normal development of stem conducting tissues and assimilative leaf area of silver birch (*Betula pendula*)

N. N. Nikolaeva, L. L. Novitskaya;
Forest Research Institute of the Karelian Research Center of Russian Academy of Sciences, Petrozavodsk, Russian Federation.

Investigations into silver birch forms with normal wood (common birch) and abnormal wood (patterned and wavy birches) have lead us to a conclusion that structural abnormalities of conducting tissues in woody plants can be induced by high sucrose concentrations.

Sucrose is supplied to the trunk from green leaves. We investigated the foliage structural and functional characteristics in common, patterned and wavy birch trees.

The dynamics of shoot and leaf surface area growth, total leaf area of different shoot types, leaf dry mass per unit leaf area, foliage weight and leaf surface area per unit trunk weight have been studied. The common birch and patterned birch differed notably in most of the parameters considered, and wavy birch occupied an intermediate position. The data suggest that the foliage of patterned birch obviously produces more sucrose, which influx to trunk is the cause of abnormal development of conducting tissues.

Experimental stimulation of the leaf surface area development in young common birch plants caused tissue abnormalities typical of patterned plants.

The grant of RFBR N02-04-49866.

P0428. The plant cuticle - a role for mechanical stability?

H. Bargel, C. Neinhuis;
Institut fÃ¼r Botanik, TU Dresden, Dresden, Germany.

The cuticle is a natural composite built of the biopolyester cutin, lipids, and variable amounts of cell wall fibres. Phenolics and a second polymer named cutan are frequently abundant. The main function is limitation of water loss, while it acts as a multifunctional protective interface between plants and the environment. Evidence is high that it also adds mechanical support for tissue integrity and organ stability. In tomato fruit, the cuticle becomes increasingly important as a structural component during fruit maturation in addition to the epidermis. In an analogous way, the cuticle of leaves and primary stems of several species of different life forms and from varying habitats were mechanically characterized. Depending on the species, the results indicate that the cuticle seems to inherit a considerable role as a mechanically stabilising component in the plant's 'blueprint' in addition to the epidermal cell wall and sclerenchymatic fibres that has been largely neglected to date.

P0429. Biomorphological adaptations of the amphibious plants in Apiaceae family

S. E. Petrova, R. P. Barykina;
Moscow State University, Moscow, Russian Federation.

Life forms and structural adaptations of 5 amphibious plants from Apiaceae have been studied. 5 life forms have been identified: perennial polycarpics with adventive roots only, same with rhizomes, stolons, pseudoannual and winter annual plants. Various life forms are typical of Oenanthe aquatica, which could be winter annual, pseudoannual or perennial plant. The ability to produce water and terrestrial ecoforms is a distinctive feature of O.aquatica, Sium latifolium, Cicuta virosa. Plasticity of plant`s structure, depending on the extent of submergence in the water, is typical of O.aquatica, S.latifolium and is manifested in heterophylly, forming short or long internodes, orthotropic or plagiotropic axes, in morpho-functional differentiation of adventive roots. Numerous stolons of Berula erecta serve for fast vegetative reproduction. Anatomical specialization, such as forming aerenchyma and reduction of mechanical tissues in the submerged organs of plants, emergence of the storage organs, such as rhizomes of C.virosa and adventive roots of S. sisaroideum, high content of toxins are also the distinctive features of studied amphibious Apiaceae.

P0430. Applying mutant analysis to the interpretation of the fossil record: A new perspective on leaf evolution

H. L. Sanders, G. W. Rothwell, S. Wyatt;
Ohio University, Athens, OH, United States.

From the fossil record we can see a transformational series in leaf form which illuminates critical steps that may have evolved in parallel in leptosporangiate ferns and seed plants. Both clades appear to have leaves that are derived from axes of the most ancient vascular plants. Studies of leaf development in model species, such as *Arabidopsis*, have identified a network of regulatory pathways. Large scale changes in leaf morphology can be effected by modifications in a relatively small number of developmental genes. Therefore, these same genes could provide clues to the evolution of leaves from axes. Alterations in the development of mutants with abnormal leaves can be correlated with steps in the transformational series of leaf evolution revealed by the fossil record. In this study, building on previous work, the hypothesis tested is that the same developmental mechanisms were recruited and modified independently in each clade. Taxa with characters that reflect steps in leaf evolution are being studied to identify the pattern of evolution for leaves of each clade.

P0431. Using L-systems and Markovian models to simulate multi-scale phenotypic differences between apple tree cultivars

M. Renton[1], C. Godin[2], Y. Guédon[2], **E. Costes**[1];
[1]UMR BEPC, Montpellier, France, [2]UMR AMAP, Montpellier, France.

An approach for modelling and simulating the architectural development of apple trees is presented. The approach is based on using an L-systems framework to integrate local-scale Markovian models of terminal and axial bud fate at tree level. These models represent either branching patterns observed at node level along annual growth units or the succession of growth units along axes. Model parameters were estimated from architectural data collected on two different cultivars, Fuji and Braeburn. The integration of these models enabled us to simulate the development of the whole tree representing its topology at different scales. Tree simulations were used to evaluate what degree of complexity is needed in the local-scale models to capture emerging properties at the tree level, such as the number and distribution of fruits in the tree. We then investigate how this approach can be used to give insight into the way that phenotype varies between different genotypes.

P0432. A biophysical growth model for root tips. Concentration gradients of auxin and cytokinin to focus zones of expansion and gravitropism response.

A. Chavarria-Krauser[1], K. A. Nagel[1], H. Scharr[1], A. Walter[1], W. Jaeger[2], U. Schurr[1];
[1]ICG-III (Phytosphere), Research Center Juelich, Juelich, Germany, [2]Institute of Applied Mathematics, University of Heidelberg, Heidelberg, Germany.

Root growth and its response to external stimuli are mediated by hormones, auxin and cytokinin. We present a biophysical model for root growth, which relates the distribution of the two hormones to that of turgor, osmotic potential and wall extensibiliy, assuming a one dimensional string of cells. The hormone equations were given by a combination of diffusion, production, degradation, dilution and polar transport while the growth equations were derived by combining the Lockhart- Equation and a water influx equation. The model was successfully applied to characterize the distribution of relative elemental growth rate (REGR) under changing auxin concentrations. The implications of the new model are discussed in light of the distribution of gravitropic response that was recently revealed with high spatio-temporal resolution. We observed that curvature production occurs in three zones, i.e. the meristem and the zones apical and basal to the elongation maximum. Downward curvature was mostly found basal, wheras over one third was in the meristem. Interestingly, the presence of upward curvature was detected in the apical zone.

P0433. Real mutations in simulated architecture: implications for architectural evolution

T. G. Wong;
Bryn Mawr College, Bryn Mawr, PA, United States.

Genetic mutations such as lateral suppressor and self-pruning generally have obvious effects, either on inflorescence architecture on on whole-plant architecture. I examine the architectural variation that can be generated by known architectural mutations when incorporated into a rule-based, meristem-centered architectural simulation which is similar to a biologically elaborated L-system. I compare this variation with observed architectural variation within and among tomato species. Comparisons include visual similarity as well as standard quantitative architectural descriptors: height, order profile, path-length statistics, and metamer-demographic statistics. I suggest that the large-effect genes identified in mutant screens cannot account for subtler changes during architectural evolution, and I use this project to motivate a larger project on the computational inference of branching rules.

P0434. What makes floral phyllotaxis in *Magnolia* diverse - a lesson from virtual garden.

B. M. Zagorska-Marek, S. Stoma;
Institute of Plant Biology, Wroclaw, Poland.

Exceptional diversity of floral phyllotaxis in ancient *Magnolia* plant has remained a mystery for a long time. Among many patterns, spiral and whorled, some are very unique, hard to encounter elshewere. Also they transform frequently, one type into another, along the generative axis. This indicates much greater intricacy of phyllotaxis in *Magnolia* than in any other plant, with not known explanation of this fact. Simulating process of floral parts initiation by floral apex with a computer program, being improved version of Battjes' program Phyllotaxis, we were able to produce very different phyllotactic patterns by changing primordia size at different rates. It is known that in real apices the size of primordia is changing with their identity twice: first between large tepal and small stamen primordia and then between small stamen and slightly bigger carpel primordia. Accumulation of geometric effects of these fluctuations leads to unpredictable final effect and results in diverse floral phyllotaxis. However, it is still not known why, with such seemingly random process, individual magnolia trees give a priority to some phyllotactic patterns over the others.

P0435. Roles of Determinancy and Specification of Meristem Identity in Pisum sativum Inflorescence Architecture

J. E. VanderMeer, A. P. Williamson, H. J. Mullen, S. L. Maki, S. R. Singer;
Carleton College, Northfield, MN, United States.

We are modeling genetic regulation of *Pisum sativum* architecture, focusing on meristem determinancy and meristem identity. *UNI* (*PsLFY*) and *COCH* have quite global roles in regulating determinancy, while *DET* (*PsCEN*) appears to be limited to inflorescence meristems. Axillary bud and bract suppression in inflorescences depend on *PIM* (*PsAP1*), *BRAC* and *COCH*. Floral meristem identity is regulated by *PIM, BROC,* and *VEG1*. Gene interactions provide insight into pathways regulating inflorescence architecture. Double mutants of *pim* and the most severe allele of *coch* fail to flower. Double mutants of *pim* and other *coch* alleles flower in some early flowering time backgrounds. True terminal flowers form in *det veg-1* unlike WT. Plants homozygous for *uni* have a *det* phenotype, indicating that *UNI* is needed for *DET* expression. We are using a candidate gene approach to map and clone inflorescence architecture genes with phenotypes. Relative quantification of *PsAP1*, *PsCEN*, and *PsLFY* transcript levels in isolated WT, *uni*, *det*, *veg-1*, and *coch* meristems is being used to test and modify our model for the regulation of pattern in pea inflorescences. (Supported by NSF 0422840)

P0436. Visualization of experimental data using 3-dimensional computer models of developing barley seeds

S. Gubatz[1], C. Brüß[1], V. J. Dercksen[2], V. Radchuk[1], R. Radchuk[1], W. Weschke[1], U. Wobus[1];
[1]Institute of Plant Genetics and Crop Plant Research, Gatersleben, Germany, [2]Zuse Institute Berlin, Berlin, Germany.

Three-dimensional computer models of developing barley caryopses at anthesis (1), at a stage showing syncytial (2) and cellularized endosperm (3) were constructed on the basis of series of thin cross sections. Caryopses were embedded in plastic resin and sectioned completely. High resolution digital images of all sections were taken. 3-D model building was carried out with commercially available software on a Windows® system. At first images were aligned according to their original position in the seed. In the following procedure all pixels in each of the images were assigned to the tissues they represent, e.g. the areas showing endosperm, embryo, integument. After all discernible morphological structures had been labeled in the images, the 3-D models were generated.
Sections from independent caryopses of comparable developmental stages were used for *in- situ*-hybridizations and immunohistological experiments. Experimental data were integrated into the models and spatial visualization of the expression patterns achieved.

P0437. Equivalent genetic regulatory networks in different contexts recover the spatial cellular patterns in the Arabidopsis root and leaf epidermis: a dynamial formal model

C. Espinosa-Soto[1], P. Padilla-Longoria[2], E. R. Alvarez-Buylla[1];
[1]Institute of Ecology (IE-UNAM), Mexico, D.F., Mexico, [2]Research Institute in Applied Mathematics and Systems (IIMAS-UNAM), Mexico, D.F., Mexico.

A qualitative model of the gene networks that regulate cell spatial patterning in Arabidopsis thaliana root (trichoblast vs atrichoblast) and leaf (trichome vs non-trichome) epidermis is used to explicitly test if equivalent dynamic genetic systems may yield contrasting cellular spatial patterns when subject to contrasting signalling contexts. We reduced networks derived from experimental data into Turing-like reaction-diffusion systems for leaf and root networks and modeled them under different cellular contexts assuming both fixed and growing spatial domains. In all cases tested we obtained patterns that closely resemble observed Arabidopsis root hair and leaf trichomes spatial patterns. Our results suggest that equivalent gene networks may create different spatial cellular patterns under the influence of contrasting cellular contexts in Arabidopsis epidermis, and that this may be the case in other biological systems. This study contributes to a general understanding of network structure, function and evolution interplay and pattern formation in living organisms.

P0438. Phyllotaxis - an e-learning unit for beginners and lovers

A. Bernhard, **E. Pfeifer**, R. Rutishauser;
Institute of Systematic Botany, Zurich, Switzerland.

What does the shoot apical meristem (SAM) do and how does it do it? Phyllotaxis is the mode of arrangement of leaves, scales, or bracts with flowers along the plant stem. An e-learning unit is now available on CD in English and German (ISBN 3-905677-06-7).

Beginners will understand some basics of regular pattern formation in vascular plants. Computer animations allow the user to admire virtual plants with most phyllotactic patterns observable in nature, including transformations between frequent patterns (e.g. Fibonacci systems) and rare ones (e.g. Lucas). These animations are based on graphic tools by O. Deussen et al. (see www.computerpflanzen.de). The presentation of unique and rare phyllotactic patterns (including exceptions to Hofmeister's rule) allow improved estimation of the developmental control of phyllotactic pattern formation. Students in plant systematics, biomathematics and developmental biology should not miss this elegant and simple introduction into a fascinating and puzzling topic of botany.

P0439. The photosynthetic response of heat-induced electrical signaling in poplar

S. Lautner[1], T. E. E. Grams[2], R. Matyssek[2], **J. Fromm**[1];
[1]Wood Biology, TUM, Munich, Germany, [2]Plant Ecophysiology, TUM, Munich, Germany.

Plants respond to various abiotic stimuli by generation and propagation of electrical signals. To get more information on the response of photosystem II (PSII) in higher plants, we investigated heat-induced long and short-distance signalling in poplar trees (*Populus trichocarpa*) by means of chlorophyll fluorescence imaging. In both types of signalling, PSII quantum yield of electron transport is reduced significantly. Two-dimensional imaging analysis of the fluorescence signal manifests the yield reduction which spreads via the veins through the leaves. The different types of signal propagation were shown by microelectrode measurements in leaf-vein phloem. Moreover, gas exchange measurements revealed that the depolarising signals travel distances across the stem to neighbouring leaves where the net CO_2 uptake rate is temporarily depressed towards compensation.We therefore conclude that electrical signals significantly affect the photosynthetic performance of poplar leaves.

P0440. The selfish module: the emergence of complexity in plant form and function

R. Hunt[1], R. L. Colasanti[2];
[1]Department of Biological Sciences, University of Exeter, United Kingdom, [2]School of Applied Science, University of Glamorgan, United Kingdom.

Although individual plants exhibit a wide range of complex behaviour in response to environmental stimuli, they appear to do so without any identifiable centres of organisation. One way of explaining this is to suppose that plants are modular organisms, with whole-plant organization and behaviour emerging solely from the interactions of individual modules. Behaviour at the population and community levels of organization might also emerge from this same source. To test these ideas, we created a cellular automaton model of plant growth: a two-dimensional section depicting the plant in its above- and below-ground environments. The whole plant is represented by branching structures made up from identical 'modules'. From real experiments done on these virtual plants we have reproduced a wide range of whole-plant-, population- and community-level behaviour. All of these properties emerged successfully from a ruleset acting only at the level of the individual module.

P0441. Influence of salt stress on biosynthesis and emission of BVOC from grey poplar (*Populus x canescens*)

M. Teuber[1], J. Kreuzwieser[2], J. Schnitzler[1];
[1]Institut für Meteorologie und Klimaforschung (IMK-IFU), Garmisch-Partenkirchen, Germany, [2]Institut für Forstbotanik und Baumphysiologie, Professur für Baumphysiologie, Freiburg i.B., Germany.

Many plants produce isoprene via the plastidic isoprenoid pathway in large quantities. Light and temperature are known as the most important factors triggering isoprene emission at short and long term scales, while about the influence of other environmental factors less information is present. The actual study on poplar therefore aimed to elucidate if salt stress, an environmental stress factor with globally increasing importance, influences isoprene biosynthesis as well as the emission of other volatile organic compounds as acetaldehyde.

The presentation summarizes our actual knowledge on gene expression and biochemistry of isoprenoid genes, as well as photosynthetic gas exchange and VOC emission rates. The observation that biosynthesis and emission of isoprene and oxygenated VOC were abided under salt stress even when photosynthesis was significantly lowered and leaves started to become damaged gave raise to further questions concerning the physiological function of this behaviour.

P0442. Shade-avoidance response in tomato, *Lycopersicum esculentum* Mill.

I. G. Tarakanov, A. I. Dovganiuk;
Department of Plant Physiology, Timiryazev Agricultural Academy, Moscow, Russian Federation.

Plants have evolved a number of photosensory systems that allow them to sense neighbors and compete for light or to decrease negative consequences of poor light under the canopy. The signal role of light in the adaptive response triggering was studied in tomato genotypes representing various morphological biotypes and various coenotic strategies. An early neighbor-sensing resulted in the predicted shade-avoidance response due to the unique mechanisms based on the "outstripping reality reflection" (pre-adaptation). There was a significant coenotic effect in the indeterminate growth forms as compared to determinate and dwarf ones. Two-phase response mode in the ontogenetic changes of the successive leaf blade area and specific leaf area was observed. Accelerated early growth was followed by the reduction of dry matter accumulation due to the lack of substrate light for photosynthesis. Later, transition to flowering and changes in the source-sink relations stimulated plant photosynthetic activity again.

P0443. Ethylene is involved in vascular cavity formation in pea (Pisum sativum) primary roots.

T. Niki[1], D. K. Gladish[2];
[1]Takushoku University, Hachioji, Japan, [2]Miami University, Hamilton, OH, United States.

A large cavity usually forms in the vascular cylinders of pea primary roots in response to sudden flooding at 25 C. This is thought to be a form of aerenchyma. Ethylene has been shown to mediate inducible aerenchyma in maize, therefore the role of ethylene in the formation of cavities in pea roots was examined. Pea seeds were germinated and grown in suitable containers for 4 d at 25 C in the dark in slightly moist vermiculite. Containers were then exposed to various concentrations of ethylene for 1 d or were flooded and endogenous ethylene measured periodically by GC. Also pea seedlings grown for 4 d in 2 l beakers in slightly moist vermiculite were flooded with solutions containing ethylene inhibitors or EGTA. Free-hand sections of the roots were taken. Ethylene caused cavities to form in a dose-dependent manner. Flooding increased ethylene amounts in the air space above the medium surface. Inhibitors of ethylene and EGTA suppressed cavity formation in flooded roots.

P0444. Winter-deciduous woody plants living under Mediterranean climate: phenology and internal nutrient cycling in *Amelanchier ovalis* Medicus

R. Milla[1], S. Palacio-Blasco[1], P. Castro-Díez[2], M. Maestro-Martínez[1], G. Montserrat-Martí[1];
[1]Instituto Pirenaico de Ecologia. CSIC., Zaragoza, Spain,
[2]Departamento de Ecología. Universidad de Alcalá, Alcalá de Henares, Spain.

The goals of this work were 1) to investigate whether *Amelanchier ovalis*, a winter-deciduous shrub of Mediterranean and sub-Mediterranean regions, has nutritional and phenological traits in common with temperate-deciduous phanaerophytes; and 2) to determine the constraints of the Mediterranean environmental conditions on these traits. Phenology and leaf NPK in the crown were monitored monthly over two years. Leaf survivorship and nutrient resorption from senescing leaves were used to infer retention times of nutrients. Bud-burst occurred earlier than it does in temperate-deciduous phanaerophytes. Most of the vegetative and reproductive growth was carried out in spring, although some phenological development occurred during the summer drought, chiefly fruit growth. Leaf shedding was very gradual, which might be due to water shortages in summer. Nutrient retention times were short compared to temperate-deciduous plants and co-occurring Mediterranean evergreens. *A. ovalis* showed phenological development appropriate for Mediterranean climates, although its limited ability to retain nutrients likely restricts the types of sites it can occupy.

P0445. Systematics and Pollination Biology of *Ophrys* (Orchidaceae)

D. S. Devey[1,2], R. M. Bateman[1], M. F. Fay[3];
[1]Natural History Museum, London, United Kingdom, [2]University of Reading, Reading, United Kingdom, [3]Royal Botanic Gardens Kew, London, United Kingdom.

Ophrys, a charismatic terrestrial insect-mimicking orchid genus with a mainly Mediterranean distribution, has long divided systematists as to the number of truly biological species. Use of standard morphometric techniques alone has been insufficient to distinguish the 215 currently named species. Here we utilise amplified fragment length polymorphism (AFLP) markers in conjunction with classical morphometrics and ordination analyses to further elucidate evolutionary relationships. A total of 75 putative species representing 23 of the 26 *Ophrys* groups recognised by Delforge, were collected throughout Europe and phylogenetic reconstructions based on UPGMA and Neighbor-Joining techniques were obtained. The preliminary results allow us to confirm the polyphyletic status of Section *Ophrys* and the monophyly of Section *Pseudophrys* (*sensu* Bateman). Additionally, we can establish that section *Ophrys* is not derived from section *Pseudophrys* (*sensu* Delforge), and we discuss convergent evolution of pollinator driven floral morphologies within Delforge's *O. fuciflora* s.l. and O. *bornmuelleri* groups.

P0446. Do pollinators really act as isolating factors in the sexually deceptive orchid *Ophrys*?

P. M. Schlüter[1,2], P. M. Ruas[1,3], C. F. Ruas[1,3], G. Kohl[1], T. F. Stuessy[1], H. F. Paulus[2];
[1]Institute of Botany, Vienna, Austria, [2]Institute of Zoology, Vienna, Austria, [3]Departamento de Biologia Geral, Londrina, Brazil.

The Mediterranean genus *Ophrys* (Orchidaceae) is pollinated by sexual deception. High pollination specificity by male insects is attained by mimicry of the pollinator female's sex pheromone. This potentially enables pollinators to serve as isolating factors and therefore variation in odour bouquets may cause a pollinator shift which may in turn lead to sympatric speciation. The island of Crete is remarkable for its diversity of *Ophrys fusca*-like taxa that are pollinated by different species of *Andrena* (Hymenoptera: Andrenidae) and several orchid taxa have been described based upon different pollinator specificities. Thus, we have used molecular markers to infer the phylogenetic history of east Mediterranean *O. fusca s.l.* taxa so as to test the hypothesis that pollinator specificity may serve to delimit evolutionary units. Genetic data, with an emphasis on AFLP fingerprint data, will be presented and their implications discussed.

P0447. Observations on Pollination Ecology of Seasonal Ornamental Plants

J. A. Tidke, R. O. Dharamkar;
Department of Botany, Amravati, India.

This paper discusses the pollen production, pollen viability, visitors census and behavior of insect visitors in *Papaver rhoeas* Linn., *Antirrhinum majus* Linn. and *Salvia farinacea* Benth. The observations on different aspects involved in the studies of pollination ecology were undertaken during 2001 to 2004. The insect visitors were observed for their activity and behavior during the visits. Flowering poppies attract large number of insect visitors especially honeybees for collection of the pollen grains. In *A.majus* and *S.farinacea* also bees visit the flowers to collect the pollen grains and the butterflies for nectar. The insect visitors of these plants were bees ; mostly *A. florea*, *A. dorsata* and *A. cerana indica*. Butterflies *Catopsilia pyranthe*, *Eurema hecabe*, *Danaus chrysippus, Danaus lymneus* visit the flowers frequently. The average pollen production per flower was found to be in the range of 535440±1087800 in *P.rhoeas*, 100800± 253680 in *A.majus* and 6160±14280 in *S.farinacea*. The viability percentage was found to be in the range of 91.09 -94.17% in *P.rhoeas*, 98.29 -99.83% in *A.majus* and 94.09 - 96.96% in *S.farinacea*.

P0448. Pollination system and seed propagation of rare species and natural hybrids *Cypripedium* L. (Orchidaceae).

E. V. Andronova;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

The experiences for artificial pollination and hybridization and the studying of seed and seedlings developmental biology in introduced plants (*C.macranthon* Sw., *C. calceolus* L., *C. shanxiense* S.F. Chen and natural hybrids) were carrying out during ten years. Seed production in case of artificial self-pollination reduced. Pollen abnormality and a low seed set is characteristic feature of *C*.x *ventricosum*. Not numerous seedlings were unviable. Abundant seeds formed in crossing *C*.x *ventricosum* with *C.macranthon* and *C. calceolus* (back crossing). They germinated fast, seedlings develop normal, and it is similar with protocorm development in *C.macranthon* and *C. calceolus* and in interspecific hybrid (F1). A few characteristic features of reproductive structures in *C. shanxiense, C.macranthon*, and *C. calceolus* indicate that autogamy may take place in Far - Eastern population. Analysis of results for natural and artificial systems of pollination and crossing and a reason of high level of variability was carried out.

P0449. Structure of the labellum of *Ophrys bombyliflora* (Orchidaceae)

A. Francisco, L. Ascensão;
Centro de Biotecnologia Vegetal, Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal.

Ophrys orchids developed a highly specialized pollination system by sexual deceit. Flowers attract hymenoptera insect males by mimicking the females' appearance (shape, pilosity, colour pattern) and even the odour of their sexual pheromones. The morphology and anatomy of the labellum of *O. bombyliflora* are studied. The indumentum of its adaxial surface is composed by various types of epidermal cells whose distribution pattern changes according to the lip region. The basal part of the labellum is glabrous while the lateral lobes are villous. On the median region, the short-pointed unicellular trichomes of the speculum become smaller and scarcer near the lip margins. Conversely, the trichomes become longer and denser towards the distal part of the apical lip, where they acquire a moniliform shape. In this region, the labellum is thinner and bends abruptly downwards, giving rise to a reflexus appendix that is almost glabrous. The presence, on its abaxial surface, of epidermal papillae with secretory features and parenchyma cells with starch-rich plastids suggests that the appendix may be the osmophore, i.e. the site of synthesis and elimination of volatiles.

P0450. Lack of floral rewards promotes outcrossing: nectar supplementation experiments with *Disa pulchra* (Orchidaceae)

J. Jersakova[1,2], S. D. Johnson[2];
[1]University of South Bohemia, Ceske Budejovice, Czech Republic, [2]University of KwaZulu-Natal, Pietermaritzburg, South Africa.

The absence of nectar in many orchids has been hypothesized to cause pollinators to visit fewer flowers on a plant, and thus reduce self-pollination. This could increase fitness by reducing inbreeding depression and promoting pollen export. Previous investigations of this hypothesis have been conducted on bee-pollinated orchids. We studied the effects of adding sucrose solution to the spurs of the non-rewarding long-proboscid fly-pollinated orchid *Disa pulchra.* Addition of nectar significantly increased the number of flowers probed by flies (2.6 times), the time spent on a flower (4.5 times), the number of pollinia removed per inflorescence (4.8 times) and the probability of removed pollen being deposited on self-stigmas (3 times). Distances flown by pollinators on departure from experimental inflorescences (a possible measure of the likelihood of bi-parental inbreeding) were not significantly influenced by the presence of rewards. These findings provide strong empirical support for the idea that floral deception serves to minimize self-pollination and maximize pollen export.

P0450a. Pollination of *Brassia antherotes* Rchb.f. (Orchidaceae) in a Tropical Humid Forest at the Research Center La Montaña del Ocaso (Quindio-Colombia)

N. H. Ospina, M. Diazgranados;
Herbarium Pontificia Universidad Javeriana, Bogotá, Colombia.

We studied the reproductive phenology of Brassia antherotes in a tropical humid forest in the Colombian Central Andes. For the genus Brassia botanist have reported pollination by deceit, although contradictory evidences exist. The population analyzed is about 60 adult plants with a vertical distribution between 0.5 and 30m. The anthesis happens at 4:30h, and between 11-16h the flowers have a strong fragrance. Each flower stays opened along 7 days and the inflorescence along 15 days. All the population blossoms synchronically during 6 weeks with a peak of flowering between the 4th and 5th week, with 70% and 58.6% opened flowers, respectively. We found highly significant differences between the number of opened flowers (OF) and numbers of lost anthers (LA) and closed stigmas (CS) during the 4th week (OF 285, LA 167, CS 14, Ŭ 0.05, P 0.0001). In contrast, at the 5th week there were minor significant differences (OF 346, LA 344, CS 88, Ŭ 0.05, P 0.0171). This displacement of the phenophases coincides with other studies about deceit and mimicry syndromes. Finally, we found at the end of flowering 80 closed stigmas that formed 18 fruits, and after 3 months they began dehiscence.

P0451. Anodic Asymmetry of the Secondary Leaves of *Croton variegatus* 'Banana'

R. W. Korn;
Bellarmine, Louisville, KY, United States.

Secondary leaves of *Croton variegatus* 'Banana' form off primary leaf blades and have no petiole. All 260 secondary leaves were on the anodic side of the primary leaf blade whether the genetic spiral was clockwise (39) or counterclockwise (42). In all 12 cases of secondary branches changing genetic spiral direction the secondary leaves also changed direction to remain anodic. Three other cases were also examined. The larger of two axillary buds in *Acalypha virginica* (three-seeded mercury) in all of 119 leaves examined were anodic regardless of the direction of the genetic spiral. Also, the midrib in all 160 leaves of *Syngonoium podophyllum* examined were curved in the anodic direction as were the coiling in 32 of 35 embryonic leaves. The data suggests that any phyllotactic model has to include a physical connection between leaves and this connection has to have an asymmetric component. It seems only the primary vein model of Esau and Sterling has this feature.

P0452. Developmental stability in leaves of *Plantago major* L. (Plantaginaceae)

M. V. Velickovic, S. V. Perisic;
Institute for Biological Research Sinisa Stankovic, Belgrade, Serbia and Montenegro.

During June of 2004, leaves of common plantain *(Plantago major* L., Plantaginacea), were sampled from a polluted site (Karaburma) and from a reference area (Zemun/Gornji Grad). Developmental stability of leaf traits (leaf width and vein distances within a leaf) is estimated using four indices of fluctuating asymmetry (FA$_{4,}$ FA$_{5,}$ FA$_{10}$ and ů$_{i}^{2}$) and by directional asymmetry (DA). Plants from the polluted site had sharply increased levels of FAs compared with plants from the control area. Comparison of the ů$_{i}^{2}$ values between the two sites show that plants from the polluted area had significantly higher level of FA, for vein distances within a leaf, compared to those from the reference site ($F=6.167$, $p<0.01$). Results on directional asymmetry show significantly higher value of directional asymmetry for vein distances within a leaf in polluted area than in the reference one ($F=49.014$, $p<0.01$). Obtained data from fluctuation asymmetry analysis are in accordance with the directional asymmetry estimates. Reporting higher values of DA on the environmentally stressed site, our study corroborates the potential of DA as an indicator of developmental instability.

P0453. Apple genes that control the switch from vegetative to reproductive phase

N. Kotoda, H. Iwanami, S. Takahashi, K. Abe;
National Institute of Fruit Tree Science, Morioka, Japan.

Studies on the mechanism of flower bud formation in the crops are very important because the process of flower bud formation is linked directly to the production and the quality of the crops. In tree fruits, the mechanism of flowering has remained to be cleared. Thus, we have studied the apple (*Malus* x *domestica*) genes putatively involved in the regulation of the switch from vegetative to reproductive phase to clear the function of the genes and to apply them to the reduction of the juvenile phase in fruit trees such as apple. Expression and function analysis of *MdAP1* (*APETALA1* ortholog) and *MdTFL1* (*TERMINAL FLOWER1* ortholog) demonstrated that *MdAP1* accelerates the flowering and that *MdTFL1* represses the flowering in transgenic Arabidopsis ectopically expressing *MdAP1* or *MdTFL1*. *MdAP1* starts to be expressed 2-3 month after flower bud differentiation in apple, suggesting that it is not involved directly in flower induction. On the other hand, *MdTFL1* is expressed transiently before and after flower bud differentiation in the SAM. Recent transgenic works in apple suggest that *MdTFL1* functions as one of the regulators of the switch from vegetative to reproductive phase.

P0454. Functional Characterization of Pollen Specific Gene *zm401* from *Zea mays*

J. J. Yu, C. X. Li, X. Y. Dai, J. X. Ma, Q. Zhao, G. M. Ao;
State Key Laboratory for Agrobiotechnology College of Biological Sciences, Beijing, China.

By differential screening of pollen cDNA library of *Zea mays*, we obtained nine clones. The full length of one of these clones, designed *zm401*, was obtained by 5' RACE. Molecular analysis showed that *zm401* is specifically expressed in pollens. This suggests that *zm401* likely functions in pollen growth and/or development. *zm401* was ectopically expressed in tobacco and overexpressed in maize under the control of a pollen specific promoter *zm13*. Interestingly, all transgenic tobacco and maize plants showed various levels of sterility, ranging from abortive flower development to male sterility. Further analyses on anther development indicated multiple abnormalities of anther development at late stages. These abnormalities include lagged degradation of the tapetum and connective tissue, failed deposition of fibrous bands in endothecial cells, and aborted pollen grain development. These strongly suggest that *zm401* has essential roles in anther development and its ability to perturb the anther development in heterogeneous dicotyledonous tobacco and maize indicates that *zm401* functions in a molecular mechanism possibly conserved in both monocots and dicots.

P0455. Determination of the division site in brown algal cells

D. Karyophyllis, B. D. Galatis, C. I. Katsaros;
Faculty of Biology, Athens, Greece.

Different and sometimes contradictory mechanisms have been described for brown algal cytokinesis. Although brown algal cells lack cortical microtubules (MTs) and thus preprophase MT band as well as phragmoplast or phycoplast, both cytoskeletal elements, i.e. MTs and actin filaments (AFs) participate in the formation and fixation of the cytokinetic diaphragm. Treatment with anti-MT or anti-actin drugs inhibits cytokinesis. In the present work dividing cells of *Sphacelaria rigidula* were monitored during recovery after treatment with nocodazole and cytochalasin B that impair MT dynamics and cause AF fragmentation respectively. In both cases a ring of wall material displaying numerous plasmodesmata was formed in the expected cytokinetic plane, even in cases the daughter nuclei do not occupy the correct positions as well as in cases in which the forming cytokinetic diaphragm was displaced by large vacuoles. These data suggest that the division site in brown algal cells is determined before cytokinesis or that in this site some mechanism(s) function, favouring wall deposition in the absence of both MTs and AFs.

P0456. Novel mutants for the study of hydrotropism in Arabidopsis roots

A. Kobayashi, A. Takahashi, Y. Kakimoto, Y. Miyazawa, N. Fujii, A. Higashitani, **H. Takahashi**;
Graduate School of Life Sciences, Tohoku University, Aoba-ku, Sendai, Japan.

We found that Arabidopsis roots easily displayed hydrotropism in response to moisture gradient. Using this system, we isolated Arabidopsis mutants of which root hydrotropism was impaired or altered, and named *root hydrotropism* (*rhy*). Roots of *rhy1* and *rhy4* did not show hydrotropism but normally exhibited gravitropism, phototropism and waving response. Roots of *rhy2*, *rhy3* and *rhy5* showed reduced hydrotropism together with altered response in gravitropism, phototropism and/or waving response. Elongation growth of *rhy* mutant roots, except for *rhy3*, was similar to that of the wild type. However, roots of *rhy4* and *rhy5* showed a reduced elongation growth when waving response and hydrotropic response were, respectively, induced. Thus, we obtained unique hydrotropism mutants of Arabidopsis, which will enable us to dissect molecular mechanisms for hydrotropism and its interaction with other growth movement in roots.

P0457. The theory of critical periods in flowering plants ontogenesis.

T. B. Batygina;
Komarov Botanical Institute, St.-Petersburg, Russian Federation.

The theory of critical periods in plant ontogenesis has been elaborated from studies of integral morphogenetic processes on different organization levels. Periodization of verious reproductive structures development has been worked out from data on morphogenesis using systemic & complex approaches. Critical phases, stages & periods have been revealed, e.g. the stage of embryo autonomy in angiosperms by means of culture in vitro. The concepts of "critical period" & "critical mass" in relation to embryonal structure periodization are discussed. Also adressed are the question of allometry & the significance of morphogenetic fields & rhythms of cell division for revealing critical periods and the management of ontogenesis. In development of anthers and ovules has discovered 3 common critical periods: premeiotic, meiotic & postmeiotic. Embryo development in angiosperms is characterized by 2 phases (proembryonal & embryonal) and 5 critical periods (zygote, proembryo, globular, heart- & torpedo-shaped, mature embryo). Switching of the developmental program at certain critical periods is caused probably by the functioning of stem cells in various organs.

P0458. Effect of Electrogenic Flower Induction on Expression of *FLORICAULA/LEAFY* Orthologue in *Chenopodium rubrum* L.

J. T. Albrechtova[1], E. Lopacinska[1,2], J. Veit[1], L. Lehner[1], H. Storchova[3], E. Wagner[1];
[1]University of Freiburg, Institute of Biology II, Freiburg, Germany, [2]Forest Research Agency, Freiburg, Germany, [3]Institute of Experimental Botany, Praha, Czech Republic.

Signal transduction during photoperiodic flower induction includes a network of both molecular and physiological changes. The transcription factor *LEAFY (LFY)* of *Arabidopsis* is homologue to *FLORICAULA (FLO)* of *Antirrhinum* and is assumed to be involved in flower initiation. We have identified the *FLO/LFY* orthologue in *C. rubrum* (*CrFL*). The expression pattern of *CrFL* at the shoot apex is modulated by photoperiodic flower induction. We succeeded to substitute the inductive photoperiod by a specific pulse-pattern of applied electric current. In order to analyse the role of putative electric signals in the signalling network, we followed expression of *CrFL* under electrogenic flower induction using real time PCR. We could show that the expression pattern of *CrFL* changes under electrogenic flower induction. Therefore, electric signals seam to lead to flowering over similar signalling pathways as the flower inducing photoperiod. We assume that electric signals might indeed play a role in signal transduction in flower initiation.

P0459. Concept of plant stem cells (smbryological view)

T. B. Batygina, I. V. Rudsky;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

Analysis of data on embryology of flowering plants and stem cells (Barlow 1978, 1997) allowed firstly manifest that the formation stem cells occurs in all organs (flower, stem, leaf, root), at all stages of life cycle (sporophyte, gametophyte). Their functioning first of all depends on their localization & destination. Zygote is a unique stem cell - "grandparent" of not only apical root & shoot meristem, but also stem cells of other orders (hypophyseal & epiphyseal in sexual embryo, cambium, "dormant" meristem in leaves, apical part of primordia of ovule & anther & also the initial cells of somatic embryos of different origin). The main features of plant stem cells are given: 1) toti- or pluripotency (ability to form tissues, organs & new individual); 2) relative dormancy; 3) two types of division: symmetrical divisions cause self-maintaining pool of stem cells, asymmetrical - formation "nishes" & initial cells of different tissues; 4) the pulsating & multistage character of formation & the capacity to switching over the developmental program. The differences of plant stem cells & their functioning in the system of "reserves & refusals" are discussed.

P0460. Jasmonic acid and wounding promotes apospory in fern leaf culture

J. Ambro iļ -Dolin ek[1], M. Camloh[2], J. el[2];
[1]University of Maribor, Faculty of Education, Departmen of Biology, Maribor, Slovenia, [2]National Institute of Biology, Department of Plant Physiology and Biotechnology, Ljubljana, Slovenia.

The effect of jasmonic acid (JA) and wounding on apospory - development of gametophytes from sporophytic tissue without meiosis - in leaf culture of the fern *Platycerium bifurcatum* (Cav.) C. Chr. was investigated.
Wounded and intact leaves were placed flat with the abaxial side on MS growth media with different concentrations of JA (0; 0.1; 1; 10; 100 µM) and 0.01 % sucrose. JA promoted development of aposporous gametophytes in wounded leaves and had no effect on the intact leaves. On the medium with 0.1-10 µM JA the number of aposporous gametophytes was higher compared to the medium without JA. There was no influence on the number of leaves with apospory. Aposporous gametophytes developed on both sides of the leaves. Beside gametophytes, rhizoids and adventitious shoots also developed. Our findings suggest that JA in combination with wounding may be involved in apospory development.

P0461. Expression and localization of *Arabidopsis* synaptotagmins

B. Voigt[1], M. Craxton[2], P. J. Hussey[3], D. Menzel[1], F. Baluska[1];
[1]Institute of Molecular and Cellular Biology, Bonn, Germany, [2]MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, [3]Integrative Cell Biology Laboratory, University of Durham, United Kingdom.

Synaptotagmins are known Ca^{2+} dependent triggers of exocytosis and endocytosis in animals with nervous system. Sequence analysis of various animal and plant genomes revealed the presence of synaptotagmin genes in all animals and land plants, but there is no evidence of synaptotagmin genes in unicellular organisms or those with simple forms of multicellularity. Synaptotagmins have a common structure, a N-terminal transmembrane sequence is followed by a linker and two distinct C2 domains, C2A and C2B. These two domains are known Ca^{2+} binding domains, but there is nothing more known about the function of the proteins in plants. To get more information about the 6 members of the *Arabidopsis* synaptotagmin gene family, we are investigating expression patterns by promotor-GUS fusions and cellular localizations by GFP-fusions as well as antibody labelings. Preliminary data suggest that the members of the synaptotagmin gene family are differently expressed, but show similar cellular localization.

P0462. Root - Shoot - Signaling in *Chenopodium rubrum* L. as Studied by ^{15}O Labeled Water Uptake

T. Ohya[1], Y. Hayashi[1], K. Tanoi[1], H. Rai[1], K. Suzuki[2], J. T. P. Albrechtova[3], T. M. Nakanishi[1], E. Wagner[3];
[1]The University of Tokyo, The Graduate School of Agricultural and Life Sciences, Tokyo, Japan, [2]National Institute of Radiological Sciences, Chiba, Japan, [3]University of Freiburg, Institute of Biology II, Freiburg, Germany.

It has been demonstrated with *C. rubrum* that the different organ systems are transmitting surface action potentials which might be the basis for systemic signal transduction. Shoot tip respectively root generated action potentials travel along the stem axis. Shoot tip generated action potentials arriving at the basis can be reflected and travel upwards. The radioactive labeling technique was established at the NIRS in Inage, Japan. About 2GBq of ^{15}O-labeled Hoagland's solution was supplied to the plant root or cut stem in a phytotron at 25°C with 45 % of relative humidity and continuous light. By cutting the shoot apical bud and the apices of main side branches the uptake of ^{15}O labeled water was inhibited in plants with intact roots but not in plants with roots cut. Because of the short half-life of ^{15}O (2 min), experiments could be repeated in hourly intervals. Cutting the apex probably limits root water uptake via a hydraulic-electrochemical signal. The results are discussed with respect to the significance of a continuous communication between the root system and the shoot apical meristem(s) in the adaptation of plants to their environment.

P0463. Phosphoinositides in endocytic pathways: Can the phosphate position change the endosomal targeting?

A. Hlavacka[1], B. Voigt[1], Z. Avramova[2], D. Volkmann[1], D. Menzel[1], F. Baluska[1];
[1]Institute of Cellular and Molecular Botany, University of Bonn, Bonn, Germany, [2]University of Nebraska, Lincoln, NE, United States.

Phosphoinositide-based signalling is thought to be a part of plant responses to various biotic or abiotic stresses. Upon a stress, plant cells can produce various phospholipids that play role in cell signalling by usage of protein with specific lipid-binding sites, like FYVE, PH or PX. We demonstrate that GFP-FYVE fusion protein is recruited by endosomes via interaction with PI3P being abundant in early/recycling endosomes which are highly motile and serve as a sorting stations for endocytic cargo. On the other hand, *Arabidopsis* TRITHORAX1 is a chromatin remodelling protein that binds specifically PI5P. Surprisingly, TRITHORAX1 localize besides nuclei also to the plasma membrane and to non-motile endosome-like compartments. Myotubularins phosphatases can change the position of the phosphate on the phosphoinositides to generate PI5P from PI3P. This conformational change is predicted to recruit ATX1 to the endosomal membrane via changing of its targeting. *Arabidopsis* genome encodes two myotubularin homologues allowing us to dissect the endocytic pathways based on PI3P and PI5P phosphoinositides.

P0464. Is the control of the cambial cells readjustment based on the negative feedback?

P. L. KOJS[1,2], M. Iqbal[3], W. Wǧoch[1,4], A. Wilczek[1];
[1]Botanical Garden - Centre for Biological Diversity Conservation of the Polish Academy of Sciences, 02-973 Warszawa 76, Poland, [2]Faculty of Ethnology and Education, Silesian University, 43-400 Cieszyn, Poland, [3]Jamia Hamdard, Department of Botany, New Delhi-110062, India, [4]Department of Biophysics and Cell Biology, Silesian University, 40-032 Katowice, Poland.

Intrusive growth of cambial initials has a role in readjustment of cells in the vascular cambium as it affects changes in cell orientation, cell tip inclination and mutual arrangement of fusiform initials as also the changes in shape and / or inclination of rays. Based on experimental data, it was assumed that cambial cells readjustment is strictly connected with changes in the patterns of mechanical stresses. The existing hypotheses explain the phenomenon of cambial cells readjustment as a linear relationship e.g with auxin flow. Our studies propose existence of a system, based on the negative feedback, for the control of cambial cells readjustment. This system includes relations between all cell events and the tension, compression and shear stresses, showing the plurality of environmental modifiers of the process. The proposed hypothesis considers the cambium as an early-warning, self-regulating system which enables the tree to adapt its structure to the constantly changing conditions of the internal and external environments. This regulating system relaxes the threshold stresses smoothly before they may become a threat to the plant.

P0465. The guild of hummingbird-pollinated species in an Atlantic forest remnant, northeastern Brazil

A. V. Lopes[1,2], I. C. Machado[2], M. Sazima[3];
[1]Pós-Graduação em Biologia Vegetal, Universidade Estadual de Campinas, CAPES, Campinas, Brazil, [2]Depto. Botânica, Universidade Federal de Pernambuco, CNPq, Recife, Brazil, [3]Depto. Botânica, Universidade Estadual de Campinas, CNPq, Campinas, Brazil.

Hummingbirds are the major vertebrate pollinators of Neotropical plants and pollination by these birds is found in many botanical families. Studies on pollination guilds are an efficient way to understand ecological processes in natural ecosystems. In a two-year study of the ornithophilous guild of an Atlantic forest remnant, in northeastern Brazil, 29 species from 17 families and 25 genera were recorded. Species of Bromeliaceae are predominant (27.6%). Most species of this guild are epiphytes (64.3%), and the majority showed reddish/pink flowers (55.2%) of the tube type (79.3%). Nectar sugar concentration and volume ranged from 10.2-46.8% and 2.5-97.4 µl, respectively. A high number of species (91.7%) bloomed in the rainy season. Eight hummingbird species were recorded, being the Phaethornithinae, Glaucis hirsuta and Phaethornis ruber, and the Trochilinae, Amazilia fimbriata the main pollinators. Among them, Glaucis hirsuta behaved as the dominant species. In comparison with ornithophilous guilds of other Neotropical areas, this forest remnant revealed richness of species and interactions.

P0466. Breeding System of Campanula lusitanica L.(Campanulaceae)

J. Cano, M. Arista, P. L. Ortiz, S. Talavera;
Dpto. Biología Vegetal y Ecología. Facultad de Biología, Sevilla, Spain.

Phenology, floral charasteristics, pollinator spectrum and breeding system of *Campanula lusitanica* s.s, were studied in two population from Southern Spain. Flowering extends from early May to mid-June. Flowers are protandrous and male phase lasted 2-3 days. Total floral longevity ranged from 5 to 6 days. Diptera and Himenoptera were the main visitors of *C. lusitanica* flowers, and fruit set in natural populations was very high ranging from 88.6 to 93.3 %. Results of geitononogamous pollinations showed that this species is self-incompatible and observations of pollen tube growth indicate that the incompatibility system is gametophytic.

Hand pollinations between *Campanula lusitanica* s.s with both *C. lusitanica* var. *broussonetiana* and *C. lusitanica* subsp. *specularioides* results in absence of fruiting. These preliminary results suggest the existence of hybridation barriers between the taxa included in *Campanula lusitanica* group.

P0467. The asymmetric flower of *Vigna caracalla* (Fabaceae: Papilionoideae): mechanical aspects of its pollination mechanism.

A. V. Etcheverry[1], E. E. Alanís[2], G. G. Romero[1];
[1]Universidad Nacional de Salta, Salta, Argentina, [2]Universidad Nacional de Salta,, Salta, Argentina.

The flower of *Vigna caracalla* (L.) Verdc. has a pronounced asymmetry and 5 revolutions of the keel. Instead of its complexity, it resulted functional enough, with a brush mechanism activated by pollinators capable of execute a considerable strength (*Bombus morio*, *Xylocopa eximia* and *Centris bicolor*). To reach the nectar chamber, the bees have to lower the left wing with their legs, and this effort results in the emergency of the stigma and *ca.* half turn of the stylar brush charged with pollen. A force of 0.053 ± 0.006 N is needed to trigger the flower. The distance from the centre of rotation was 14.6 ± 0.3 mm, resulting a moment of rotation of $7.3 \times 10^{-4} \pm 1.03 \times 10^{-4}$ N m. Calculating with the weight of *B. morio* (36 mg), an lever arm of 21 cm would be necessary if the insect tried to open the flower by weight only. *Apis mellifera* and some species of Lepidoptera were unable to operate the pollination mechanism of *V. caracalla*.

P0468. The feature correlations in mutant plants of Verbena canadensis Britt.

A. Shirokova, A. S. Demidov;
Main Botanical Garden, Moscow, Russian Federation.

To induce variation of decorative features for use in selection, seeds of V. canadensis were treated by diethyl sulfate. The morphologies and colours of the resulting M1-M6 flowers have been analysed. The nine flower colours ranged from pale rose to purple including lilac colour and differed in intensity, a bluish shade and the presence of a white eye. The flowers differed in sizes, shapes, the tube dimensions and the limb diameter, the features found to be correlated.

All F1 hybrids from the reciprocal crosses plants with large pale rose and small violet-purple flowers had the rosy lavender large flowers. The flowers of different colours were pollinated by different insects, the control magenta-rose flowers by butterflies, the violet and lilac-coloured ones by bumble bees (Bombus), and the pale rose and lavender hybrids by hawk moths (Sphingidae) even in the cloudy weather. The model population of the mutants showed apparent linkage of the flower colour to the other traits and to the pollinators.

P0469. Seasonality in ornithophilous flora and hummingbirds in a montane Atlantic forest of Southeastern Brazil.

M. B. Canela[1,2], M. Sazima[3], L. Freitas[2], I. Aximoff[2];
[1]Pós-Graduação em Biologia Vegetal, Universidade Estadual de Campinas, CAPES, Campinas, Brazil, [2]Programa Mata Atlântica, Jardim Botânico do Rio de Janeiro, Petrobrás, Rio de Janeiro, Brazil, [3]Depto. Botânica, Universidade Estadual de Campinas, CNPq, Campinas, Brazil.

Studies of plant-pollinator interactions in plant communities can contribute to an understanding of evolutionary and ecological questions. A community of ornithophilous plants was studied in a montane forest in the Parque Nacional do Itatiaia, with the aim to relate floral morphology and biology to the characteristics of their hummingbird pollinators. In a two-year study 30 plant species were recorded, being epiphytic/herbaceous species of Bromeliaceae, Gesneriaceae and Acanthaceae the most frequent. Effective corolla length was short (<2 cm) in 5 species, medium (2-4 cm) in 21 species and long (>4 cm) in 4 species. Flowers with medium and long corollas predominated during the dry period (winter), and short flowers predominated during the rainy period. Accompanying the seasonal variation in flower size, visits of two long-billed hummingbird species predominated during the winter, and visits from a short-billed species were frequent in the wet period. These results indicate that the seasonality of flowering in species with different flower sizes may be an adaptive response to the different availabilities of hummingbird pollinators during the year.

P0470. Rushes are different

S. G. Michalski, W. Durka;
UFZ-Environmental Research Centre Leipzig-Halle GmbH, Halle, Germany.

We analysed the breeding system of Juncus atratus by a combination of genetic, phenological and modelling approaches. Unlike other wind-pollinated taxa in the genus Juncus low pollen to ovule ratios are found which leads to the assumption of high selfing rates.

However, microsatellite analysis in Juncus atratus revealed a contrasting view. Outcrossing rates obtained from Fis contradict an autogamous breeding system.

Two possible explanations can be specified: 1) Selection for heterozygosity. 2) Increased outcrossing rate despite low P/O ratios.

Many members of the genus show a very peculiar flower phenology, best described as synchronous pulsed flowering. The flowers of a whole population simultaneously open for a few days in a more or less even rhythm.

This phenomenon may lead to a higher outcrossing rate. This can be supported by a model using empirical data and could explain in part the discrepancy between the autogamous appearance of the flowering syndrome and the genetic findings.

A genetic analysis of single seeds will provide a direct measure for the amount of outbreeding in Juncus atratus and can show the effectiveness of this special flower phenology.

P0471. Floral resource for birds in the canopy: S*pirotheca passifloroides* (Bombacaceae) and its visitors in the rainforest of Southeastern Brazil

M. A. Rocca[1], M. Sazima[2];
[1]Pós-Graduação em Biologia Vegetal, Universidade Estadual de Campinas, CAPES, Biota/FAPESP, Funcamp/Unicamp, TNC, Campinas, Brazil, [2]Depto. Botânica, Universidade Estadual de Campinas, CNPq, Campinas, Brazil.

Birds are a very important component for plant reproduction in tropical ecosystems, being hummingbirds the most important vertebrate pollinators in the neotropics. In a two-year study on floral resource availability for birds were recorded 56 species visited by hummingbirds, from these only four species were also visited by other birds. Most species are epiphytes, few are shrubs, lianas or trees; the majority occurs in the understory and flowers during the wet season. A few species occur in the canopy, such as *Spirotheca passifloroides* an up to 30m high tree, which flowers during the drier season. Individuals may open up to 180 flowers/day, which are red and tubular (40mm length x 11mm diameter). Accumulated nectar volume and concentration is on average 142µl and 6%, respectively. These big flowers were visited by 11 bird species, among hummingbirds, passerines and non-passerines. Although these bird species have different sizes and visiting behavior, most of them are pollinators of *S. passifloroides*. This Bombacaceae diverges from most species in the community and is an important canopy resource in a period of food scarcity.

P0472. Asymmetric flowers and phylogeny in *Senna* (Leguminosae, Cassiinae)

B. Marazzi[1], E. Conti[1], L. Paganucci de Queiroz[2], P. K. Endress[1];
[1]Institute of Systematic Botany, University of Zurich, Switzerland, [2]Departamento de Biología, Universidade Estadual Feira de Santana, Brazil.

Senna (Leguminosae) is a large and diverse genus with buzz-pollinated flowers and many species are characterized by asymmetrical (enantiostylous) flowers. Our maximum parsimony analyses based on the plastid regions *rps16*, *rpl16*, and *matK* (exon part) are aimed at testing the current classification of the genus and reconstructing the evolution of enantiostyly in *Senna*. Of the six existing sections, only sect. *Psilorhegma* is monophyletic. Sections *Chamaefistula*, *Peiranisia* (with prominent floral asymmetry in addition to mere enantiostyly) and *Senna* are polyphyletic. The monotypic sections *Astroites* and *Paradictyon* group with species of sections *Chamaefistula* and *Senna*, respectively. The phylogenetic analysis retrieved seven major clades. Two clades include all taxa with monosymmetric flowers. The five clades with enantiostylous flowers are each characterized by a distinctive variant of floral asymmetry, in which different floral parts are involved in addition to the gynoecium. We will show current results of our morphological and developmental studies aimed at understanding the diversity of floral asymmetries and their evolution in *Senna*.

P0473. Identification of the ABC floral gene orthologs in *Viola pubescens*

Y. Wang, S. Wyatt, H. Ballard;
Environmental and Plant Biology, Ohio University, Athens, OH, United States.

Most violets can produce both chasmogamous and cleistogamous flowers. Since the ABC model suggests A, B and C classes of genes play essential roles in the flower development, we are using PCR (polymerase chain reaction) to identify the ABC floral gene orthologs in a widespread violet, *Viola pubescen*s, in hope of better understanding the molecular mechanism underlying this floral dimorphism. Primers were designed by aligning the known “ABC” orthologs in other plant species. Genomic DNA extracted from *V. pubescens* was used as the template. PCR products were cloned and sequenced. The sequences were then subjected to the nucleotide-nucleotide BLAST (basic local alignment search tool) to verify their identities. In this way, two A class orthologs, two B class orthologs and one C class ortholog were identified. The future work is to compare the expression of these ABC orthologs along the development of the two types of flowers and to study their regulation. Our research will improve the knowledge of the development of the two types of flowers in *Viola* from the molecular point of view.

P0474. Keel anatomy of two *Mucuna* species (Leguminosae, Faboideae) helps to understand the explosive opening of their flowers

K. Agostini[1], M. d. M. Castro[2], M. Sazima[3];
[1]Pós-Graduação em Biologia Vegetal, Universidade Estadual de Campinas, Fapesp, Campinas, Brazil, [2]Dept. Botânica, Universidade Estadual de Campinas, Campinas, Brazil, [3]Dept. Botânica, Universidade Estadual de Campinas, CNPq, Campinas, Brazil.

The exhibition of the reproductive organs in *Mucuna* happens through explosive flower opening. At the tip of the keel the petals are united to some extent and stiff, features which probably act as a support to bring about flower explosion after a visit. The anatomy of the apical region of the keel of *Mucuna japira* and *M. urens* was studied to verify how these features influence flower opening. In both species the inner mesophyll shows cell wall lignification, but secondary wall thickenings occur only in *M. japira*. In the non-lignified part of the inner epidermis of both species occur entwined secretory papillae, which keep the petals firmly united. Flowers of *M. japira* are more difficult to open than those of *M. urens;* the secondary wall thickening of the former could be associated to this characteristic. These features are related to the pollination biology of the *Mucuna* species, since *M. japira* is pollinated by a large passerine bird, *Cacicus haemorrhous* (Icteridae) and *M. urens* by a small bat, *Glossophaga soricina* (Glossophaginae), which have different foraging behaviors and apply different strength due to their sizes to trigger the explosive flower opening.

P0475. Nectar drinks for all, from lizards to doves: the vertebrate pollinators of a leguminous tree on an oceanic island off Brazil

I. Sazima[1], C. Sazima[1,2], M. Sazima[3];
[1]Dept. Zoologia and Museu de História Natural, Universidade Estadual de Campinas, CNPq and Fapesp, Campinas, Brazil, [2]Dept. Zoologia, Universidade Estadual Paulista, Rio Claro, Brazil, [3]Dept. Botânica, Universidade Estadual de Campinas, CNPq, Campinas, Brazil.

Oceanic islands provide remarkable instances of relationships between vertebrates and plants. At Fernando de Noronha Archipelago, off north-eastern Brazil, we found that all four native terrestrial vertebrates rely on the flowers of a leguminous tree. The lizard *Euprepis atlanticus*, the dove *Zenaida auriculata noronha*, and two perching birds, *Elaenia ridleyana* and *Vireo gracilirostris* visit and pollinate the tree *Erythrina velutina*. The trees’ blooming period coincides with the dry season on the island, and the orange flowers are visited from dawn to sunset. The nectar is dilute (~10%) but produced all day long and copiously - an hourly secretion rate of up to 100 ml. A large tree may bear about 300 inflorescences, each with two to eight open flowers daily. As none of the visitors seem to depend energetically on nectar (the lizard eats anything edible, the dove is mostly a seed-eater, and the perching birds feed mostly on insects), we suggest that these visitors seek the flowers both for sugar and water intake. Additionally, we suggest that vertebrates’ visits to flowers on small islands worldwide may serve a dual purpose: energy acquisition and water balance.

P0476. Legume leaf patterning genes

J. M. I. Hofer, A. Smooker, F. Sainsbury, A. Tattersall, M. Ambrose, N. Ellis;
John Innes Centre, Norwich, United Kingdom.

The garden pea (*Pisum sativum*) is studied for comparative developmental genetics. In common with many other legumes, pea has architectural features that differ from other well-studied model species, including secondary inflorescences, bisymmetrical flowers and pinnate leaves. The ongoing identification of morphological mutants and their corresponding genes is beginning to reveal mechanisms that determine form in pea, particularly those that pattern the specialised compound leaf. *CRISPA* was identified recently as the orthologue of the Arabidopsis gene, *ASYMMETRICLEAVES1*. Mutant *crispa* leaves form ectopic stipules along the length of their petioles and this is associated with ectopic expression of the homeobox gene *PSKN2*. The *crispa* mutant phenotype resembles the winged petioles of some *Lathyrus* species eg. *L. annum. Pisum* and *Lathyrus* are closely related genera in the "vicioid" clade of papilionoid legumes. We are investigating shared and divergent morphological features in *Pisum* and *Lathyrus* by asking whether mutant pea phenotypes recapitulate *Lathyrus* species phenotypes and whether we can identify associated molecular markers.

P0477. Programmed Cell Death in the development of Tillandsia (Bromeliaceae) trichomes

A. Papini, L. Brighigna;
University of Florence, Firenze, Italy.

Tillands use their epidermal trichomes for absorbing water and mineral and organic nutrients from the atmosphere. The absorbing trichome in Tillandsia has a nail-like shape and is formed by an axis of 1-6 cells, connected to the internal tissues of the leave, and to an external shield (or head). This last structure is mono-layered and formed by dead cells extending their surface over the epidermis. The solutions coming from the external environment go through the shield cells and follow a way through the axis cells of the trichome to reach the underlying mesophyll parenchyma.

The first studies on trichomes of Tillandsia and observations on the ontogeny of Tillandsia trichomes are of 1904, with Light Microscopy. Also because of some methodological difficulty, ultrastructural studies in Tillandsia are relatively few and not recent.

In this contribution we discuss the ultrastructure of the ontogeny of Tillandsia trichomes, with particular attention to the last stage in which the wing cells die at maturity. The ultrastructural features of these cells in the last stage of development are similar to those observed in other cases of Programmed Cell Death in plants.

P0478. Inflorescence morphology in Balanophoraceae: moving in a twilight zone.

R. K. Eberwein;
Kärntner Botanikzentrum, Klagenfurt, Austria.

The pantropically distributed holo-and root-parasitic family Balanophoraceae has panicled, mostly spadiceous inflorescence types with a remarkable variety of different designs. Contrary to other authors, all inflorescences are initiated endogenously in subterranean globose or sometimes elongated tubers. Racemes (subfam. Mystropetaloideae, Helosidoideae and Balanophoroideae), double racemes (subfam. Dactylanthoideae and Lophophytoideae) and triple female racemes (subfam. Sarcophytoideae) can be found. In tribe Helosieae spadices are covered by a dense layer of hexagonal, umbrella like structures which could be identified as bracts (not secondary axes as discussed before), showing an up to now unknown and for leaves unusual developmental pathway of peltation. Balanophoroideae possess spadices without secondary branching (in tribe Langsdorffieae they are designed like Asteracean heads). Structures covering the spadix, formerly described as axes ("spadicelli"), turned out to be transformed bracts. But it is still unclear if these "spadicelli" originate from numerous individual bracts or few multiple splitted bracts.

P0479. Acquisition of root hemiparasitism and other life history traits in Santalales

V. Malécot[1], D. L. Nickrent[2];
[1]UMR A 462 - Institut National d'Horticulture, Angers, France,
[2]Southern Illinois University, Carbondale, IL, United States.

Based on molecular analyses, we examined the acquisition of hemiparasitism in Santalales, particularly Olacaceae s.l. Mapping of life history characters on molecular cladograms suggests a single origin for an ancestral root hemiparasite that can be assumed to be one of two ecological types. The first is an under-shrub with relatively small fruits. This type, likely occurring in a humid forest, is reminiscent of the extant genus *Ptychopetalum*. The second type is a small tree with relatively large fruits. This type likely occurred in dryer areas (e.g. margins of humid forests and savannas) and is reminiscent of the genus *Ximenia*. After the acquisition of root hemiparasitism in Olacaceae, additional trends include: the acquisition of accrescent structures around fruits, large tree habit (*Ongokea*), and hummingbird pollination (*Chaunochiton*). Other trends seen in Santalales include: five independent acquisitions of the mistletoe habit; several independent derivations of an herbaceous habit within Santalaceae; reduction in leaf size, venation and changes in phyllotaxy (Santalaceae and Loranthaceae); and pollination syndromes (Loranthaceae).

P0480. Taxonomic Revision of the genus Cunila (Lamiaceae) in North America and Central America

M. Garcia - Peña, H. Ochoterena;
Instituto de Biología. UNAM, México City, Mexico.

Cunila D. Royen ex L., an American genus belonging in tribe Mentheae, includes approximately 20 species. Geographically has a disjunct distribution, one centre of diversity extends from the eastern United States to Panama and another group of species is located in south eastern Brazil, northern Argentina and Uruguay. Cunila is distinguished from other Lamiaceae by having five-teeth calyx and two exerted stamens. The genus, has never been the object of a complete revision, there is only a synopsis of the South American species. In this treatment, 7 species are recognized for the Northern region, the nomenclature is resolved and characters with systematic value are suggested. Examples of them are: growth habits, inflorescences, pedicel and peduncle length, calyx teeth symmetry and the way the trichomes are inserted in the calyx throat, as well as the morphology of the nutlets, these are apparently more useful for classification in the genus than pollen morphology, which is similar among species. Economic (medicinal and ornamental) importance and vernacular names are included for some species when known.

P0481. Force measurements in *Salvia* flowers

S. Thimm[1], M. Reith[2], T. Speck[2], R. Claßen-Bockhoff[1];
[1]Institut für Spezielle Botanik, Universität Mainz, Germany, [2]Plant Biomechanics Group, Universität Freiburg, Germany.

Salvia flowers are characterised by the staminal lever mechanism. Insects and birds searching for nectar have to push back a barrier originating from the lower connective arms of the lever-like modified stamens. To test the hypothesis that weak insects are restricted by this barrier the forces needed to release the lever were measured by means of a special device. The forces of 25 species including bee pollinated and bird pollinated flowers do not show significant differences. Altogether they are rather low. They range from 0.10 mN ± 0.54 to 21.34 mN ± 21.88 showing high standard deviations in each species. No correlation was found with the age of the flowers, their size, the levers' proportions and the flower classes. These results indicate that there is no selection pressure on high or precise forces, that the lever movement instead has been selected to go easily and to allow a large range of insects access to nectar. It is assumed that the lever mechanism increases the precision of pollen transfer and possibly contributes to mechanical isolation among co-occurring species.

P0482. Study of anatomical structures, ontogeny and karyotipic Characteristics of Two Species of *Salvia*

A. S. Afshar, F. S. Nematpour;
azad university of broujerd, Broujerd, Islamic Republic of Iran.

Salvia, the largest genus of Lamiaceae, includes about 900 species, widespread throughout the world. In the present study, anatomical structures of meristems, ontogeny of flower organs, microsporogenesis, megasporogenesis, embryogenesis, karyotipic specificities of two species of *Salvia* genus (*S. officinalis* L. and *S. sclarea* L.) were investigated and compared. The anatomical structure and ontogenical stages were similar in the two species. The inflorescences comprise verticillasters generally possessing 4-6 flowers with the bracts exceeding 20-30 corolla which can be purple or white in color with the upper lip strongly falcate. Anatomical studies showed that protruding meristems and indefinite inflorescences were similar in these two species. Study of ontogeny of flower organs showed that sepals and petals appeared simultaneously and the stamens and the ovary appeared later. Ovules were anathropus and contained an integument, which was well developed. The embryo contained two small cotyledons and the seed contained a vast endosperm. Cytogenetic studies revealed the number of chromosomes in *S. officinalis* to be 2n=14 and in *S. sclarea* it was 2n=22.

P0483. The glandular structures of *Leonotis leonurus* during the course of flower ontogenesis

L. Ascensão, C. Francisquinho;
Centro de Biotecnologia Vegetal, Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal.

Pursuing our studies in *Leonotis leonurus,* an African Lamiaceae species, the aim of this work is to characterize the secretory structures present on the flower during its ontogeny. In *L. leonurus*, the calyx abaxial surface presents a dense indumentum of mixed peltate and capitate trichomes, mostly covered by nonglandular hairs. On the corolla, capitate trichomes are rare while peltate are clustered on the abaxial side, mainly on the median region of the corolla tube, being sparse on the adaxial surface. On the stamens and carpels, capitate trichomes are absent. Peltate trichomes are abundant on the lower side of the anther, between the two lobes, and on the top of the ovary. A four-lobed asymmetrical nectary disc is observed on the base of the ovary. The nectar, sucrose-dominant, is released by modified stomata on the inner side of the nectary's largest lobe. On the inner basal region of the corolla tube five levels of well developed finger-like projections occur. These are columnar cells of a multi-layered glandular epidermis, which produce a lipophilic secretion. The function of these different types of glandular structures is discussed in relation to pollination.

P0484. Floral morphology of Stachys L. (Labiatae) and some aspects of its pollination.

T. V. Krestovskaya;
Komarov Botanical Institute, Saint-Petersburg, Russian Federation.

The floral architecture of most Stachys species is investigated. In general, its structure is rather monotonous (indistinctly bilabiate calyx and 2-lipped corolla, with stamens directed towards the posterior lip, rarely almost hidden in the tube). Some new diagnostic characters to separate Stachys sections and subsections are revealed, such as features of calyx, corolla and placement of stamens. Also, based on the character of long protruding stamens and some other features, the new subgenus Menitskia from West Himalayas is described. The structure of flowers is analysed in the context of pollination. The calyx is of little importance for pollination. The anterior corolla lip has a coloured "nectar-guides". In general, Stachys is a melittophilous genus. American species of the section Calostachys adapted to ornithophily. They have red corolla with long straight tube. Some Southern African species with long narrow corolla tube have long-proboscid flies as pollinators.

P0485. Phylogeny and Floral Evolution in Lamiaceae

P. D. Cantino[1], Y. Yuan[2], R. G. Olmstead[2];
[1]Ohio University, Athens, OH, United States, [2]University of Washington, Seattle, WA, United States.

A phylogeny based on cpDNA sequences (ndhF and trnL-F) provides a basis to explore the patterns of floral evolution in Lamiaceae. Because sampling was designed to establish a phylogenetic framework for Lamiaceae as a whole, some large, well supported clades (e.g., Nepetoideae) are represented by only a few exemplars in the analysis. Mapping of morphological data onto the strict consensus tree reveals homoplasy in many floral characters that have traditionally been used to delimit lamiaceous taxa. For example, a gynobasic style evolved separately in Nepetoideae and Lamioideae, and a sunken style (intermediate between terminal and gynobasic) evolved independently in Prostantheroideae and Ajugoideae (probably several times in the latter). Dimidiate stamens evolved independently in Scutellaria, Anisomeles, and a subclade of Prostantheroideae. Other characters that evolved more than twice within Lamiaceae include actinomorphic corolla, persistent style, elongate anther connective, and confluence of anther locules.

P0486. Nectar production of three Lamiaceae species in relation to microclimatic conditions

M. P. Macukanovic-Jocic[1], S. Duletic-Lausevic[2], G. D. Jocic[3];
[1]Faculty of Veterinary Medicine, Belgrade, Serbia and Montenegro, [2]Institute of Botany and Botanical Garden, Belgrade, Serbia and Montenegro, [3]``Karadjordje`` Experimental School, Belgrade, Serbia and Montenegro.

The nectar production of *Lamium maculatum*, *Lamiastrum galeobdolon* and *Ajuga reptans*, grown under different microclimatic habitat conditions (forest and experimental field), was evaluated by determining the total daily nectar quantity per flower, per plant and per square unit, diurnal dynamics of nectar secretion and nectar sugar concentration.

Nectar amount and sugar concentration varied among the studied species as a function of microclimatic parameters (air temperature, air humidity and evaporation) and corolla morphology. Higher nectar production and lower sugar concentration were recorded in *L. maculatum* and *L. galeobdolon* grown in the forest, while for *A. reptans* in the same habitat, the reverse results were obtained. Total daily nectar volume per plant was the highest in *L. maculatum* (30.1 ml/pl). The highest nectar yield per square unit was found in *L. maculatum* and the lowest in *A. reptans*. Regarding nectar secretion rate, *A. reptans* is the slowest producer, secreting less than 0.02 ml/ h. With respect to secretion intensity, total daily nectar production per flower and the density of species population, the most melliferous species is *L. maculatum.*

P0487. Sharing without mixing? Quantitative analyses of pollen placement on *Apis mellifera* as a pollinator of *Salvia pratensis* and *Salvia nemorosa.*

M. Reith[1], G. Baumann[1], R. Claßen-Bockhoff[2], T. Speck[1];
[1]Botanischer Garten der Universität, Plant Biomechanics Group, sal-via@gmx.de, Universität Freiburg, Germany, [2]Institut für Spezielle Systematik und Botanischer Garten, Universität Mainz, Germany.

If sympatric *Salvia* species share the same pollinator, two scenarios are possible: (a) pollen is mixed and hybrids between the species may occur, or (b) pollen is not mixed because it is deposited on distinctly separated areas on the pollinators body. Our new data on pollen-placement of *Salvia pratensis* and *Salvia nemorosa* indicate that the pollen of these two species is mixed on the body of *Apis mellifera,* a pollinator shared by both *Salvia*-species. This finding is corroborated by the fact, that rare natural hybrids of these two species are reported by many authors. This raises the question why these two species are stable and do not merge to a single one. We list a number of mechanisms that might reduce (1) the frequency of hybrid formation and (2) the reproductive success of the hybrids. These considerations support the idea that selection against hybrids of *Salvia pratensis* and *Salvia nemorosa* is a complex multi-factorial process. An evaluation of the contribution of a single factor (as pollen placement) to the selection against hybrids requires a quantitative analysis of the processes as a whole.

P0488. The architeture of inflorescences in the brazilian genus Diplusodon (Pohl) Lythraceae.

T. B. Cavalcanti;
Embrapa Genetic Resources and Biotechnology, Brasília, Brazil.

In the monotelic type of inflorescence the axis terminates in a flower. In the polytelic lacks a terminal flower. In Lythraceae most of the genera are polytelic. In Diplusodon, one generally finds the polytelic pattern with flowers organized in a botry. In addition to the polytelic type described for Diplusodon, D. ovatus and D. panniculatus were found with monotelic inflorescence called thyrsoid, where the cymose partial florescences are triads, being able to continue to produce lateral flowers in the axils of prophylls and form a dichasium. Is considered that the polytelic type of inflorescence has been derived from the monotelic type, by loss of the terminal flower and specialization of the paraclades.In Diplusodon there are examples that correspond to the transition between the two types. One can see also in the two species that in their monotelic thyrsoids, the cymes that precede the terminal flower are reduced to botyroids, suggesting a transition for the polytelic pattern. The inflorescences in Diplusodon can be organized according to the evolutionary hypothesis for the inflorescences from the monotelic, toward the polytelic and reduction of flowers.

P0489. Radiation and evolution of the large woody genus *Guatteria* (Annonaceae)

R. H. J. Erkens, L. W. Chatrou;
National Herbarium of the Netherlands - Utrecht branch, Utrecht, The Netherlands.

The Neotropical genus Guatteria is the largest within the family of Annonaceae and one of the largest woody plant genera in the Neotropics, comprising ~260 species. In the last revision (1939) division in 30 sections was based on few macromorphological characters. Up to now Guatteria is the only major genus of Neotropical Annonaceae that awaits revision. Because of its uniformity in many morphological characters it is very difficult to understand the systematics and evolution of the genus. In this study the position of Guatteria within the family and the relationships with three closely related smaller genera, Guatteriopsis, Guatteriella, and Heteropetalum, were investigated. To this end a parsimony analysis was performed using plastid sequence data. Although the position of Guatteria within the family has not been resolved fully, it is clear that Guatteria is sitting at the end of a long node, but divergence levels among the species are low. Furthermore, Guatteria forms a well supported monophyletic group, but Guatteriopsis seems to be paraphyletic with respect to Guatteria as a whole. It is also clear that the decribed sections can no longer be uphelt.

P0490. Evolutionary Trends in Ovule Development and Organization

I. I. Shamrov;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

Ontogenetic variations in ovule expression might have occurred during its evolution. At first the nucellus was connected to integument(s) by a stalk, and chalaza was only comprised by integument derivatives. Fusion of the nucellar and integumentary bases (unitegmic crassinucellate ovules of Betulaceae, Fagaceae have a partial fusion) resulted in mesochalazal ovules. Ancestral bitegmic crassinucellate ones probably gave rise to a variety of monocot and dicot ovules, undergoing independent developmental pathways. Major directions of subsequent evolution were associated with the emergence of medionucellate ovules. Evolution in monocots presumably proceeded through medionucellate ovules with multilayered lateral and basal nucellar regions. Ovules, which are crassinucellate at early developmental stages, gradually become secondarily medionucellate due to collapse of the parietal tissue (Agavaceae, Butomaceae). Evolution in dicots proceeded from bitegmic crassinucellate ovules to unitegmic tenuinucellate ones characterized by complete nucellus degeneration prior to fertilization and endothelium formation (Alangiaceae, Cornaceae).

P0491. Phenology of *Plathymenia reticulata* (Leguminosae - Mimosoideae): characterization and variability in patterns within and among populations from areas of Brazilian Cerrado, Atlantic Forest and transitional sites between biomes

M. F. Goulart, M. B. Lovato, **J. P. de Lemos Filho**;
ICB- Univ. Fed. de Minas Gerais, Belo Horizonte- Minas Gerais, Brazil.

Plathymenia reticulata is a Brazilian tree that occurs in environmentally different biomes: Cerrado (savanna vegetation) and Atlantic Forest. Phenology variability within and among populations from these biomes and in transitional zone was accessed during 15 months in ten populations from Minas Gerais State. Trees were monthly evaluated according to vegetative (leaf fall, leaf flush and mature leaves) and reproductive phases (floral buds, flowers, immature fruits and seed dispersal). In general populations showed similar phenological behavior but there were differences, related mainly to leaf fall, a process that starts months earlier in dryer areas and latter in humid sites. Most of phenological diversity was due to differences among individuals within populations and only about 10% of the total diversity was attributed to differences among biomes. In addition, the flowering periods were similar in the biomes, suggesting that populations may inbreed, and so do not contrary the new taxonomic proposal that suggested the existence of only one species of *Plathymenia* and not a species from Atlantic Forest and another from Cerrado as previously considered.

P0492. Structural organization of dicot and monocot embryos and identity of some its types (in relation to monocotyly problem)

G. E. Titova;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

New classification of angiosperm embryo types is suggested on the base of developmental patterns of their axial and appendicular organs and morphogenetic activity at germination. The ancient embryo type (basal dicots) arose as a result of polymerization of first leaf organs (cotyledons) in one node of axis. Two main, derived from the ancient, embryo types - “typically dicotyledonous” and “typically monocotyledonous” ones, characteristic for most of dicots (eudicots) and monocots, respectively, are principally distinguished not only by cotyledon number but also by complex of known characters. Specific manifestation of types, deviating from the main ones, within both classes correlates with the change of cotyledonary apparatus structure. The analysis of identity of different types allows understand some aspects of monocotyly origin: appearance of monocotyledony in some basal dicots (via syncotyly) is true but not pseudomonocotyledony; dicotyledonous type in some monocots (reliable showed for *Agapanthus, Cyrtanthus, Allium, Dioscorea*) displays the traces of mentioned above polymerization but does not cause principal changes in embryo structure.

P0493. Tree inventory from the north-east dry forests of the Venezuelan Guayana

E. J. Sanoja;
Universidad Nacional de Guayana, Jardin Botanico del Orinoco, Estado Bolivar, Venezuela.

Deciduous forests represent the most endangered and unknown tree ecosystems in the Venezuelan Guayana. Inventory of the trees since was carried-out in forests communities around 10 km from Upata city (Bolivar state, 8°00’ Lat. N, 62°23’ Long. W, 360-680 m asl; 1.166 mm/year). A list with 295 trees species (including 5 Arecaceae and 2 Poaceae) and comments on the floristics are given. 24 % of species are legumes, 6 tree species are novelties for the Venezuelan Guayana, and 24 % of all tree species are found in the Caribbean region. Orographic stability of the Guiana shield hillside**,** the relatively dry nonextreme and narrow ecological gradient, could explain the presence of few endemic species at the regional level (3,5 %) and at local level (1 %) finded up to now.

P0494. The ecology of the plant of the genus Cirsium on the border of its distribution in the Russian plain

V. Basov;
Department of Biology, Yelets State University, Yelets, Russian Federation.

The ecology of 13 species of Cirsium and 4 hybrids has been studied in the central, northern and eastern part Russian plain and Pre-Ural in the years of 1983-2004. Several thistle species of the Russian plain are growing on the borders of their distribution; some hybrids and endemic species are distributed in this region only.

The Cirsium plants in the local populations on the border area have: 1) smaller height, smaller number of flower heads per specimen, than plant growing in the centre of their distribution; 2) many species of Cirsium form hybrids among themselves in these populations; 3) the plants are infested by more unspecialised insects.

4) The fauna of specialised phytophages of Cirsium is more diverse in the centre of the species distribution.

Taking into account the absence of specialised phytophages in many cases of introduced plants and on the grounds of the studied fauna of phytophages of Cirsium and its hybrids we conclude that *C. palustre*, *C. incanum* and *C. esculentum* are not native in the investigated regions. This contradicts the view of many botanists about the formation of the modern thistle flora of this region and on the Russian plain

P0495. Neither inbreeding depression nor sex allocation appears to maintain the sexual polymorphism in *Opuntia*.

R. F. del Castillo, S. Trujillo;
Instituto Politecnico Nacional, Xoxocotlan, Oaxaca, Mexico.

Several models have been proposed for explaining the evolution of unisexuality from hermaphroditism. Comprehensive studies testing the predictions of the models are needed. *Opuntia robusta* is a sexually polymorphic cactus with hermaphroditic, dioecious, and trioecious populations. We compared the vegetative and reproductive performance of males, females and hermaphrodites in a trioecious population. In consistency with the sex allocation theory, the potential reproductive output of the functional sex was higher in unisexuals when compared to that of hermaphrodites. Moreover, a disproportional increase found males is required for unisexuals to invade an original hermaphroditic population with the features of hermaphrodites: prior- and overriding selfing, no detectable pollen discounting nor inbreeding depression. These results might explain the existence of dioecious populations, but in our population, female seed output had a similar mean but a higher variance than hermaphrodite's. Vegetative changes related with the sexual polymorphism, and unreliable pollination services appear to be the major determinants of the observed polymorphism.

P0496. Population strategy of the genus Allium species

V. A. Cheryomushkina;
Central Siberian Botanical Garden of the Siberian Branch of Russian Academy of Sciences, Novosibirsk, Russian Federation.

Onions hold different positions in phytocoenosis. They may dominate or be subordinate. One or other role in the community results from population biology.

Ontogenesis, propagation by seeds, vegetative reproduction, ontogenetic structure and coenopopulation density were studied in 40 species of the genus Allium L. in different habitation conditions in Siberia, Kazakhstan and Middle Asia. Six types of ontogenesis were described. The correlation between the way of propagation and the type of ontogenesis was established. The ontogenetic spectra and types of self-preservation of the coenopopulations were characterized.

Using concepts of plant strategies (Ramensky, 1938; Grime, 1979, 2000; Rabotnov, 1985; and Smirnova, 1987), we identified several population strategies in onions on the basis of studied specific features of species biology. They were named by the dominance of one of the properties: competitive ability, reactivity and tolerance. Competitive , reactive, tolerant and tolerant-reactive species were determined among the species of the genus Allium.

P0497. Predispersal seed predation and its influence on the fitness of the rare carnation *Dianthus hinoxianus* Gallego

F. Balao, R. Casimiro-Soriguer, S. Talavera;
Departamento de Biología Vegetal y Ecología, Universidad de Sevilla, Sevilla, Spain.

Phenology, breeding system and seed predation of *Dianthus hinoxianus* Gallego (Caryophyllaceae) , an endemic hemicrytophyte specie in shrublands on paleodunes of SW Spain, were studied. Dianthus hinoxianus is a gynodioecious and self-compatible species but natural self-pollination is rare due to marked protandry. Nectar production was not significantly different between sexual phases. Flowering takes place in June-August and flowers are pollinated by diurnal and nocturnal lepidopteran, mostly hawk moths (*Macroglossum stellatarum* and *Hyles lineata*). Lepidopteran larva, born from eggs laid inside the flowers, fed on seeds inside the capsules. An experiment of selective exclusion of pollinators showed that eggs were laid mainly by night. In this study, of a total of 42 monitored patches about 97.6% had at least one flowerdamaged and 54.9% of the flowers (N=855) were damaged. All the populations showed a high rate of predation with significant inter- and intra-population differences.

P0498. What is the special floral scent of willows?

U. Füssel[1], A. Jürgens[2], S. Dötterl[2], G. Aas[1];
[1]Ecological-Botanical Garden, University of Bayreuth, Bayreuth, Germany, [2]Department of Plant Systematics, University of Bayreuth, Bayreuth, Germany.

The genus *Salix* (willows) is composed of dioecious woody plants with a high taxonomic and ecological diversity. Inflorescences of most willow species show adaptations to insect pollination. The pollinators are believed to play a role in limiting interspecific gene flow. The floral and pollen scents are assumed to be the key components for attracting the pollinators. However, only few data are available characterising volatile compounds of willows and their functions.

Floral odours of different willow species were analysed using dynamic-headspace MicroSPE methods.

Investigations on three willow species (*Salix caprea, S. cinerea* and *S. alba*) revealed benzoids (e.g. 1,4-Dimethoxybenzene) and isoprenoids (e.g. Ŭ-Pinene, D-Limonene) as main compound classes of floral scents. The benzoid compound 1,4-Dimethoxybenzene could only be found in *S. caprea* and *S. cinerea*, but not in *S. alba*.The role of different volatiles in attracting specific pollinators is discussed.

P0499. Taxonomy and reproductive biology of *Cerasus fruticosa (Rosaceae*) in Slovakia

T. Baranec, R. Krchnava, P. Elias jun.;
Slovak University of Agriculture in Nitra, Nitra, Slovakia.

Cerasus fruticosa (Pall.) Woronov is a rare species on the territory of Carpathian basin and the result of hybridization with cultivated taxa of genus *Cerasus* the *C.* × *eminens* (Beck) Buia and *C.* × *mohacsyana* (Kárpáty) Janch. were confirmed in our study. The process of the microsporogenesis and microgametogenesis of *C. fruticosa* is normal, the level of degenerated pollen grains of both hybrids was rather high (20 - 60%). Germination of pollen grains *C.* × *eminens* was 0 % and *C.* × *mohacsyana* 20%. Two ovules differentiation in each carpel of these taxa and degeneration of the secondary ovule seems to be genetically programmed. Sometimes we observed degeneration of both ovules. We didn't find viable ovules in May in the pistils of the *C.* × *eminens* and production of any seeds during years 1998-2004 were noticed. In the flowers of *C.* × *mohacsyana* from 2 to 5 carpels was formed and some irregularities in development of female gametophyte has been achieved.

P0500. Size dependent gender diphasy and pollen movement in Arisaema serratum (Thunb.) Schott (Araceae)

T. Nishizawa[1], E. Kinoshita[1], Y. Watano[2], T. Kawahara[3], **K. Ueda**[1];
[1]Kanazawa University, Kanazawa, Japan, [2]Chiba University, Chiba, Japan, [3]Forestry and Forest Products Research Institute, Sapporo, Japan.

Arisaema serratum possesses a pitfall-trap flower pollination system. However, little is known about the efficiency and pattern of pollen movement in this species. Thus, the aims of this study are: (1) to determine the paternal parents of the seeds and (2) to elucidate pollen movement in a natural population.

Seeds were collected from the natural population of *A. serratum* in 2001 at Horigane, Japan. Small midges were trapped in female spathe tubes during the flowering period. Paternity analysis using microsatellite markers was performed. We found that: (1) seeds in a fruit were fertilized by multiple sires; (2) a few males contributed to a great extent as sires; (3) distance from a female was not a factor in the inequality of reproductive success among males; (4) male reproductive success was not correlated with its size.

We conclude that pollen carryover and the trap-flower pollination system are most likely to result in multiple paternity and inequality in male success. This study sheds light on the pollination syndrome in trap-flower pollination, or provides a basis on which to test the size-advantage hypothesis in A*. serratum*.

P0501. Genus Dipcadi Medik. (Liliaceae) in Indian subcontinent: cytogeography and speciation.

U. S. Yadav;
Willingdon College, Sangli, India.

Genus *Dipcadi* Medik (Liliaceae) is represented by about 9 species in Indian subcontinent of which 6 occur in the northern Western Ghats. The remaining three Indian species namely *Dipcadi erythraeum* Webb. et Berth., *D. reidii* Deb and Dasgupta and *D. serotinum* (L.) Medik. are distributed in hilly regions of arid zones of Rajasthan, in West Himalaya and in Western Himalaya and Nepal, respectively. The present study reports on the distribution, field status and karyomorphology of 8 Indian species of *Dipcadi*. Among Indian species of *Dipcadi*, *D. montanum* with 2 median, 5 submedian and 3 subterminal chromosomes has comparatively primitive karyotype. Three *Dipcadi* species with 2n=12 have 3 submedian and 3 subterminal chromosomes. Among Indian species of *Dipcadi*, highest somatic chromosome number, i.e. 2n=22, has been observed in *D. erythraeum*. The paper discusses cytogeography, interrelationship and speciation of *Dipcadi* species in India and the northern Western Ghats as one of the likely area for diversification of the genus in Indian subcontinent.

P0502. Irregular patterns of flowering and fruiting and androdioecy in *Phillyrea latifolia L.* in Israel

G. Pollak[1], R. Schwartz-Tzachor[2];
[1]Kibbutzim College of Education, Tel Aviv, Israel, [2]"Ramat Hanadiv Project", Yad Hanadiv and the Society for Protection of Nature, Ramat Hanadiv, Israel.

Frequency, rate and intensity of flowering and fruiting in the two sex types of the anderodioecious shrub *Phillyrea latifolia* L. were monitored. High inter-annual fluctuations in rates and intensity of flowering and fruiting occur. Functional male individuals (normal ovary in the flower, smaller stigmata, no fruit production) flower more frequently and intensively than hermaphrodites. Many individuals avoid flowering at all. Disturbance (shrub removal together with grazing) increases the rate, frequency and intensity of flowering. Fruiting rates of hermaphrodites are generally low and the fruit yields vary highly among individuals. Many individuals do not produce fruits at all, while only few produce significant fruit yield. Observations were made on *Probruggmanniella phillyreae* (Diptera, Cecidomyidae) which attacks the ovaries both in functional males and hermaphrodites and causes the formation of distorted ovary galls instead of normal fruits.

The role of climatic gradient, disturbances and insect damage as selection factors behind the androdioecy and the irregular patterns of the reproductive traits in *P. latifolia*, is discussed

P0503. Pollen flow within and between subpopulations of *Magnolia stellata*

S. Setsuko[1], K. Ishida[2], S. Ueno[3], Y. Tsumura[3], N. Tomaru[1];
[1]Nagoya University, Nagoya-shi, Japan, [2]Kansai Research Center, Forestry and Forest Products Research Institute, Kyoto-shi, Japan, [3]Forestry and Forest Products Research Institute, Tsukuba-shi, Japan.

Magnolia stellata (formerly also known as *M. tomentosa*) is a deciduous, clone-forming tree of the Magnoliaceae. It is now a threatened species, classed as “vulnerable” in the “Red Data Book of Japanese vascular plants”. Disappearance and / or fragmentation of populations disturb gene flow and accelerate differentiation among populations. In order to provide baseline information for the genetic diversity in *M. stellata*, pollen flow within and between subpopulations was investigated by using 10 microsatellite markers developed in *M. stellata* and *M. obovata*. Paternity analysis was conducted for 418 seeds collected from nine maternal genets in a subpopulation located at the center of a population. The population was composed of eight subpopulations where a total of 313 flowering genets were growing. Out of the 418 seeds, 97.4 % were offspring sired by paternal genets within the subpopulation and the remaining 2.6 % were by paternal genets in the other subpopulations, indicating predominance of short-distance pollen flow in the population. The paternal genets were mostly large-sized, with long flowering periods, and located near the maternal genets.

P0504. Floral capitate hairs of Veronica (Scrophulariaceae): structure and function

M. R. Leont'eva;
Biological Faculty, Moscow, Russian Federation.

Glandular hairs densely cover gynoecium in some species of Veronica. The hair consists of a long multicellular stalk and a large two-celled head. The TEM study showed that lipids are accumulated in the head cells. At the beginning of blossoming, before nectar secretion, they penetrate in the cell wall, which changes its structure in these places. It becomes looser, the areas between fibrils of cellulose contain similar to lipids substances. Lipids come through and accumulate under cuticle, making small swelling. After cuticle rupture oil drops evaporate. The exudation of lipid drops can happen either several places of the same cell (eg. V. longifolia, V.teucrium) or in one place - on the top of the hair head (V. officinalis). Thus the glandular hair apparently play the role of osmophores. It is interesting that we are the first to discover such type of glandular hair on the large nectar disk in V. officinalis. In this case nectaries play the double exudation role - evaporation of smelling essence first by hair and nectar secretion through stomata in future.

P0505. Parasitism effect by bruchids (Coleoptera-Bruchidae) on seed germination of *Mimosa* species (Leguminosae-Mimosoideae) in Mexican semi-arid ecosystems

S. L. Camargo-Ricalde[1], M. S. Orozco-Almanza[2], R. Grether[1], J. Carrillo-Cisneros[1], J. Romero-Nápoles[3], C. D. Johnson[4];
[1]Universidad Autónoma Metropolitana-Iztapalapa, México, D. F., Mexico, [2]Universidad Nacional Autónoma de México, México, D. F., Mexico, [3]Colegio de Postgraduados, Montecillo, Estado de México, Mexico, [4]Northern Arizona University, Flagstaff, AZ, United States.

Genus *Mimosa* is well spread over Mexico with 110 species. Some *Mimosa* species occur in semi-arid ecosystems being dominant within their communities and forming resource islands, which favor soil and biodiversity conservation. These species are used by local people. Eight species and two varieties were sampled, all endemic to Mexico. These species produce ca. 4000-15000 seeds/plant; although, a high percentage of seeds is not viable (30%-75%) due to bruchid parasitism. Germination capacity was compared between healthy and infected seeds. A high seed germination was recorded (>90%) either in the laboratory and in the field, optimal temperature was 25°C. However, infected seeds only reached <20% of germination. There is an inverse relation between seed coat thickness and seed vulnerability to bruchid infection. A bruchid data base is being developed, including 12 species of genus *Acanthoscelides* and 3 of genus *Stator*, that infect ca. 50 Mexican *Mimosa* species. This study contributes to the understanding of *Mimosa* reproductive biology and is an attempt to develop a method to evaluate the impact of these coleoptera seed beetles against native *Mimosa* populations.

P0506. Autecology of *Isoëtes echinospora* and *I. lacustris*, critically endangered species of glacial lakes in the Bohemian Forest, Czech Republic

M. Ļtvrtlíková[1], P. Hekera[2], A. Létal[3], J. Rydlová[4], R. Sudová[4];
[1]Palacký University, Faculty of Natural Sciences, Department of Botany, lechtitelŢ 11, 78371 Olomouc, Czech Republic, [2]Palacký University, Faculty of Natural Sciences, Department of Ecology and Environment, lechtitelŢ 11, 78371 Olomouc, Czech Republic, [3]Palacký University, Faculty of Natural Sciences, Department of Geography, tŚ Svobody 26, 77146 Olomouc, Czech Republic, [4]Academy of Sciences of the Czech Republic, Institute of Botany, 252 43 PrŢhonice, Czech Republic.

Isoëtes echinospora and *I. lacustris*, submerged lycopodiophyts, are glacial relicts and critically endangered species of the Czech flora. In the Czech Republic, they occur only in two strongly acidified and anthropically disturbed lakes of the Bohemian Forest, Cerne and Plesne. Lack of information on viability of the populations and speculations about their limited reproduction raised a need for recent underwater investigations of reproduction biology and autecology. Quillworts are periodically monitored on permanent study plots and their 3D delimitation within populations and biometric characteristics are assessed. Experiments on survival ability in other parts of the lakes and simulations of repatriation are conducted in plant nurseries. Environmental conditions are recorded by dataloggers and sediment and water are analysed. In laboratory experiments, the influence of environmental factors on spore germination and sporophyte development are studied and temperature, pH and Al limits were already established. In the roots of both quillwort species sampled in the lakes, colonisation by arbuscular mycorrhizal fungi was frequently observed.

P0507. *Centaurea phrygia* agg. in central Europe: morphological, karyological and isozyme variations and introgressive hybridization

P. Koutecky;
Faculty of Biological Sciences, Ceske Budejovice, Czech Republic.

Three taxa were recognised within *C. phrygia* agg. on a basis of multivariate morphometric analysis and chromosome counts: *C. pseudophrygia* (diploid), *C. stenolepis* (diploid) and *C. phrygia* s.str. (diploid and tetraploid, the ploidy levels seem to be geographically separated and no mixed populations were found). Morphologically intermediate populations, which have not been reported by recent authors, were found: (1) between *C. pseudophrygia* and *C. stenolepis* and (2) between *C. phrygia* (tetraploid cytotype) and *C. oxylepis* (from *C. jacea* agg.; tetraploid). They probably originate from an introgressive hybridization. Results of an inquiry of their distribution and karyological and isozyme variations support this hypothesis. The intermediate populations occur in contact zones of the putative parental species. They have the same number of chromosomes as the putative parents, which is an unavoidable condition for repeated hybridization in *Centaurea*. Isozymes were studied for *C. pseudophrygia* - *C. stenolepis* pair: the pattern of variation of isozymes within possibly hybridogenous populations is intermediate between the putative parents.

P0508. Extensive self-pollination in an endangered population of *Pinus parviflora* var. *parviflora*

T. Sase[1], **Y. Watano**[1], T. A. Ohsawa[1], K. Ozaki[2], N. Tani[3], H. Ikeda[4], M. Suzuki[4], R. Endo[5], K. Touhei[6];

[1]Faculty of Science, Chiba University, Chiba, Japan, [2]Natural Histry Museum and Institute, Chiba, Japan, [3]Forestry and Forest Products Research Institute, Tsukuba, Japan, [4]University Forest in Chiba, Graduate School of Agricultural and Life Science, the University of Tokyo, Chiba, Japan, [5]China Prefectural Forestry Research Center, Chiba, Japan, [6]Chiba Ecology Center, Chiba, Japan.

Plants of *Pinus parviflora* var. *parviflora* in the Boso Peninsula, Japan have been rapidly decreased in number in recent decades. The population is severly frangmented, and only 80 plants survived at present. For the purpose of conservation, we examined pollen dispersal pattern within and among the fragmented patches by using seven microsatellite markers. DNAs of all mature plants and megagametophtes and embryos of 72 seeds from twelve maternal plants were extracted and their genotypes were determined. Paternity exculsion analysis revealed that extensive self-pollination occurred in this population; among 72 seeds, 67 (93%) were selfed ones, and the other five were outcrossed ones (one intra-patch, two inter-patch, and two by unknown paternal plants). The low outcrossing rate (7%) seems to be extraordinal, because most of pine species have been considered to be predominantly outcrossing. Limitation of pollen available for outcrossing was also suggested by a low full-filled seed rate (17%) in this population. Possibly, this population is involved in extinction vortex by the decrease in number and inbreeding.

P0509. Reduction of geitonogamy: Flower abscission for departure of pollinators

E. Ito[1], K. Kikuzawa[2];
[1]Forestry and Forest Products Research Institute, Tsukuba, Japan, [2]Kyoto University, Kyoto, Japan.

Overproduction of flowers increases the attractiveness of a plant to pollinators, but results in increased geitonogamy. Problems of geitonogamy are probably most severe in large trees because they produce large numbers of flowers and because of their overall size. In general, flower abscission has been considered to be an event subsequent to the overproduction of flowers. Tilia japonica is a self-incompatible, insect-pollinated tree. T. japonica produces morphologically perfect and protandrous flowers, however some of the flowers are aborted before the female phase to regulate flexibley its sex allocation. We observed pollinator behavior in T. japonica and found that pollinators sequentially visited inflorescences within a tree; however, when they met with flower abortion by abscission, they were apt to move long distances and leave the tree. We propose that plants may utilize flower abscission as a method for regulating the movements of pollinators by disturbing them in order to prevent geitonogamy.

P0510. Arrangement of multiple sequence variants at telomeres of Hyacinthaceae

M. Dvorackova[1], M. Sklenickova-Meznikova[2], E. Sykorova[2,3], K. Y. Lim[3], A. R. Leitch[3], J. Fajkus[1,2];
[1]Masaryk University, Brno, Czech Republic, [2]Institute of Biophysics, Brno, Czech Republic, [3]Queen Mary University of London, London, United Kingdom.

Telomeric sequences are considered as highly conserved across a broad phylogenetic spectrum. In many higher plants Arabidopsis motive (TTTAGGG)n is common. However, there is an evidence that typical plant telomeric motive is absent in several species. A group of monocotyledonous plants Asparagales, forming a distinct clade in phylogenetic analyses, was previously reported to lack typical "Arabidopsis" type telomere. According to the type of their telomeric sequences Asparagales order can be subdivided into three goups - plant type (e.g. orchids), human type (e.g. asparagus) and unknown type (e.g. onion).
Telomerase of Hyacinthaceae plants species - e.g. Ornithogalum, Muscari, Scilla - synthetize human-type telomeres with high error rate in vitro. Using FISH, fiber-FISH, and Southern hybridisation, we characterize structure of telomeres in these plants by analyzing co-localisation between major (human-type) and minor (Arabidopsis-type or Tetrahymena-type) sequences.
This work was supported by the project GACR521/05/0055 and the isntitutional support (MSM0021622415, AVOZ50040507)

P0511. Spatio-temporal fluctuations in sex ratio which cause pollen limitation in the dioecious herb Antennaria dioica

M. Öster, O. Eriksson;
Department of Botany, Stockholm, Sweden.

Dioecious plants may be more sensitive to habitat fragmentation than hermaphrodite plants due to the spatial separation of the sexes. This is in part depenedent on the pollination system of the plant. We have studied *Antennaria dioica*, which has a potentially good pollen transfer system with many types of insects as vectors (eg. Anthomyiidae, Calliphoridae, Geometridae). We monitored the phenology pattern of the species for three years at a local scale, and during one year at a regional scale. We also conducted a pollination study to assess the impact of isolation between male and female plants on seed set. Our results suggest that there are large fluctuations in sex ratio and flower number between years. Small populations of the species tend to have a more skewed sex ratio, compared to larger populations. We also found that some patches of the species, but not all, where pollen limited and thus had a lower natural seed set. This variation in pollen limitation could be explained by the sex ratio and abundance of males within a short distance from the patch. Our results have implications for the conservation and management of dioecious and other obligate outcrossing plants.

P0512. 08 The pollination biology of *Ilex* species in Hong Kong, China

C. W. A. Tsang, R. T. Corlett;
University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China.

The pollination biology of fourteen native *Ilex* species in Hong Kong was studied. All species flowered annually between March and June. Male plants produced 2.4-11.2 times as many flowers on an 8-mm diameter branch as female plants. Nectar amount and chemistry varied among species and between sexes. *Apis cerana* accounted for >87% of diurnal flower visits for all species and male flowers received more visits than female flowers. Minor diurnal visitors included other bees, wasps, butterflies, ants and beetles. Moths and beetles were the major nocturnal visitors, but the visitation rate was very low. Across species, the *Apis* visitation rate per flower was strongly related to the estimated total number of flowers on the plant in both male and female plants, but was not related to nectar production or flower size. The percentage fruit set varied widely between species (8-73%) but was not significantly related to *Apis* or total visitation rates.

P0513. “The Uncertainty Principle” of Molecular Systematics

D. Fu[1,2];
[1]Institute of Botany, Beijing, China, [2]Botanic Garden of Southern China, CAS, Guangzhou, China.

Molecular clock principle in the Neutral Theory of Molecular Evolution is applied to analyze evolutionary relationship of extant taxa by comparing their DNA sequences. This methodology has been a fashion in molecular systematics, but it has inherent limitations similar to predicaments in Classic Mechanics, which is subsequently called an Uncertainty Principle in Quantum Mechanics. The Uncertainty Principle is also suitable for DNA sequence comparison because the number and location of nucleotide variation can be sequenced, but their occurring time and influence on structural function cannot be measured. Differential accumulation of nucleotide variation from extant taxa only reflexes relative temporal distances from their own ancestors. If there were theoretically proportional relationships with differential accumulation of nucleotide variation among different taxa, it would create comparatively feasible results to elucidate their evolutionary relationships. However, extant taxa are not actually diversified from their ancestors by proportional time, so DNA sequencing results cannot mirror true evolutionary relationships among taxa.

P0514. Morphology and anatomy of the fruit and seed in development of Piper crassinervium H.B.& K. (Piperaceae)

A. A. S. Paoli[1], A. L. M. Albiero[2], L. A. Souza[2], K. S. M. Mourão[2];
[1]Universidade Estadual Paulista, Rio Claro/SP, Brazil, [2]Universidade Estadual, Maringá/PR, Brazil.

The purpose was describe the morpho-anatomy of the fruit and seed of P. crassinervium. The material consisted of spikes in different stages of development. Analyses were made in fresh and fixed material . Permanent and semi-permanent slides were prepared according to standard procedures. The erects spikes are displaced in a opposite position of the leaf. The achlamydeous and bisexual flowers grow in the axile of bracts . The uniseriate epidermis of the bracts presents stomata, trichomes and with the oils cells. The mesophyll is homogenous and with the oils cells.

The unilocular and superior ovary presents sessil stigmas.The unic ovule, with basal placentation, is orthotropous, bitegmic and crassinucellate. The outer integument shows three or four cell layers, and the inner four. The micropyle, is filled by an obturator. The mature seed is orthotropous, endotegmic and perisperm. The ovary wall is constituted by uniseriate epidermis. The parenchymatic ovarian mesophyll presents elongated radially cells and the oils cells. The ventral epidermis is uniseriate . The pericarp in mature fruit is similar to the ovary wall during all development. (CAPES/FUNDUNESP)

P0515. Anatomical and ontogenetical studies of the corona, operculum and limen in species of Passiflora L. subg. Decaloba (DC.) Rchb. (Passifloraceae).

M. A. M. Azevedo[1], M. C. Valente[2], **J. F. A. Baumgratz**[3];
[1]Instituto de Pesquisas Jardim Botânico do Rio de Janeiro; Museu Nacional/UFRJ; Bolsista CNPq, Rio de Janeiro, Brazil, [2]Instituto de Pesquisas Jardim Botânico do Rio de Janeiro, Rio de Janeiro, Brazil, [3]Instituto de Pesquisas Jardim Botânico do Rio de Janeiro; Bolsista CNPq, Rio de Janeiro, Brazil.

It is carries out an anatomical and ontogenitical study of the corona, operculum and limen of Passiflora capsularis L. and P. suberosa L. (subg. Decaloba), besides discussing the origin of those structures. This subgenus is characterized by the flowers frequently small, solitary or in pairs, 5-merous, hypanthium campanulate or dish-shaped, with corona uni or bisseriate, disposing the filaments in successive circular series. In P. capsularis the flowers have sepals and petals and the only filaments series of the corona and the opereculum have origin in the hypanthium, with the filaments united in the base as a annular membrane. In P. suberosa the flowers have only sepals and both filaments series of the corona and the operculum originate simultaneously from the hypanthium. In both species only the corona has vascular bundles. The operculum is the most intern verticilo of the corona and it resembles a annular membrane, folded into pleats, with the apex fimbriate or denticulate. The limen, a annular membrane, is the most intern part of the corona and it originates close from the base of the androgynophore.

P0516. Complexity of the plant surface function in the multitrophic system: plant surfaces as environment for the predatory mirid bug Dicyphus errans Wolff (Heteroptera, Miridae)

D. Voigt, E. Gorb, S. Gorb;
MPI for Metals Research, Stuttgart, Germany.

The common function of plant trichomes is the protection of plants against water loss, solar radiation and phytophagous insects. Many insects may be deterred or killed by hooked and glandular trichomes. Some insect species, f. e. the omnivorous D. errans, are associated with pilose plant surfaces. This bug shows morphological (slim body, long slight legs, elongated curved claws) and behavioural (way of locomotion) adaptations which allow close interactions between hairy plant substrates and the bugs. To study the influence of different types of plant leaf surface on the attachment of the bugs, screening experiments and force tests were conducted. The screening of leaf surfaces of 40 plant species belonging to 25 families showed successful attachment of bugs on plant substrates covered with glandular and non-glandular trichomes. In traction force tests on 15 leaf surfaces, insects also performed better on hairy substrates. The force correlated significantly with trichome length and diameter. The results show that hairy plant surfaces may not only protect the plant against herbivorous insects, but also provide the suitable environment for predatory insects.

P0517. Isolation mechanisms between *Heloniopsis orientalis* and *Heloniopsis breviscapa* (Liliales: Melanthiaceae)

S. Fuse[1], M. N. Tamura[2];
[1]Museum of Nature and Human Activities, Hyogo, Sanda, Japan, [2]Botanical Gardens, Graduate School of Science, Osaka City University, Katano, Japan.

Heloniopsis orientalis and *H. breviscapa* grow sympatrically in Kinki and Shikoku Districts, Japan. In this study, we investigated two sympatric populations of them using morphological, plastid DNA and microsatellite markers in order to clarify how the two species are isolated. At the population in Kinki, *H. orientalis* and *H. breviscapa* var. *flavida* proved to be isolated primarily by ecological and floral factors. However, a vegetative character and molecular markers demonstrate a certain level of introgression of a trait from *H. breviscapa* var. *flavida* into *H. orientalis*. Floral characters (flower color and nectary position) show no introgression, and may be considered to be under selective control, although their floral morphologies are primarily basic among monocot ones without any marked appendages such as a spur. At the population in Shikoku, seasonal factors may be decisive in isolation between *H. orientalis* and *H. breviscapa* var. *breviscapa*. Their flowering periods were not overlapped with one-week gap in 2004. Thus, isolation mechanism between *H. orientalis* and *H. breviscapa* varies from locality to locality and / or from variety to variety.

P0518. On the phylogenetic continuity of the telome of Rhyniophyta and the phytomer of monocotyledons

I. G. Levichev;
Komarov Botanical Institute of the Russian Academy of Sciences, Sankt-Petersburg, Russian Federation.

The segmented body of plants is organized on a principle: the following phytomer arises from the previous one. The initial unit - a telome in Rhyniophyta and an embryo (phytomer) in Monocots - repeat itself many times, specializing along the shoot into growth-units of 3-5 types. The telome is an axis with 2 initials at the upper end and 2 at the lower end. The prothallus of Psilotum and Tmesipteris are autonomous 5-axial mesomoids. The phytomer of Monocots (an evolutionarily modified 5-axial mesomoid with anisotomous right and left halves) has besides the axis four appendicular developments: on the innovative half, a leaf (a homologue of the originally terminal sporangium), and a root (a homologue of the rhizomoid); new phytomers accrue on the retarded half: from the upper initial - "monopodialy", from the lower (a lateral bud) - sympodially. The lateral bud, like the rhizomoid, is orientated downwards. Therefore the prophyll of a sympodium is always addorsalized and has 2 keels. The dichopodial nature of the phytomer determines the invariably lateral position of a leaf primordium. The unifaciality of the sporangium is forerunner of the cotyledonary sheath of Monocots.

P0519. Myrmecochorous diaspors as baby-food for ants

S. M. Ölzant[1], R. Fischer[2], W. Wanek[2], V. Mayer[3];
[1]Department of Pharmakognosy, Vienna, Austria, [2]Department of Chemical Ecology and Ecosystem Research, Vienna, Austria, [3]Department of Palynology and Structural Botany, Vienna, Austria.

Ants carry myrmecochorous diasporas usually into their nests where the lipid-rich appendage of the diaspores (elaiosome) is consumed. Here we present a study on the distribution of *Corydalis cava* (Fumariaceae) elaiosomes between the larvae and the working caste of laboratory colonies of *Myrmica rubra* (Myrmicinae: Formicidae). In a combined ^{13}C and ^{15}N labelling experiment elaiosomes proved to be a far more attractive diet for the larvae than Bhatkar diet, contributing 86.8% ± 2.0 of the daily nitrogen and 79.2% ± 2.8 of daily carbon incorporation of larvae. Workers incorporated less carbon and nitrogen based on dry body mass during the experiment - for nitrogen these proportions were lower by a factor of 1.6 to 13.1 and for carbon by a factor of 1.8 to 10.3. Laboratory ants stored diaspores within their nests for up to four days. We therefore hypothesize that elaiosomes may not only be a major food source for growing larvae, but also an important nutrient buffer for ant colonies under natural conditions where food supply might be highly discontinuous.

P0520. Sexual reproduction of *Espeletia grandiflora* var. *multiflora* in a high andean paramo of Colombia

J. Sánchez Zambrano, M. A. Bonilla Gómez;
Universidad Nacional de Colombia, Bogotá, Colombia.

Some aspects of reproductive strategy of *Espeletia multiflora* var. *grandiflora* were studied. Three patches of Espeletia´s plants characterized by agricultural activities in the surroundings, and located in a high andean páramo of Colombia were chosen. The field experimental phase was made since July to December in 2003. Four hypotheses were tested: 1. Disturbances can reduce the seed production in native ecosystem; 2. Disturbances can induce increases in viable seed production by autogamy; 3. There is a direct relationship between plants´ height and investments in reproductive structures; 4. The time expected for phenological phases is different in accord with the conservation state of the place. Results were compared with another study made in the Chingaza´s Paramo (Fagua 2002), characterized by better degree of conservation. For this place was reported lower viability percentage, higher autoincompatibility index, lower seed plant production, and shorter phenological phases that in Chingaza´s Paramo. Differences of conservation degree, climate, and genetic composition of *E. grandiflora* between both places can explain the different results.

P0521. Is *Cycas revoluta* (Cycadaceae) anemophilous or entomophilous ?

M. Kono, H. Tobe;
Department of Botany, Graduate School of Science, Kyoto University, Kyoto, Japan.

Cycas revoluta has been considered anemophilous. However, we have encountered a few indications of entomophily, such as the presence of a strong odor emitted by male and female cones at the time of pollination. In this paper we report the results of our experiments to determine the method of pollination. Pollen exclusion experiments were devised to test if wind is a sufficient vector effect pollination on Yonaguni Isl. (Okinawa, Japan), where thousands of individuals grow and produce fertile seeds under natural conditions. Insect exclusion resulted in a notable decrease in seed production in most cases, but a few female plants growing close to male cones bore as many seeds as the controls. Airborne pollen grains were few except within a 2 m radius of male cones. Anemophily, therefore, appears effective only over short distances. In contrast, various kinds of insects were collected from female cones. Among them, one species of Nitidulidae (Coleoptera) bore pollen grains of *C. revoluta* on their body. Consequently, insects appear to play an important role in the pollination of *Cycas revoluta*, especially in transferring pollen grains over long distances.

P0522. Adaptation of plants to nutritional needs of diaspore-dispersing ants

R. C. Fischer, A. Richter, F. Hadacek, V. Mayer;
Faculty of Life Sciences, Vienna, Austria.

The nutritional composition of the appendages of the diaspores (elaiosomes) compared with the respective seeds has received little attention so far. We therefore analyzed seeds and elaiosomes of 15 Central European ant-dispersed (myrmecochorous) plants for their content of lipids, amino acids, soluble carbohydrates, proteins and starch.

In most of the seeds and elaiosomes, lipids were the main constituent. While seeds had a significantly higher protein content (6% in seeds vs. 3% in elaiosomes) and on an average more lipids (26% in seeds vs. 20% in elaiosomes), elaiosomes contained significantly more free amino acids (7% in elaiosomes vs. 1% in seeds).

Although the overall nutrient quality was similar in diaspores and elaiosomes, the specific composition of individual fatty acids, amino acids and carbohydrates differed markedly between elaiosomes and diaspores. The fatty acid pattern in seeds were taxon-specific while it was homogenous in elaiosomes.

This suggests a directed adaptation of the elaiosomes' composition to the ants' nutritional needs.

P0523. Floral Biology of three páramo rosettes in the Eastern Andes of Colombia

M. A. Bonilla, F. A. CHAVES;
Universidad Nacional de Colombia, Bogotá, Colombia.

We described the floral biology of *Espeletia barclayana*, *Espeletia argentea* and *Espeletiopsis corymbosa* at the Páramo de Guerrero (3200-3600m; 5°04' N, 74°06' W) in the Eastern Andes of Colombia. The three species are monoecious, their capitula are protoginous and last about 15 days. The female flowers are ligulate and peripheral, and are receptive since the second day of anthesis. They live as long as the capitulum and do not produce nectar. The male florets constitute the central disc and initiate anthesis one or two days after female ones. They open centripetally, last one day and produce pollen and nectar. *E. barclayana* produces 140 male florets and 82 female flowers in average in a head, *E. corymbosa* produces 37 male flowers and 25 female and *E. argentea* produces 67 male florets and 46 female flowers. *E. corymbosa* presented the highest number of inflorescences per plant and heads per inflorescence but shows the smallest heads. On the other hand, *E. barclayana* produces the lowest number of inflorescences per plant and capitula per inflorescences but has the largest heads. These results may indicate a trade off between size and number of capitula for these species.

P0524. Reproductive systems of three páramo rosettes in the Eastern Andes of Colombia

F. A. Chaves, M. A. Bonilla;
Universidad Nacional de Colombia, Bogotá, Colombia.

We studied the reproductive system of *Espeletia barclayana*, *Espeletia argentea* and *Espeletiopsis corymbosa* at the Páramo de Guerrero (3200-3600m; 5°04' N, 74°06' W) in the Eastern Andes of Colombia. *E. argentea* and *E. corymbosa* were partially self-incompatible (ISI= 0.356 y 0.304, respectively) but *E. barclayana* was strongly self-incompatible (ISI=0.0114). The proportion of viable seeds was higher in cross pollinated heads than in self pollinated, as it was expected. In the control treatment (pollination under natural conditions) *E. barclayana* presented the lowest proportion of viable seeds and *E. argentea* the highest. On the other hand, in the cross pollination treatment (artificial) *E. barclayana* produced the highest proportion of viable seeds and the other two species (*E. argentea* and *E. corymbosa*) produced a lower proportion. This shows us that in natural conditions *E. barclayana* has limitations for its reproductive success. The pollination efficiency, measured as the proportion of female flowers in a head that became achenes, was relatively low for the three species, ranging from 38 to 65%, indicating pollinator limitation or their low efficiency.

P0525. Critical re-evaluation of the function of 1,2 diolein as trigger for ant-dispersal

I. Djukic, S. Ölzant, V. Mayer;
Faculty Center for Botany, Vienna, Austria.

The trigger of myrmecochorus diaspore dispersal is still debated. The currently most accepted hypothesis is that 1,2 diolein, a diacylglycerol of oleic acid causes stereotypical carrying behaviour. We investigated the mechanical and biochemical background of three myrmecochorous plants from Central Europe (*Corydalis cava*, *Galanthus nivalis, Knautia dipsacifolia*) and four colonies of two ant species (*Formica fusca*, *Myrmica rubra*) in experiments using natural diaspores and artificial seeds/elaiosomes with the respective extracts. Elaiosome extracts were compared to seed extracts of the same species. Seed extracts were collected, but without clear preference. A general preference for mixtures of elaiosome extracts was observed, followed by the fat extract, amino acids/sugar extract and, finally, protein extract (descending sequence).

The significant preference of elaiosome extract mixtures over the fat fraction and pure 1,2 diolein, indicates that the nutrient quality and complex chemical composition of the elaiosomes and not a single chemical compound is essential for carrying behaviour of the ants and thus an important factor in the mutualism.

P0526. The comparative carpology and taxonomy of the family *Celastraceae* R.Br. s.l.

I. A. Savinov;
Moscow State University of Applied Biotechnology, Moscow, Russian Federation.

The complex comparative morphological and anatomical study of structure of fruits and seeds of 108 species from 39 genera of the family *Celastraceae* is conducted. It was determined taxonomical importance of features which in most cases to well correlated with types of living forms, texture of stomatal complex, structure of flowers and pollen granules.

Then the data was processed by cladistic and SYNAP-methods. The following conclusions was draw. 1) The family *Celastraceae* R.Br. it is necessarily consideration in wide sense, including *Hippocrateaceae* A. Juss. 2) The tribe *Lophopetaleae* Loes. is formed one clade with *Hippocrateaceae*. 3) Subfamily *Tripterygioideae* Loes. is monophyletic and monotetic taxon with one important feature - one-seeding nut-like fruit. 4) *Sarawakodendron* with *Brassiantha* and *Dicarpellum* are related and an isolated genera in the family *Celastraceae*, represents an independent group within the family - subfamily *Sarawakodendroideae* I. Savinov et Melikian. Moreover, molecular data best of all to be used to determine of volume and relationships of separate genera.

P0527. Style diverstiy in the family Cactaceae

T. Terrazas, M. Fuentes-Pérez, M. Vázquez-Sánchez;
Colegio de Postgraduados, Montecillo, Mexico.

Our goal was to describe and compare the diversity of stylar anatomy in the Cactaceae family to gain insight in its evolutionary significance. Various developmental stages of floral buds and flowers in anthesis of more than 50 species belonging to the Cactaceae subfamilies were studied through sections and scanning electron microscope. Among the distinctive characters are the papillous epidermal cells as for *Mammillaria* and *Gymnocalycium* species and the different organic and inorganic compounds occluding the epidermal cells. Although the transmitting tissue has similar type of cells, its width and shape varies among genera. In addition, the centre of the style is open conforming a stylar canal along its length in members of Opuntioideae and Cactoideae. A semi-solid center was observed in species of *Myrtillocactus* and a solid one in *Mammillaria* species. When the stylar cavity is present, papillae with dark-staining deposits or lacking is distinctive. Moreover the stigma has one vascular bundle per lobule, with collenchyma cells in few species. A number of style and stigma anatomical characters with phylogenetic signal will be highlighted.

P0528. Diversity of flower structure as criterion of systematics and phylogeny of *Aizoaceae*.

M. S. Wowk;
D. Halytsky Lviv National Medical University, Lviv, Ukraine.

Undoubtedly, flower evolution in Aizoaceae occured in direction of epigyny formation which at most specialized Ruschioideae was accompanied by change of placentation type that is connected to gynoecium deformation owing to receptacles invagination. Within the family there are flowers with various degree of evolutionary specialization, which main features are ovary type (perigyny up to complete epigyny), placentation type (central-angular up to basal and parietal), androecium structure (single up to numerous) and perianth structure (simple up to complex). The degree of placentae displacement directly depends on epigyny level. So, at weak-epigynous genera the transitive type between central-angular to basal, at semi-epigynous - basal placentation type are observed. At some epigynous genera is present the intermediate basal-parietal placentation type. At most specialised epigynous genera are developed a parietal placentation with placentae arrangement extremely on peripheral ovary walls. Such variety of flower structure is a systematic attribute and may be a reliable criterion of phylogeny and a level of primitiveness or evolutionary advances.

P0529. Floral development in Calceolariaceae: Intergeneric variation and comparison with allied groups

E. M. Mayr, A. Weber;
Faculty Center for Botany, Vienna, Austria.

Floral development of the recently established Calceolariaceae was studied to clarify their controversial floral morphology and the relationships with other groups of Lamiales. 12 selected species (*Calceolaria*: 8, *Jovellana*: 3, *Stemotria triandra*) were studied from flower initiation to anthesis by means of SEM. All genera share a similar pattern of organ initiation. The four-parted calyx is the first floral series initiated, with the lobes emerging in a clear dorso-ventral succession. In *Calceolaria* and *Jovellana* the two corolla lips arise as uniform ridges. In contrast, the lower lip of *Stemotria* is bilobed, resulting in a trimerous corolla. This is paralleld by the presence of three stamens instead of two. A similar architecture was also found in teratological flowers of *Calceolaria*. These results suggest that the perianth of Calceolariaceae is truly tetramerous and not derived from pentamery. These findings are in agreement with the separation of Calceolariaceae from Scrophulariaceae, suggested by recent molecular data, and with their placement in basal Lamiales, following the Oleaceae and Tetrachondraceae with clearly tetramerous flowers.

P0530. Comparative floral development in Calycanthaceae (incl. Idiospermaceae)

Y. M. Städler[1], P. H. Weston[2], P. K. Endress[1];
[1]University of Zurich, Zurich, Switzerland, [2]Royal Botanic Gardens, Sydney, Australia.

Calycanthaceae have a prominent position in basal angiosperms as they appear as sister to all other Laurales in molecular phylogenetic analyses. Reproductive structures of representatives of the four extant genera of the family (*Calycanthus, Chimonanthus*, *Sinocalycanthus*, and *Idiospermum*) have never been comparatively studied. The aim of this work is to provide a comparative investigation of floral structure and development, with emphasis on floral phyllotaxis, development of androecium and gynoecium, and floral behaviour just prior to and at anthesis. Previous studies on floral phyllotaxis were all based on a single species (*Calycanthus floridus*). All studied species have a spiral floral phyllotaxis according to the Fibonacci pattern, which begins after a number of decussate organs. Correlated with spiral phyllotaxis is variability in organ number; however, stamens tend to appear in series of Fibonacci numbers (varying between taxa). Carpel differentiation in the paucicarpellate genus *Idiospermum* is different from that in pluricarpellate genera, but all genera have in common a plicate or only weakly ascidiate carpel form.

P0531. Floral and inflorescence anatomy in the Lecointea clade (Leguminosae, Papilionoideae, Swartzieae *sensu lato*)

V. F. Mansano[1], S. P. Teixeira[2];
[1]Instituto de Pesquisas Jardim Botânico do Rio de Janeiro, Rio de Janeiro, Brazil, [2]Universidade de São Paulo, Ribeirão Preto, Brazil.

Floral and inflorescence anatomy were studied in *Exostyles*, *Harleyodendron*, *Holocalyx*, *Lecointea*, and *Zollernia* (*Lecointea* clade). Common features include: anther, ovary, petals, sepals and bracts supepidermal cells with phenolic compounds (except in *Holocalyx balansae*); tector trichomes at the bracteoles inner base and on the calyx outer surface, including the species with colleters (except in *Exostyles godoyensis*). Significant anatomical features include colleters in *Holocalyx balansae* and in *Zollernia ilicifolia* and tector trichomes in *Exostyles venusta, Harleyodendron unifoliolatum, Lecointea hatschbachii* and *Zollernia magnifica*; trichomes at the anther epidermis in *Lecointea hatschbachii* and *Holocalyx balansae*, a very uncommon characteristic; synchronic pollen development into the anthers in *Exostyles venusta, E. godoyensis, Holocalyx balansae* and *Zollernia illicifolia* and asynchronic in *Lecointea hatschbachii*; vascular bundles surrounded by lignified fibers in *Harleyodendron unifoliolatum*. The genera of the *Lecointea* clade share some rare characteristics in Leguminosae showing an anatomical affinity among them (FAPESP).

P0532. Flower structure and its morphological transformation in *Polygonaceae*

O. V. Yurtseva, V. V. Choob;
Moscow State University, Moscow, Russian Federation.

All the diversity of flower structure could be described in terms of merosity and completeness. The flower merosity is calculated as the number of tepals per whorl, and depends: on the meristem size and shape, and on the size of presumptive tepal primordia, related to meristem, at the moment of spatial pattern formation in the flower. Merosity increases as a result of floral meristem diameter enlargement and/or of size reduction of tepal primordia. The number of sites for stamen positioning is correlated with the tepal number. The number of sites for inner stamens is influenced by the number and position of carpels. The flower completeness is related to the reduction /enrichment of flower structure, caused by changes in stamen number in the sites of stamen positioning (from 0 to 4), and in perianth whorl number (1 or 2). The number of stamens in any positioning site depends on the ratio of stamen primordia size to the available space of this site. The flower polymorphism in some genera covers several structures, different in merosity and completeness, whereas the same flower structure occurs in far related taxa of the family.

P0533. Androecial pattern in Didiereaceae and the relationships of the family

C. Erbar, P. Leins;
HIP - Biodiversity and Plant Systematics, University of Heidelberg, Germany.

According to molecular data Didiereaceae belong within the Caryophyllales to the monophyletic portulacaceous group: Two clades within paraphyletic Portulacaceae have given rise to the families Didiereaceae and Cactaceae, resp. (e.g. Applequist & Wallace 2001). Within the core Caryophyllales the number of stamens is variable (from many to few). Multistaminate androecia develop centrifugally, those with fewer stamens varying in number mostly are formed in one series on a small ring primordium. In isomerous androecia the primordia may initiate directly at the floral axis. We present for the first time floral developmental data from members of all four genera of Didiereaceae: The 6-12 stamens arranged in one series are formed nearly simultaneously on a more or less prominent ring primordium. This ring primordium may be interpreted as homologous with a larger one found in the Dilleniaceae, sister to a broadly defined caryophyllid clade, judged from molecular data (Soltis et al. 2000). Further ontogenetical studies are required in the portulacaceous alliance contributing to current phylogenetic relationships in this still controversially discussed group.

P0534. The Scanning-Transferring; Dried and Fresh Plant Materials to the Computer with Isik Kutusu

N. Demirkuк, **M. Fırat**;
Yüzüncü Yıl University Education Faculty, Van, Turkey.

Abstract body

The **ISIK KUTUSU** for transferring pictures, images of motionless beings and objects to the computer, depending on the quality of the scanner.

This device provides remarkably good results in transferring three-dimensional images of motionless beings and objects to the computer with a qualitated imaging and printing when used with scanners. Our device also provides facility for the analysis of the images of various entities in a number of fields in digital environment with a magnitude up to 60 times bigger than the real object (6000 %). An equality has been formulated in order to give the approximate count of the real magnitude depending on the dpi and the zooming counts. The device is patented, up to 2007 http://www.biyolojiegitim.yyu.edu.tr/proje/kutu/index.htm But recently the description of device will be free for everybody on the web page. We will demonstrate; preparing, scanning and transferring plant materials to the computer with **ISIK KUTUSU**. Also the plant images of The Virtual Herbarium of Van Province is prepared with using **ISIK KUTUSU** will be introduce on web page http://www.biyolojiegitim.yyu.edu.tr/flora/ingindex.htm

P0535. Testing molecular-based sister group relationships: floral ontogeny and morphology of the *Antirrhinum*-containing subclade revisited

M. Bello[1], P. J. Rudall[2], F. González[3], J. Fernández-Alonso[3];
[1]The School of Plant Sciences, The University of Reading, Berkshire RG6 6AS, Reading, United Kingdom, [2]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, Surrey TW9 3AB, United Kingdom, [3]Institute of Natural Sciences, Faculty of Sciences, National University of Colombia AA7495, Bogotá, Colombia.

Inflorescence and floral morphology and development were studied in *Aragoa* (Plantaginaceae) and related genera. Inflorescences of *Aragoa* and *Plantago* are lateral racemes. In *Aragoa*, the five sepals emerge from the abaxial to the adaxial side of the floral apex, but the mature calyx becomes actinomorphic. The four stamens arise simultaneously and before petal initiation. The four petals emerge unidirectionally but the corolla becomes actinomorphic. Aestivation is cochlear ascendent. The abaxial-adaxial inception of the calyx and corolla during early floral development in genera such as *Aragoa, Digitalis, Plantago* and *Veronica* may indicate that zygomorphy is ancestral in those genera. The tetramerous corolla, which is actinomorphic during middle and late development, and tetrandry are potential synapomorphies of the clade *Aragoa* + *Plantago*. Pentamery of the calyx and corolla appears to be plesiomorphic in the broader *Aragoa-Angelonia* clade. Inflorescence and floral development and morphology of *Aragoa* are essentially similar to those found in *Plantago*, which is consistent with the molecular-based sister group relationship between these genera.

P0536. Pollen morphological study of *Halimocnemis*, *Halanthium*, *Halocharis* and allied genera of tribe Salsoleae (Chenopodiaceae) in Iran.

M. -. Ghobadnejhad;
Tehran University, Tehran, Islamic Republic of Iran.

The pollen grains in Chenopodiaceae have been mostly considered to show no variation. Present studies were conducted to evaluate some characters including pore number and pollen diameter as distinctive features taxonomically.The comparative pollen morphology of the genera *Halanthium*, *Halimocnemis*, *Halocharis*, *Petrosimonia*, *Gamanthus* and *Climacoptera* belonging to a problematic complex and microscopic data by LM and SEM are given. Pollen morphological studies of specimens clearly show distinctive position of *Petrosimonia*, with the highest pore number and the least pore number can be seen in *Halocharis*. The obvious different between pore number of the two species of *Gamanthus* suggests that they can be included in different genera.

Different communities of the species *Climacoptera turcomanica* showed different pore numbers distinctively which can be attributed to the possibility that this species can be divided to smaller taxa. The position of the genus *Climacoptera* in pollen pore diagram showed considerable distance from *Salsola* which confirms the acceptance of *Climacoptera* as an independent genus from *Salsola*.

P0537. Pre-meiotic RNA polymerases are sufficient for male but not female gametophyte development and fertilization in Arabidopsis

Y. Onodera[1], T. Mikami[1], C. S. Pikaard[2];
[1]Hokkaido University, Sapporo, Japan, [2]Washington University, Saint Louis, MO, United States.

Unlike animals, whose gametes are direct products of meiosis, plant meiotic products undergo additional mitoses, differentiation and development to produce multi-cellular haploid gametophytes (gamete plants) that contain the egg and sperm cells. The complex development and metabolic activities of plant haploid gametophytes is presumed to select against deleterious loss-of-function mutations that cannot be complemented in the haploid state. Consistent with this expectation, we show that female gametophytes defective for nuclear RNA polymerases I, II or III arrest early in development, indicating that the female gametophyte relies on transcriptional machinery encoded by its haploid genome. However, male gametophytes (pollen) bearing defective polymerase genes survive, grow and transmit the mutant genes to the next generation, showing that transcriptional machinery derived from the pre-meiotic pollen mother cell is sufficient for pollen development and fertilization.

P0538. Anther Development in *Melilotus indica*- some interesting features

N. Gautam;
Dauалt Ram College, Delhi, India.

Melilotus indica is an annual fodder legume that flowers during winter months. Leaves are trifoliate and flowers are yellow in colour arranged in a racemose manner. Pods are very small and one-seeded. The anther is tetrasporangiate. Anther wall development follows the dicotyledonous type. The mature anther wall is comprised of an outermost epidermis, edothecium, one middle layer and the inner most tapetal layer. The tapetum is of secretary type. At the sporogenous stage of microsporogenesis, tapetal cells become irregular and during late ontogeny a transverse septum is observed in the microsporangia. The septum is of tapetal origin that seems to be an adaptation for better nourishment of developing microspores. The mature pollen grain of *Melilotus indica* is tricolporate. The exine is reticulate, well differentiated into ectexine and endexine. The ectexine is distinguished in a tectum, bacula and foot-layer. Aggregation of pollen grains by means of small exinal connections has also been observed. Another interesting feature noticed during this study is the *in situ* germination of pollen grains.

P0539. A re-investigation of *Tetracera* pollen.

O. A. Gavrilova;
Komarov Botanical Institution RAS, Saint-Petersburg, Russian Federation.

Among 29 investigated dillenioid species only 6 neotropical *Tetracera* species have pollen dimorphism. We have studied 31 pollen specimens of bisexual and male flowers of 15 *Tetracera* species by LM and SEM. 6 of them are from Old World and have only 3-colporate pollen as other species in subfamily Tetraceroideae. 11 male flowers patterns and 2 bisexual flowers patterns (*T.tigarea*) have 3-colporate pollen grains, 11 bisexual flowers pollen patterns are cryptoporate. Exine is tectate, microperforate, endexine is very thin. Round pores are disposed in endexine. However, species have different number of pores, their exposition are not similar too. So, *T.parviflora* have 3-8-cryptoporate pollen grains with exposed pores. Endopores in *T.willdenowiana* pollen are hardly observed. We have found 1 specimen (*T.jamaicensis*) with a combination of 3-5-multicryptoporate, 3-porate and 3-short-coporate pollen. True cryptoaperturate pollen is known also for some species of *Crameria* (Crameriaceae), but its exine and apertural structure is quite distinct. This phenomenon and its significance have discussed.

P0540. Pollen morphology of the genus *Patrinia* Juss. (Valerianaceae) and its systematic implication

E. H. Jung, J. H. Song, S. P. Hong;
Laboratory of Plant systematics, Department of Biology, Kyung Hee University, Seoul, Republic of Korea.

Pollen of 17 taxa (13 species, 2 subspecies, 2 varieties; 40 specimens in total) of the genus *Patrinia* Juss. in Valerianaceae was examined with LM, SEM, and TEM. Pollen grains are mostly medium to large in size, tricolpate (rarely tetracolpate) with the characteristric halo surrounding the aperture, and oblate to prolate-spheroidal in shape.

In equatorial view, the pollen is elliptic to circular, and in polar view, they are mostly circular or rarely 3-lobed. The ornamentation of exine is echinate and the exine thickness is uniform throughout. Two major pollen types can be recognized on the basis of exine sculpturing patterns; - (1) Type I: exine is composed of only echinae (1.0-4.0 µm) without micro-echinae, and verrucae shallow (0.3-3.8 µm, in most taxa) or rarely absent (in *P. speciosa*). (2) Type II: exine is composed of massive echinae (4.0-8.0 µm) together with sparsely or densely micro-echinae, and prominent verrucae (4.0-7.4 µm, in *P. gibbosa*, *P. saniculifolia*, *P. triloba* var. *palmata* and *P. triloba* var. *triloba*). The earlier infrageneric classification systems of *Patrinia* are evaluated on the basis of the present data.

P0541. Pollen morphology of the Astragaleae (Leguminosae, Fabaceae) in Queretaro, Mexico

D. L. Quiroz, M. L. Arreguín;
Instituto Politécnico Nacional, México, D.F., Mexico.

The pollen of 13 genera and 40 species of the tribe Astragaleae (Leguminosae, subfamily Fabaceae) from the state of Queretaro is described and illustrated. Observations of pollen grains were carried out under light microscopy (ML) and scanning electron microscopy (SEM).

In the Astragaleae the occurrence of single grains is a constant feature. The principal differences in pollen among the various species involved size, shape, and sculpture pattern. The common type, occurring within the largest number of genera (8) is the tricolporate, reticulate single grain. *Coursetia*, *Cracca*, *Indigofera* and *Psoralea* have 3- colporate pollen grains with a microreticulate to tectate-perforate sexine. The pollen grains of *Brongniartia*, *Dalea*, *Harpalice* and *Marina* are 3-colpate with a microreticulate sexine. *Astragalus*, *Diphysa*, *Eysenhardtia*, *Piscidia* and *Tephrosia* have 3-colporate pollen grains with a microreticulate sexine. The pollen of the Astragaleae is rather heterogeneous; however must be emphasised the limited use of the apertural types when not considered in conjunction with the exine characters.

P0542. Pollen diversity in Mexican and Central American species of *Mimosa* (Leguminosae, Mimosoideae)

A. Martínez-Bernal, **R. Grether**, M. Fraile-Ortega, S. Camargo-Ricalde;
Depto. Biología, División CBS, Universidad Autónoma Metropolitana-Iztapalapa, Mexico, D.F., Mexico.

About 115 species of *Mimosa* occur in Mexico and Central America, belonging to the five sections of the genus. Their pollen diversity includes that of the whole genus, with polyads, bitetrads, and tetrads of diverse shapes and sizes. Sect. *Mimadenia* groups mainly vines with 12-16-grained polyads (Southern Mexico to Brazil, Ecuador, Peru, and Bolivia). Sect. *Batocaulon* (Southern USA to Argentina), includes mainly shrubs and trees with bitetrads, which relate this section to the Old World species of *Mimosa*. Sect. *Calothamnos* (Guatemala to Argentina), *Habbasia* and *Mimosa* (both from Mexico to Argentina) share the pollen grains arranged in tetrads. Although these three tropical sections group trees and shrubs, the latter includes most herbaceous species with the smallest tetrahedric tetrads. Pollen diversity contributes important systematic characters for understanding the relationship among infrageneric taxa of *Mimosa*. Bitetrads found in a species of sect. *Mimadenia*, and rarely observed in sect. *Mimosa*, suggest a link with members of sect. *Batocaulon*. Furthermore, polyads in sect. *Mimadenia* support the relationship between *Mimosa* and *Piptadenia*.

P0543. Pollen tube behaviour of the "feronia" mutant in Arabidopsis thaliana

J. M. Escobar, N. Huck, V. Gagliardini, J. Gheyselinck, U. Grossniklaus;
Institute of Plant Biology, University of Zurich, Switzerland.

Accomplishment of fertilization in higher plants requires the direct interaction of male gametophytes, i.e. pollen and pollen tube, with the female reproductive organs including the female gametophyte (embryo sac). In wild-type plants the pollen tube enters the degenerated synergid, arrests and releases the sperm cells, which are targeted to the egg and central cell, respectively. The female gametophytic mutant *feronia,* shows a failure in the direct interaction of pollen tube and embryo sac. In this mutant pollen tubes continue to grow inside the degenerated synergid and get tangled up within the micropylar tip of the female gametophyte. The study of synergid marker expression and the ultra-structural analysis of female gametophytes suggest that the synergids are normally specified and differentiated in mutant embryo sacs. Therefore the defect in *feronia* is likely due to the disruption of a direct interaction between the male and female gametophyte. We will report on the molecular isolation of FERONIA, which provides new insights into this novel signaling pathway in flowering plants

P0544. Angiosperm micropyle selects a single pollen grain from many for fertilization

A. Sogo, H. Tobe;
Graduate School of Science, Kyoto University, Kyoto, Japan.

In contrast to gymnosperms, whose naked ovules usually receive many pollen grains, angiosperm ovules enclosed in a pistil receive only a single pollen (tube) for fertilization. The pollen tube is guided by and reaches the embryo sac through tissue of the pistil. To discuss where and how a pollen tube is guided and selected, we show that in *Fagus japonica*, where ovules are immature at pollination, growth of the pollen tube stops at the ovarian locule and micropyle, then grows intermittently in three steps for about 5 weeks. In the 1st step, the pollen tube proceeds irrespective of mature sporophytic tissue in the ovule and differentiation of the embryo sac; step 2 proceeds after formation of ovular sporophytic tissue and differation of the embryo sac; step 3 occurs after maturation of the embryo sac. Pollen tubes are guided to the micropyle by sporophytic tissue in the pistil, and from the micropyle to the embryo sac by the embryo sac itself. Besides, the micropyle selects a single pollen grain from among what have survived after competition in the pistil. The selection of a single pollen grain by the micropyle may have contributed to the explosive evolution of angiosperms.

P0545. Investigation of the reproductive potential of Serbian spruce - correlations of microstrobiles, pollen and seed properties

B. Batos, B. Nikolic;
Institute of forestry, Belgrade, Serbia and Montenegro.

Endemic and relic tree species, Serbian spruce (Picea omorica Panc./Purkyne), is especially significant for the region of the Balkan Peninsula. The study of the genetic potential of the reproductive material of this conifer (microstrobiles, pollen and seed) contributes to the provision and availability of good-quality seed and plants. The observed material originated from 25 test trees in forest plantation at the locality Bela Zemlja near Užice in Serbia and Montenegro. Morphological and physiological properties of microstrobiles, pollen and seed (dimension, vitality, germination percentage) on the level of the population and on the level of theindividual tree were analysed. Results have shown the diversity structure and the potential of this population. This potential is important for the further breeding of Serbian spruce and for application in forestry and in environmental protection.

P0546. Pollen studies in the subfamily Bromelioideae (Bromeliaceae)

B. A. Moreira, M. A. V. Cruz-Barros, M. G. L. Wanderley;
Instituto de Botânica, São Paulo, Brazil.

Bromelioideae is the most diverse subfamily of Bromeliaceae, mainly distributed in Brazil. It is considered an euripolinic group and has some genus with a complex circumscription. In order to support a better classification in Bromelioideae were studied the pollen morphology of 30 species in the genera: *Acanthostachys* (1), *Aechmea* (9), *Billbergia* (2), *Edmundoa* (2), *Fernesea* (1), *Nidularium* (12), *Quesnelia* (2), and *Wittrockia* (1), which 14 species are analysed for the first time. The material was submitted to lactic acetolize, measured and applied statistical treatments with graphic representation, described and photomicrographed under light and SEM. The pollen grains vary from medium to large size, elliptical, ovulate or subrectangular amb, porate or colpate, exine reticulate or rugulate. The preliminary results separate some species through morphologic types as a size, form and aperture that were considered important diagnostics characters for some genus and species.

P0547. The pollen morphology of the wild Primula L. (Primulaceae) species in Turkey

N. Pinar, D. Doĵ an, G. Akgül, F. Geven;
Ankara University, Faculty of Science, Ankara, Turkey.

8 species (P. davisii W. W. Sm., P. vulgaris Huds., P. veris L., P. elatior (L.) Hill., P. megaseifolia Boiss & Bal. Ex Boiss, P. longipes Freyn & Sint., P. auriculata Lam. & P. algida Adams) and 7 subspecies (P. vulgaris Huds. subsp. vulgaris, P. vulgaris Huds. subsp. sibthorpii (Hoffm.) Smith & Forr., P. veris L. subsp. columnae (Ten.) Lüdi., P. veris L. subsp. macrocalyx (Bunge) Ludi., P. elatior (L.) Hill. subsp. meyeri (Rupr.) Val. & Lam., P. elatior (L.) Hill. subsp. pallasii (Lehm.) Smith & Farr. and P. elatior (L.) Hill. subsp. pseudoelatior) of Primula L. (Primulaceae) were studied palynologically by light and scanning electron microscopy . The pollen is tricolpate, triparasyncolpate, polycolpate or spiraaperture with reticulate sculpturing. Aperture of Primula taxa are changing from polycolpate to triparasyncolpate-tetracolpate, from primitive to progressive. Two pollen variants are distinguishable the short -styled species have bigger pollen and thicker exine and intine than the long-styled species.

P0548. Palynology of the Anacardiaceae: Tribe Spondieae

T. Tangtragoon, K. Oeggl;
Institute of Botany, Innsbruck, Austria.

The pollen morphology of the Anacardiaceae is studied to contribute to the systematic position of the family. At present 32 species belonging to 17 genera of the tribe Spondieae are investigated by light and scanning electron microscopy. The Spondieae pollen is characterized by 3-colporate (rarely 4-colporate) isopolar and monads. Their size and the P/E ratio averages between 21.7 to 82.1 and 0.79 to1.53 µm respectively. Pollen grains are prolatespheroidal, subprolate and prolate and they show a circular outline in polar view. The pori are mostly lalongate, rarely lolongate and vary in size. The exine thickness varies between 1.6 to 3.4 µm. The sexine is generally thicker than the nexine. Various sculptuing of the tectum is found from psilate-perforate, striate-reticulate, striate-rugulate and striate. Seven pollen types are recognized and three groups of preliminary phylogenetic morphological trends emerge from this study. These present pollen morphological results support the existing taxonomic investigations by macro morphology and molecular studies.

P0549. Microsporogenesis in Thalassia testudinum Banks ex Köning

R. Wong, B. I. van Tussenbroek, J. Márquez-Guzmán;
Universidad Nacional Autónoma de México, México, D.F., Mexico.

Thalassia testudinum is a marine angiosperm from the (sub-) tropical Western Atlantic. The species is dioecious. Present work concerns the development of male reproductive structures (microgametogenesis) and the microstructure of the pollen grains. Male floral buds at different stages of development were collected during late-winter and spring of 2001 and 2002. Part of this material was fixed in FAA and processed for paraffin inclusion, and the microtome cut sections were stained with the safranin-fast green technique. The rest of material was fixed in glutaraldehyde-paraformaldehyde s-collidine buffer, included in LRwhite and cut with a glass knife to obtain 1 m thick sections in ultramicrotome. These preparations served to present a first accurate description of Thalassia testudinum male flower development. The wall of the anther was of monocot type, the microsporogenesis is successive with linear isobilateral and T-shape tetrads and the tapetum is atypical periplamodial. The mature pollen grains were round with a thin exine layer with microequinate ornamentation.

P0550. Pollen morphology of *Acalypha* (Euphorbiaceae) in the Malesian Region

V. G. Sagun[1,2], G. A. Levin[1,2];
[1]Center for Biodiversity, Illinois Natural History Survey, Champaign, IL, United States, [2]Department of Plant Biology, University of Illinois, Urbana-Champaign, IL, United States.

In the Malesian region, about 30 species of *Acalypha* are recognized out of the 450 species known worldwide. Pollen diversity in *Acalypha* was previously examined in 73 species representing most of the taxonomic diversity in the genus using LM, SEM, and TEM. Results show that *Acalypha* pollen has two main types of exine ornamentation, one having a microrugulate to rugulate ornamentation with supratectal elements distributed on the margins of the muri, and the other having a nearly areolate ornamentation with supratectal elements scattered all over the pollen surface. These previous observations show that *Acalypha* pollen is not homogenous as described in earlier studies. We report here on the pollen morphology of *Acalypha* in Malesia. Our preliminary findings based on scanning electron microscopy include two new ornamentation types, one having areolate ornamentation with fossulae and scabrae scattered on the areolae; whereas the other exhibits a microrugulate ornamentation with fossulae on the murus. These pollen characters show a possible correlation with macromorphological characters and are potentially significant for phylogenetic analysis.

P0551. Comparative pollen biology of the tropical legume *Indigofera suffruticosa* occurring in Brazilian sea land and savanna disturbed areas

S. P. Teixeira;
Universidade de São Paulo, Ribeirão Preto, Brazil.

Micro morphology, ultra structure and cytochemistry of the pollen grain have been compared with individuals of *Indigofera suffruticosa* from Brazilian sea land (seashore) and savanna (countryside) disturbed areas. Pollen variations have occurred among populations from both vegetal formations. In the savanna, viability and pollen diameter are significantly higher than those found in the sea land. Sexine ornamentation varies from gemmate to perforate. In the vegetative cell cytoplasm mitochondriae are more ovate with well developed and contrasted crests in the savanna; in the sea land mitochondriae are less contrasted with dumbbell-shaped, less evident crests. Pollen grains from the savanna have shown more positive reactions to proteins, lipids and nucleic acids. Sea land individuals do not present abnormalities in pollen grains although there is less pollen viability. It is probable that these individuals have adopted different reproductive strategies for better environment conditions. Mitochondriae, for instance, possibly present different functioning related to their crests, types and quantities of proteins observed on membranes (FAPESP).

P0552. Pollen morphology of the perennial species of genus *Lathyrus* L. (Fabaceae) in Bulgaria

A. G. Tosheva;
University of Sofia "St. Kliment Ohridski", Sofia, Bulgaria.

The pollen morphology of all 19 perennial species from genus *Lathyrus* L. (Fabaceae) distributed in Bulgaria was studied with LO microscope and SEM as a part of biosystematical research. The results reveal that the pollen grains are 3-zonocolporate, elliptical or rectangular in equatorial view, circular to triangular-obtuse-convex in polar view, medium to large in size (P x E = 26.9-66.4 x 20.5-53.7 µm). The aperture system is composed of straight ectocolpi with thick costae along the margins and large, circular or slightly elliptical endopori. The thickness of the exine is 0.6-1.8 µm, the sexine usually as thick as the nexine. The infratectum is composed of rods and rarely of granules. The ornamentation in mesocolpium is predominantly suprareticulate with small lumina with wide muri. The apocolpium is usually psilate or with scattered puncta. The palynotaxonomical characters studied assign the pollen grains to 3 major pollen types: *subprolate* - sect. *Orobus,* sect. *Lathyrus*; *prolate* - sect. *Pratensis*, sect. *Lathyrostylis* (*L. digitatus*, *L. pannonicus*) and *prolate spheroidal* - sect. *Lathyrostylis* (*L. pallescens*, *L. pancicii*).

P0553. Pollen Morphology of Orobanchaceae Tribe Rhinantheae in Iran

S. Khoshrang Golavar, S. Kazempour Osaloo;
Tarbiat Modarres University, Tehran, Islamic Republic of Iran.

According to molecular data, tribes Rhinantheae (parasite) and Gratioleae (non-parasite), formerly belonging to Scrophulariaceae, have been considered to be members of Orobanchaceae. In this study, light microscopy and scanning electron microscopy, were used to examin the pollen of 11 species of 8 genera the tribe *Rhinantheae* plus *Lindenbergia indica* from *Gratioleae*. The resulting data showed the pollen of Rhinantheae is similar to that of Orobanchaceae s. str. as previously indicated, and thus they are closely related. The grains were typically isopolar tricolpate, radially symmetrical, more or less subprolate. Exine sculpturing is reticulate (*Pedicularis caucasica, Rhinanthus vernalis, Odontites verna*, and *Lindenbergia indica*), retipilate (*Euphrasia pectinata, E .juzepczukii*, *Bungea trifida*, and *Parentucellia latifolia*), perforate-rugulate (*Odontites aucheri*), retirugulate (*Bellardia trixago*), and scabrate-verrucate (*Rhynchocorys maxima* and *R. kurdica*). It seems that reticulate exine sculpturing is plesiomrphic among taxa studied.

Keywords: Orobanchaceae, Palynology, Rhinantheae

P0554. Echinate Compositae pollen from Middle Russia

I. Bovina;
Moscow State University, Moscow, Russian Federation.

150 species of echinate Compositae pollen divided in 12 pollen-types were studied with special attention to the sculpture. The group with rather small (<1µm) spines includes 6 pollen-types: 1) Echinops - with large pollen grains and two columella layers; 2) Scabiosa - large pollen grains with cavities; 3) Xantium with smaller pollen grains and short colpi; 4) Artemisia - rather small spherical p.g. with long colpi and circle ora; 5) Jacea - rather small elliptic pollen grains with long colpi and oval ora; 6) Cyanus - with verrucate sculpture. The group with big (>2,0 µm) spines was divided into 6 pollen-types: 1) Ambrosia - rather small p.g. with numerous spines; 2) Serratula - rather large p.g. with numerous spines; 3) Tussilago - spines rather high with sharp peaks distanced each other; 3) Bidens - spines have elongated peaks on hemisphere; 4) Helianthus - spines are narrow conic; 5) Cirsium - spines are connected with low bridges; 6) Senecio - spines are broad conic.

P0555. Evolution trends of Asterales sporoderm ultrastructure

S. V. Polevova, I. Bovina, E. Severova;
Moscow State University, Moscow, Russian Federation.

Five ultrastuctural types of sporoderm are known among Compositae: Chuquiraga, Nassauvia, Anthemis, Helianthus, Cichorium. Pollen grains of another Asterales (Goodeniaceae, Calyceraceae, Brunoniaceae) belong to Anthemis type. It is characterized by large columellae based on foot layer. The outer parts of columellae split and form reticulate infratectum. The outermost parts of columellae are straight and make comb-like appendixes connected with tectum. We suppose, this type is inicial for Compositae, through intermediate forms it is connected with Helianthus, Cichorium, Nassauvia types. The Chuquiraga type (subfamily Barnadesioideae) is isolated and most original. Pollen grains of this type have high and thin columellae with lateral appendixes. Appendixes alternate with electron dense granules and form the regular lines. Foot layer is discovered only around apertures. The analysis of Compositae sporoderm structure allows to reveal some evolutional trends: increase in sporoderm thickeness by prolongation and bifurcation of columellae; differentiation of nonapertural parts of ectexine; development of cavities and foramines.

P0556. A Study on Pollen Morphology and Viability of Summer Squash (*Cucurbita pepo* L.)

A. S. Sensoy;
Faculty of Agriculture, Antalya, Turkey.

In this study some pollen grain characteristics (pollen link type, symmetry conditions , pollen size, pore size and pore number) were determined with SEM and viability were evaluated by using staining methods with safranin (Essad 1962), IKI (MacLean and Cook 1941) and Triphenyl Tetrazolium Chlorid (TTC) (Stanley and Linskens 1974), in vitro germination test.. Pollen grains were taken from some inbred lines in I_6 for summer squash (*Cucurbita pepo* L.).

Experiment results showed summer squash pollen's link type is monad, symmetry conditions is isopolar, sizes are 126.3 µ x 117.5 µ, pore sizes are 27.45 µ x 28.86 µ, pore numbers are 11-13. Viability of pollen of summer squash the 28 % pollen viability. In staning methods , pollen viability percentages were found higher than in vitro records. This results showed that stainabilty methods give a rough estimation of pollen viability. Because pollen grains yet to mature and/or unviable may also get stained.

P0557. Earliest records of the angiospermous pollen in Razdolnenskaya basin (the South Primorye)

A. S. Shuklina;
Institute of Biology and Soil Sceinces of Far Earstern Branch of Russian Academy of Science, Vladivostok, Russian Federation.

The angiosperm sequence was studied in the continuous Barremian to the lower Cenomanian of Razdolnenskaya basin. For the first time the angiospermous pollen appeared in the early Albian. These are *Clavatipollenites incisus* Chlon*., C.* sp*., Tricolpites* sp.*, Retitricolpites* sp.

Diversity of angiosperms increased in the middle Albian. *Clavatipollenites hughesii* Coup., *Retitricolpites vulgaris* Pierce, *Asteropollis asteroides* Hedl. et Norr. appeared.

Tricolpites micromunus (Groot et Penny) Singh, *Fraxiniopollenites variabilis* Stanl.*, Rouseia delicipollis* Sriv.*, Polyporites clarus* N. Mtch. appeared in the late Albian, and *Triporopollenites* sp., *Trocolporopollenites* sp. - in the early Cenomanian.

Thus, the first rare angiosperms appeared in the early Albian and their participation and diversity in palynoflora become abundant in the early Cenomanian.

The study was supported by Presidium RAS and FEB RAS (grants 05-1-P12-022, 05-1-P25-078).

P0558. Pollen morphological study of *Halimocnemis*, *Halanthium*, *Halocharis* and allied genera of tribe Salsoleae (Chenopodiaceae) in Iran.

M. -. Ghobadnejhad;
Tehran University, Tehran, Islamic Republic of Iran.

The pollen grains in Chenopodiaceae have been mostly considered to show no variation. Present studies were conducted to evaluate some characters including pore number and pollen diameter as distinctive features taxonomically.The comparative pollen morphology of the genera *Halanthium*, *Halimocnemis*, *Halocharis*, *Petrosimonia*, *Gamanthus* and *Climacoptera* belonging to a problematic complex and microscopic data by LM and SEM are given. Pollen morphological studies of specimens clearly show distinctive position of *Petrosimonia*, with the highest pore number and the least pore number can be seen in *Halocharis*. The obvious different between pore number of the two species of *Gamanthus* suggests that they can be included in different genera.

Different communities of the species *Climacoptera turcomanica* showed different pore numbers distinctively which can be attributed to the possibility that this species can be divided to smaller taxa. The position of the genus *Climacoptera* in pollen pore diagram showed considerable distance from *Salsola* which confirms the acceptance of *Climacoptera* as an independent genus from *Salsola*.

P0559. Forensic Pollen Evidence from the Clothes by the Tape Adhesive Method

C. L. Wu[1], C. H. Yang[1], **T. C. Huang**[2];
[1]Graduate School of Forensic Science, Central Police University, Taoyuan, Taiwan Republic of China, [2]Graduate Institute of Plant Biology, Taipei, Taiwan Republic of China.

Collection and identification of pollen is becoming important in forensic applications. Many criminal cases had reported to link suspects to crime scene by analysis of pollen. Several methods had been used in the pollen collection and analysis, but they are expensive and tedious. Therefore, it is important to develop a simple method to collect pollens from clothes. We tried to recover pollen from clothing surface by using sticky tapes method. Different kind of commercial tapes, textiles and different species of pollen were included in the testing. Result showed that tape D and weave textile S had better adhesion of more pollen than other weave textile. We wear clothes that were made from textile S to collect pollen from 26 different areas mostly in northern part of Taiwan and then used tape D to recover them from different part of body. From this result, we concluded that tape adhesive method is suitable to recover pollen from clothes. We suggested that tape adhesive method could be one of methods for collecting pollen from clothes of suspects. It is simpler, faster and more inexpensive than other methods.

P0560. Nitric oxide (NO) modulates growth and development in *Micrasterias denticulata*

C. Lehner[1], H. H. Kerschbaum[2], U. Lütz-Meindl[1];
[1]Plant Physiology Division, Cell Biology Department, Salzburg, Austria, [2]Animal Physiology Division, Cell Biology Department, Salzburg, Austria.

Nitric oxide (NO), a key molecule in intracellular signalling, may modulate developmental processes as well as host defense mechanisms. We investigate the effect of NO on developmental stages of the unicellular green alga *Micrasterias denticulata* by use of S-nitroso-N-acetylpenicillamine (SNAP), a common NO-donor, and the donor molecule (N-acetylpenicillamine; NAP) alone. NAP-treated cells show no difference in development when compared to control cells, whereas cells incubated with SNAP are markedly retarded in cell growth. Investigations at the electron microscopic level reveal that the retarded cells lack a secondary cell wall. Moreover, golgi stacks are slightly involute and dictyosomal productivity is reduced. In NAP-treated and control cells both secondary cell wall formation and dictyosome morphology appear normal. Therefore, we conclude that NO either inhibits or retards secondary cell wall formation in *Micrasterias* via altering dictyosomal activity.

P0561. Study of the plant-specific myosin XI class

L. Camacho, P. J. Hussey;
School of Biological and Biomedical Sciences. University of Durham. South Road. DH1 3LE, Durham, United Kingdom.

The correct functioning of plant cells, hence of plant growth and morphogenesis, depends on several processes based on the actin cytoskeleton. Myosins are the motor proteins responsible for the actin-based motility. Phylogenetic analysis revealed that the plant myosin family has evolved in a totally divergent way among eukaryotes, suggesting that plants have adapted differently to fulfill their distinctive lifestyle. Although the currently known myosins have been grouped into 18 phylogenetic classes, all plant myosins seem to fall into only three unique and plant-specific classes - class VII, XI and XIII. In the last decade, a great deal of attention has been given to the study of the function and regulation of the different myosin proteins in animal and yeast cells. However, little is known about the function of specific myosins in plants. We focused our study on class XI of plant myosins, a class structurally similar to myosin V from animals and yeasts, and thought to be involved in vesicle trafficking in plants. The data presented will be discussed on the light of previous ones.

P0562. Acanthochlamydaceae

B. Gao, K. Kubitzki;
Chengdu Library of the Chinese Academy of Sciences, Chengdu, China.

Only one sp., Acanthochlamys bracteata P. C. Kao, subalpine xerophytic valley zone of W Sichuan and SE Tibet, SW China.

Acanthochlamys bracteata is restricted to the Hengduan Mountains at the SE margin of the Kang-Zang Plateau of SW China (Xiangcheng, Daocheng, Daofu of W Sichuan to Zhag'yab of Tibet), where it occurs in the subalpine aciculignose shrub-meadow region at an altitude of 2700-3500m.

The sieve-element plastids of Acanthochlamys differ from those of the Velloziaceae by their lack of loosely-packed crystals and from the Amaryllidaceae and all families of the order Pandanales by their small sizes.

Among all families compared here with Acanthochlamys, the absence of cell wall-bound ferulate is shared only with the Velloziaceae. Thus the morphological data point in the same direction as the molecular analysis, although the relationship between Acanthochlamys and the Velloziaceae may not be very close.

In cladistic analyses of the comparative rbcL data a 100% support for the distinction of Acanthochlamys from the Velloziaceae as well as from the other families of the order was found.

P0563. Differentiation of leaf anatomy of the genera *Dracaena* L. and *Sansevieria* Thunb. (Dracaenaceae).

J. Wiland-SzymaŒska[1,2], M. Klimko[3];
[1]A. Mickiewicz University, PoznaŒ, Poland, [2]Missouri Botanical Garden, St. Louis, MO, United States, [3]August Cieszkowski Agricultural University, PoznaŒ, Poland.

The family Dracenaceae was described by Salisbury in 1866. In recent literature it is said to include two genera: *Sansevieria* Thunb. and *Dracaena* L. or only one - *Dracaena*. Thorough anatomical leaf studies were reported only for *Sansevieria*. Studies under light microscope, SEM and confocal laser scanning microscope on living and dry, dissected material of 20 taxa of *Dracaena* and 10 taxa of *Sansevieria* have indicated, that their leaves show significant differences in sculpture and anatomical structures, which are genus specific. Both qualitative and quantitative characters were taken into consideration. Main dissimilarities are visible in: presence or lack of water tissue, type of stomata, presence or lack of cuticular band around stomata, distribution of stomata and distribution of vascular tissue. Because of specific intermidiate anatomical characters of the leaf lamina, *D. cinnabari* Balf. f. - an Soqotra endemite and *D. ellenbeckiana* Engl., should be regarded as separate cases within this family.

P0564. The occurrence of tubers in Noteroclada confluens Taylor ex Hook. & Wilson

L. Zhang, B. J. Crandall-Stotler, R. E. Stotler;
Southern Illinois University, Carbondale, IL, United States.

Noteroclada confluens is a monotypic, simple thalloid liverwort that grows in moist, montane habitats from Mexico to Tierra del Fuego and southeast Brazil. Surprisingly, we have discovered that 24.3% of 296 specimens studied from across its range produce tubers. These usually arise from branch initials on main stems, but may also develop from main shoot or long branch apices. Mature sporophytes and tubers can be present on the same plant. In some populations, the mature tubers are cylindrical, 0.42-2.52 x 0.23-1.14 mm, but in others even at maturity the tubers are spheroidal, 0.40-1.52 mm in diameter. Populations with cylindrical forms are most common in southern Brazil, while those with the spheroidal forms are more widespread. SEM and paraffin sectioning techniques were used to study the structure and development of these tubers. In young tubers the apical cell is replaced by a flattened meristem; as the tubers mature, both the surrounding leaves and the epidermal cells become thick-walled and the interior cells are packed with large starch grains. It is speculated that the tubers function primarily in nutrient storage and only secondarily as asexual propagules.

P0565. Molecular characterization of a short grain mutant isolated by rice activation tagging

M. Mori;
National Institute of Agrobiological Science, Tsukuba, Japan.

We have generated 13,000 activation-tagging lines of rice. Several mutants including lesion mimic, stripe, dwarf, and short grain were obtained in the activation-tagging lines. By the analyses of a lesion mimic mutant (*Lmm1*), we have already shown that the overexpression of a gene showing sequence similarity to an acyltransferase caused lesion mimic phenotype.

In this research, we analyzed the *Short grain 1 (Sg1)* mutant. When the T-DNA insertion is heterozygous, the grain is small, and when it is homozygous, the grain is very small, indicating that the *Sg1* phenotype is linked to the T-DNA insertion. The *Sg1* plant also shows semi-dwarf phenotype and the phenotype is restored by the addition of gibberellin. A full-length cDNA lies 1.4 kb downstream of the inserted T-DNA and it expresses mainly in the young panicle in wild type. The deduced protein shows no homology with any known proteins. These results strongly suggest that transcriptional activation of this novel gene causes the *Sg1* phenotype.

This work was supported by a grant from the Ministry of Agriculture, Forestry and Fisheries of Japan (Rice Genome Project MP-1203).

P0566. Inhibition of *FLORICAULA/LEAFY* Orthologue Expression with RNA Interference in *Chenopodium rubrum* L.

J. Veit[1], J. Prusinska[2], E. Wagner[1], J. T. P. Albrechtova[1];
[1]University of Freiburg, Institute of Biology II, Freiburg, Germany,

[2]Nicolaus Copernicus University, Institute of General and Molecular Biology, Torun, Poland.

The homologous transcription factors *FLORICAULA* of *Antirrhinum* and *LEAFY* of *Arabidopsis* share conserved roles in floral meristem identity and floral patterning. We have identified the *C. rubrum FLO/LFY* orthologue (*CrFL*), that showed changed expression during flower induction. To determine the FLO/LFY role in the floral development we suppressed its expression using the RNAi method. For this purpose, we constructed the binary vector pFGC5941 containing a 35S-promoter sequence followed by a cDNA fragment of the *CrFL* in sense orientation, an intron of the CHSA-gene and a second copy of the cDNA fragment of *CrFL* in antisense orientation. To introduce this T-DNA construct into *C. rubrum* we established a protocol for efficient *Agrobacterium*-mediated transformation through floral dip method. Herbicide selection and PCR analysis showed a very high transformation rate while using the optimized protocol. The phenotypes of transformed plants were analyzed.

P0567. On Specificity of Functional Organization and Individual Development of Modular Objects

A. A. Notov;
Tver State University, Tver, Russian Federation.

Functional specificity determines many peculiarities of individual development, ecology and evolution of modular objects. Principal difference of modular organization is that development function and regulation are connected with changes of object macrostructure. Dynamic macrostructure determines the instability of boarders of a system, high degree of interaction of main elements of organization, complexity in their splitting and independent investigation. The description of macromorphological structure includes the analysis of its dynamic and functional aspects. It makes very actual the development of theoretical model of modular object morphology. Function and development of modular objects are similar to those in population systems. Analysis of function, individual development and structural evolution of modular objects compared with unitary organism shows lower degree of integrity, development and transformation of the latter. Numerous analogies between modular and unitary systems allow to use modular organization as a model to clarify the ways of realization of general tendencies of organization transformation.

P0568. Regulation of nitrogen metabolism by amino compounds and cytokinins in poplar

P. Dluzniewska[1], H. Dietrich[1], A. Gessler[1], S. Kopriva[2], M. Strnad[3], O. Novak[3], H. Rennenberg[1];
[1]Institute of Forest Botany and Tree Physiology, Chair of Tree Physiology, Freiburg, Germany, [2]John Innes Centre, Research Park, Norwich, United Kingdom, [3]Laboratory of Growth Regulators, Palacký University & Institute of Experimental Botany, Olomouc, Czech Republic.

In the present study the effects of additional supply of glutamine or cytokinin on nitrate net uptake and expression of genes involved in N reduction were addressed in young poplar trees. Incubation of poplar roots in media containing either Gln or cytokinin (zeatin riboside, ZR) resulted in a decrease of N net uptake. Plants fed Gln revealed significant enrichment in Gln and other amino compounds of different tissues. Exogenous supply of t-ZR induced variable, incubation time-dependent expansion of the pool of Z-type CKs, while the levels of amino compounds accumulated in the tissues, were comparable to controls. Expression level of nitrate reductase in fine roots was higher as a result of the cytokinin treatment. Gln fed plants showed reduction of NR expression. Expression of the cytosolic glutamine synthetase was changed or not influenced by the treatments, dependent on the time of root incubation in the media. From these results, regulation of N-uptake at the whole plant level is discussed. The presented work was performed in collaboration with the Poplar Research Group Germany.

P0569. Leaf anatomy and its relation to the ecophysiology of 30 weed species of different seasonal performances

G. M. Fahmy[1,2], A. K. Hegazy[3], M. I. Ali[3], N. H. Gomaa[4];
[1]Department of Biological Sciences, Faculty of Arts and Sciences, University of Qatar, P.O. Box 2713 Doha, Qatar, [2]Permanent address:Department of Botany, Faculty of Science, University of Cairo, Giza 12613, Egypt, [3]Department of Botany, Faculty of Science, University of Cairo, Giza 12613, Egypt, [4]Department of Botany, Faculty of Science, University of Cairo (Beni-Suef Branch), Beni-Suef, Egypt.

The present work demonstrates the leaf anatomy of 30 weed species representing winter, summer and all-year weeds. The species were collected from the field crops of Beni-Suef governorate, Egypt. Some anatomical differences were observed between the leaves of the different weed groups. Such differences may be related to the seasonal variations in climate. Compared to winter weeds, the investigated summer weeds possess higher stomatal and trichome densities as well as higher leaf specific conductivity (*LSC)*. Moreover, summer weeds exhibit lower calculated hydraulic conductance (*Kh)* of tracheary elements supplying the transpiring areas*,* laminal area and stomatal spacing than winter weeds. For all-year weeds with either winter or summer affinity, the stomatal density is generally higher in summer than in winter season. In general, the laminal area, *Kh*, and number of tracheary elements of petiole or petiolule are significantly higher in winter than in summer season for the studied all-year weeds with winter affinity. On the other hand, the all-year weeds with summer affinity show an opposite behaviour.

P0570. Physiological Phenomena in a Range of Seeds Drawn From the New Zealand Flora

D. W. Fountain[1], A. C. MacKay[1], C. R. McGill[2], R. C. Southward[2], K. L. Kitchen[2], J. Clemens[1], M. C. Debenham[1], G. Schmidt-Adam[1], H. A. Outred[1];
[1]Institute of Molecular BioSciences, Massey University, Palmerston North, New Zealand, [2]Institute of Natural Resources, Massey University, Palmerston North, New Zealand.

Germination behaviour of seeds of New Zealand's unique flora is imperfectly known. Dormancy status and summary germination phenomenology are reported for a range of species drawn from diverse families of angiosperm seed plants including: *Myrsine australis* (Myrsinaceae), *Coprosma robusta* (Rubiaceae), *Sophora prostrata* (Fabaceae), *Muehlenbeckia australis* (Polygonaceae), *Leptospermum scoparium* (Myrtaceae), *Hebe stricta* (Scrophulariaceae), *Myosotidium hortensia*(Boraginaceae), *Euphorbia glauca* (Euphorbiaceae), *Cyperus ustulatus* (Cyperaceae), *Carex trifida* (Cyperaceae), *Phormium tenax* (Agavaceae), *Vitex lucens* (Verbenaceae), *Laurelia novae-zelandiae* (Monimiaceae), *Pachystegia insignis* (Asteraceae), *Dacrycarpus dacrydioides* (Podocarpaceae) and *Rhopalostylis sapida* (Arecaceae). Population heterogeneity, germination kinetics, dormancy mechanisms where present, seed structure, fruit-seed relationships and dispersal modes are discussed.

P0571. Influence of osmotic potential and imbibition period on priming efficience in folk silk tree seeds

S. C. Juliano Gualtieri de Andrade Perez[1], S. F. Caldeira[2], L. P. Silva de Moraes[1], C. A. Barbieri Jr[1];
[1]UFSCar, S. Carlos, Brazil, [2]UFMT, Cuiabá, Brazil.

The positive results of priming, mainly in agricultural crops, confirm its potential to improve seed and seedling vigor, but there is a lack of information about the results in Brazilian wood native species, due the wide flora biodiversity. *Chorisia speciosa* (St.Hil) (Bombacaceae) is a deciduous wood species, occurring in several Brazilian states. It is cultivated in gardens, squares, city avenues, and indicated for mix plantations in disturbed areas. Intact seeds were primed in distilled water and PEG solutions (-0.2; -0.4 and -0.8 MPa) during 24, 48 and 72 hours at 27^{o}C. The seeds were washed, dried until reach the initial weight and after exposed to thermal stress at 50^{o}C during 24, 48 and 72 hours. It was registered a decrease in the rate and germination percentage, seedling emergence and dry mass, as the thermal stress intensity increased. Priming did not overcome this effect. It is possible to conclude that PEG solutions decrease seed vigor, detected by conductivity and germination tests, but no rule could be established in relation to solution concentration, for all the tests. There was a negative effect on seed and seedling vigor as the imbibtion time increased.

P0572. Response of symbiotic and nonsymbiotic *Chlorella* to norflurazon

G. Kovaļ eviĺ [1], N. Ljube iĺ [2], B. Jeleņ iĺ [1], M. Kalafatiĺ [1];
[1]Faculty of Science, Zagreb, Croatia, [2]RuĽer Bo koviĺ Institute, Zagreb, Croatia.

The effect of norflurazon on endosymbiotic *Chlorella vulgaris* Beij. [K&H, 1992] from green hydra (*Hydra viridissima* Pallas, 1766) and asymbiotic *Chlorella kessleri* Fott et Novak. [K&H, 1992] was researched. In this work we observed the difference in response to norflurazon between high-related algae in symbiosis and out of it. Norflurazon causes the “bleaching effect” upon the newly developed chloroplasts. Organisms were treated with aqueous solutions of norflurazon (2x10^{-4}, 2x10^{-5}, 2x10^{-6}, 2x10^{-7} and 2x10^{-8} mol/L) in glass dishes, and in tubes on deep stock agar in the laboratory conditions. Depending on the concentration, norflurazon caused cytological and ultrastructural changes that were observed with binocular light microscope and TEM. Of special significance were the antichloroplastal and antimitochondrial effect. Newly developed endosymbiotic algae in green hydra were not bleached. The “bleaching effect” was present only in algae out of symbiosis, with deleterious effect upon algal thylakoidal system. Mitochondria were swollen and torn apart. Endosymbiotic alga was less damaged at all than alga out of symbiosis.

P0573. Structural and functional changing in generative organs of Siberian coniferous species under ecological stress and there biotechnology in culture in vitro

I. Tret'yakova, N. Noskova, **A. Ivanova**, N. Novoselova, A. Vyazovetskova;
V.N. Sukachev Institute of forest SB of RAS, Krasnoyarsk, Russian Federation.

Unfavorable ecological factors influences on generative organs of Coniferous species. Under the global climate warming the absent of organic dormancy in male generative buds of Siberian larch and Scotch pine in winter is observed. An early meiosis, a great number of abnormalities in the meiotic division process as well as gametophyte formation result in formation of sterile pollen, also in a weak pollination and, as a result, in a weak (or in absolute absence) cone and seed yield. Pollen sterility increases in regions with a high technogenic pollution. To overcome sterilizing and breeding improved tree genotypes of conifers species the studies of reproductive processes in culture in vitro were carried out. The cultivation of microsporophylles of Siberian larch and Scotch pine in the autumn-winter period resulted in formation androgenous callus and embryoids. Cultivation of immature zygotic embryos at the early differentiation stage promoted getting somatic embryoids and plantlets of Siberian larch and Siberian pine. Thus, androgenic cultures and somatic embryogenesis open the way for obtaining the high-value productive Siberian coniferous trees.

P0574. Seed germination of Dalbergia miscolobium Benth. a savannah tree species from Brazil.

C. A. Barbieri Jr.[1], S. C. J. Perez[1], A. G. Ferreira[2];
[1]UFSCar, São Carlos, Brazil, [2]UNB, Brasília, Brazil.

Dalbergia miscolobium Benth. (Papilionaceae) is a common tree in Brazil Cerrado biome. We describe the germinative behavior of D. miscolobium seeds, under 12 different isothermal temperatures (10, 15, 20, 24, 27, 30, 34, 38, 40,44, 48 and 50°C), water stress simulated with PEG 6000 solutions(0,-0.2,-0.3,-0.4,-0.6,-0.8,-1.0, -1.2 MPa) and thermal stress (60 and 70°C during 24, 48 and 72 hours) and the imbibition water uptake. The phase 1 of imbibition ends around 28h and the phase 2 extend nearly to 116 hours of the germination process. The optimal temperature for the germination is around 30°C and the optimal range of for germination were between 20 and 40°C. The cardinals temperatures for germination were between 10,15°C (lower limit) and 48, 50°C (higher limit). The limit of germination under water stress was between -1.0MPa and -1.2MPa and seed viability decreases with the increase of thermal stress. We conclude that D. miscolobium is a eurithermic,thermal and water stress tolerant species. Such large tolerance limits can partially explain the biogeography and the wide area where this species is nowadays scattered.

P0575. Sudden shifts in stress coping strategies along stress gradients: A case study on shoot stiffness in salt marshes

J. M. Sarneel[1,2], T. J. Bouma[1], N. P. R. Anten[2], J. van de Koppel[1];
[1]Netherlands Institute of Ecology, Yerseke, The Netherlands,
[2]Department of Plant Ecology, Utrecht University, Utrecht, The Netherlands.

We hypothesized that along stress gradients, sudden shifts between alternative stress coping strategies may occur. This was tested in vegetation in tidal habitats where hydrodynamic forces increase with decreasing elevation towards the sea. Species growing at the lowest elevations can survive the high forces there either by producing very flexible stems and go with the flow or tolerate it with very rigid and strong stems. We characterized the mechanical properties of the shoot (length, Diameter, Young’s modulus [E], breaking stress [$\mathring{u}_b$] and flexural stiffness) for ten species, and integrated these into the overall flexibility and strength of the entire shoot. Overall shoot strength and flexibility were found to be either very low or very high in species around the sea border and intermediate for species at higher elevations. Differences in overall flexibility and strength were mostly correlated with variation in diameter and height and less with E and $\mathring{u}_b$. These results confirm our hypothesis and were integrated into a general conceptual model.

P0576. Investigation of some physiological responses of two *Aeluropus* species to water deficit and salinity

F. -. Abbassi, F. -. Abbassi;
Islamic Azad University, Mashhad, Islamic Republic of Iran.

In the present investigation, stomatal resistance, soluble sugers, proline content and proxidase ensyme activities of two *Aeluropus* species (*Aeluropus littoralis and A. logopoides*) was studied in response to water deficit and salt stress. A completely randomized factorial design with four replications and different combination of four levels of water deficit(-0/3,-0/5,-10 and -15 bar), four levels of salinity (0, 20, 25 and 30 dSm^{-1}) and two species of *Aeluropus* was used under glasshouse conditions. Water deficit was induced by weight method on the basis of the amount of water lost each day. Salt stress was made by addition of sodium chloride to the initial water applied. One month after stresses were imposed, two-weekly interval stomatal resistace recorded, and after two months soluble sugers and proline content, proxidase enzyme activities were measured. Results showed that by increasing water and Salt stress, stomatal resistance was first increased and then started to decrease. Soluble sugers and proline content and proxidase activities were also increased in response to both types of stresses.

P0577. Boron remobilization in *Olea europaea* L. is regulated by external boron supply

G. Liakopoulos, S. Stavrianakou, E. Karvonis, K. Vekkos, A. Klouvatou, E. Resta, D. Nikolopoulos, G. Karabourniotis;
Agricultural University of Athens, Athens, Greece.

Boron (B) is an essential micronutrient for higher plants. Although B remobilization is restricted in many plant species, sugar-alcohol-B complexes may be translocated from developed (source) to developing (sink) organs in species that export sugar-alcohol photoassimilates in the phloem sap. In the present study, physiological factors affecting the process of B remobilization in *Olea europaea* were studied under various (adequate to deficient) levels of B supply. It was found that the concentration of B in the cell sap of source-leaf tissues is the main factor affecting the amount of B loaded in the phloem sap. Therefore, under adequate supply, higher amounts of B were remobilized, compared to those under deficient conditions. However, B deficiency dramatically increased the relative amount of B (expressed as the ratio of phloem sap B / cell sap B of the corresponding leaves) that was remobilized from source leaves. In these leaves, phloem sap mannitol concentration was 2-fold higher under deficient compared to adequate conditions. It is suggested that, in this plant species, mannitol is involved in the regulation of B remobilization as a response to B deficiency.

P0578. Phenolic content from different cultivars of sugarcane juices in response to smut, leaf scald and yellow leaf syndrome

M. E. Legaz[1], B. Fontaniella[2], M. C. Molina[2], C. Vicente[1];
[1]Complutense University, Madrid, Spain, [2]Rey Juan Carlos University, Madrid, Spain.

Sugarcane juices contain different phenolic acids which can appear both as free and conjugated forms. The aim of the present study was to compare the variation of phenolic concentration in response to different sugarcane diseases by using healthy (as control) and inoculated plants.

To study smut, two cultivars were chosen My 55-14 (resistant) and Ba 42-231 (susceptible). Distribution of free and conjugated forms can be related to resistance phenomenon. For studying leaf scald, L55-5 and C439-52 cultivars. were selected . This second cultivar resulted more susceptible on the basis of its phenolic conjugation pattern; a decrease of free forms in parallel to the increase of conjugated ones.

Yellow leaf syndrome was studied in C120-78 and C87-51 cultivars, both susceptible to phytoplasma. Both cultivars showed a begin of defence response in inoculated plants on the basis of the undergo increase of, principally free, and secondarily conjugated phenolics

P0579. Influence of plant growth regulator obtained on the basis of biocompost on growth parameters and phytopathogen resistance of winter wheat seedlings

M. Volkogon, I. Dragovoz, L. Kryuchkova;
Institute of Plant Physiology and Genetics, Kiev, Ukraine.

Influence of aqueous extracts and alkaline hydrolysate of biocompost separately and in combination (1:1 ratio) on seedlings growth parameters was studied. In first case the effect was gained due to phytohormones-stimulators presence. Alkaline hydrolysate effect was generated by the means of humic and fulvic acids. Investigated preparation was created on the basis of those products. It was studied as plant growth regulator under the steady state conditions as well as under plants infection with phytopathogens. Seedlings treatments with this preparation partially or fully decrease negative effect of seedling’s diseases on growth parameters under the artificial infection. It was established that preparation increases plant resistance to eyes pot, due to papilla formation and decrease fungi penetrations number.

Treatment with the experimental preparation ensures possibility of plant’s self-defense potential including mechanism of infection avoidance by the means of papilla formation, fungicidal and fungitoxical effects as well as reduction of pathogens influence on plant growth and productivity due to the preparation’s growth stimulatory effect.

P0580. The foliar and cambial responses of *Syzygium cumini* (L.) Skeels to coal-smoke pollution

M. Jacob[1], .. Mahmooduzzafar[1], P. Kojs[2], M. Iqbal[1];
[1]Jamia Hamdard, New Delhi, India, [2]Centre for Biological Diversity Conservation of the Polish Academy of Sciences, Warszawa, Poland.

This study reveals responses of blackberry tree to varying degree of coal-smoke pollution with specific reference to leaf behaviour and the cambial growth patterns. Leaf area, stomatal size, and stomatal index were markedly reduced under the pollution stress, compared to the control. The chlorophyll and carotenoid contents showed a reverse correlation with the degree of pollution as did the net photosynthetic rate, NR activity, protein content and nitrogen content of leaf. Stomatal conductance dropped to its lowest, whereas intercellular CO_2 increased at the most polluted site. Sugar content declined, showing a negative correlation with sulphur content. The total span of cambial activity did not alter, though the cambial reactivation was delayed by about two months under heavy pollution stress. Duration of phloem formation was reduced, whereas that of xylem formation extended. Annual wood accumulation increased at the polluted site, and the vessel elements, narrower but longer unlike the fibres, occupied a relatively small transectional area in the wood. These changes influenced the vulnerability factor and mesomorphic ratio of the test trees.

P0581. Seed formation in species with underdeveloped embryo *Pulsatilla vulgaris* Mill. and *Helleborus niger* L. (*Ranunculaceae*)

O. G. Butuzova;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

Seed formation in *Pulsailla vulgaris* Mill. and *Helleborus niger* L. characterized by the phenomenon of underdeveloped embryo, was studied. The following common features in this process were revealed: occurrence of endosperm cavity around embryo, zonality in endosperm structure, early accumulation of nutriments in embryo and endosperm, early specialization of seed coat, prolong functioning of micropylar and chalazal seed structures etc. These peculiarities were already noted for other plants with underdeveloped embryos.

The main differences between the species given concern the degree of embryo differentiation at the moment of dissemination (*P.vulgaris* - torpeda-shaped, *H.niger* - heart-shaped stages), the term of certain structures function (antipodes, podium, nucellar cap) and proceeding of some processes (nutriments accumulation, specialization of seed coat elements). This appears to be associated with different types of seed dormancy that reflects adaptation to various environmental conditions: *P.vulgaris* - forest-steppe plant with morphological seed dormancy; *H.niger* - alpine one with morphophysiological seed dormancy.

P0582. Leaf behaviour, cambial activity and wood production in *Azadirachta indica* A. Juss. as affected by coal-smoke pollution

M. Iqbal[1], J. Jura[2], W. Wloch[2], **.. Mahmooduzzafar**[1];
[1]Jamia Hamdard, New Delhi, India, [2]Silesian University, Katowice, Poland.

The study elucidates responses of neem tree (*Azadirachta indica* A. Juss.) to varying degree of coal-smoke pollution with specific reference to foliar traits and the cambial growth patterns in the stem, as observed in different seasons of an year. Leaf pigment concentrations, NR activity, reducing sugar and total N-content declined, whereas stomatal index and the nitrate and S-contents increased with growing pollution load. Stomatal conductance was low but internal CO_2 concentration of leaf was high, leading to a drop in the net photosynthetic rate under pollution stress. Cambial reactivation in the stem was delayed. Although the total span of radial growth got reduced, more wood was produced at the polluted site. Vessel proportion in the wood increased, whereas size of vessel elements and xylem fibers decreased. Vulnerability factor and mesomorphic ratio were inversely proportional to pollution stress, indicating a situation of growing water stress and a consequent tendency of plants for shifting towards xeromorphy. The mode of carbon-partitioning rather than the photosynthetic rate seemed to have influenced the process of wood formation in the species.

P0583. Effect of chlormequat (CCC) on growth and chemical composition of Ficus benjamina L. plant

M. M. Farahat;
National Research Center, Cairo, Egypt.

In greenhouse trials , Ficus benjamina L. plants were subjected to one of the following treatments.CCC at 0, 1000, 1500, 2000 ppm. CCC treatments were added to the growing medium (Sphagnum peatmoss + sand 1:1 v/v) drench , 25 ml / plant bimonthly alternately. CCC at 1000 ppm increased No. of internodes and their length, plant height, No. of leaves and branches , leaf measurements, total leaf area / plant, plant canopy, root length and FW&DW of leaves, branches , shoots, roots and whole plants. Oppositely, it decreased stem diameter, dry leaves/ branches ratio and K% in roots. CCC at 1500 ppm caused an increment in internodes length, carotenoids and phenols contents in leaves, N% in branches& roots and P&K% in branches. Whereas, it decreased stem diameter and T.C. % in roots. CCC at 2000 ppm increased dry leaves/ branches ratio, T.C.% in branches, N&P% in branches& roots and K %, indoles, phenols& amino acids in leaves. While, it decreased stem diameter and DW of leaves, branches , shoots , roots and whole plant.

P0584. Effect of salinity and drought on proteins and antioxidant enzymes in seedlings of two Astragalus species

V. Niknam, K. Shahgholi, H. Ebrahimzadeh;
Department of Biology, Faculty of Science, University of Tehran, Tehran, Islamic Republic of Iran.

The genus Astragalus is generally considered the largest genus of vascular plants with an estimated 2500-3000 species. The greatest numbers of species are found in the arid, continental regions of Western North America and Central Asia. In this research we investigated the effects of NaCl (0-200 mM) and drought (PEG 4000, PEG 6000 & Mannitol, 0-20%) on the germination percentage and some biochemical parameters in seedlings of A. squarrosus and A. microcephalus. According to the obtained results seedlings of both species tolerated NaCl up to 150 mM, PEG 4000 and PEG 6000 up to 15 % and mannitol up to 10 %. Protein and proline content was determined by the spectrophotometric method and SDS-PAGE system was used for the study of qualitative changes of proteins under stress and for comparison of protein profile in seeds of different species. Isoforms of some antioxidant enzymes such as peroxidase, catalase and polyphenol oxidase in seedlings were characterized by PAGE.

P0585. Rapid response reactions of plant shoots on changes in sodium chloride concentration at the root zone

N. V. Budagovskaya[1], V. I. Guliaev[2];
[1]Institute of Plant Physiology, Moscow, Russian Federation, [2]All-Russian Institute of Genetics and Breeding of Fruit Plants, Michurinsk, Russian Federation.

Use of a highly sensitive method (accuracy 0.07 µm) - laser interference auxanometry - made it possible to study rapid (min) and slower (h) response reactions of leaves and stems of wheat, oat, barley, rice and buckwheat plants on increase and decrease in NaCl concentration at the root zone. Addition of NaCl in increased concentration to the root zone of plants caused a two phase response reaction of leaves: decrease and the following increase in their growth rate in each phase. Duration of the 1st phase was 3-fold shorter than of the 2nd. Growth rate of leaves was restored by the end of the 2nd phase (few hours after addition of NaCl). The 1st phase may be related to rapid adaptive reactions and changes in leaf turgor, the 2nd - to slower adaptive processes - *de novo* synthesis of protectors. Introduction of NaCl in high concentration caused stoppage in leaf and stem growth and shrinking of their tissues (for 30-60 min) as result of dehydration. Washing the roots of NaCl rapidly restored the turgor of leaves and increased their growth rate. The data obtained provide information on dynamics of response reactions of shoots on increase and decrease of NaCl concentration at the root zone.

P0586. New plant type architecture for drought and salt tolerance of rice (*Oryza sativa* L. ssp. indica)

C. Kirdmanee[1], S. Cha-um[1], P. Supalerkbandit[2], P. Wanichananan[1], D. Boozaya-angoon[3];
[1]National science and Technology Development Agency, National Center for Genetic Engineering and Biotechnology, Pathumthani, Thailand, [2]Thamasat university, Pathumthani, Thailand, [3]Rice research Center, Pathumthani, Thailand.

Phenotype expressions of aroma rice were evaluated the specific characterizations of drought tolerant, drought sensitive, salt tolerant and salt sensitive lines under *in vitro* environmental control system. Vigorous root system was higher in drought and salt tolerant lines than those in drought and salt sensitive lines. The root length and root area of drought tolerant line were longer than those of drought sensitive line. Number of root and root area of salt-tolerant line were bigger than those of salt sensitive line. The osmotic potential of root increased with increasing the root surface area. High osmoprotactants, proline and betain contents, were observed in the salt-tolerant line, resulting in high osmotic potential of root and high survival under salt stress. Rice composed of vigorous root system; high osmoprotactant and high net photosynthetic rate show the high growth rate and high yield. This new plant type has been used for rice breeding program.
II.

P0587. Physiological aspect of hyacinth response to ethephon

M. V. Semenova, E. B. Kirichenko;
"N.V. Tsitsin" Main Botanical Garden, Moscow, Russian Federation.

Effect of ethephon (2-CEPA) on plant growth, physiological properties and floral stalk topple of hyacinth in the course of greenhouse forcing was studied. The significant inhibition of growth and the changes in biometric and anatomical parameters of two cultivars (Carnegie and Jan Bos) were revealed. As a consequence, the floral stalk topple was prevented. This morphogenetic effect was shown to be cultivar-specific, the response of Carnegie was more pronounced as compared with that of Jan Bos. The temporary decrease in chlorophyll content in the leaves of cv. Carnegie was detected. However chl. a/chl. b and chls/cars ratios were similar for two cultivars. The prevention of floral stalk topple due to ethylene effect was accompanied by decrease in chlorogenic acid content and increase in carbohydrates and bound forms of cytokinins and abscisic acid in the tissues. This work was suppoted by the Ministry of Education and Sciences of RF (project HScSc-1864.2003.4) and by RAS (Programme “Fundamental basis of bioresources management”).

P0588. A study of the different substratum influence to the root development of Picea abies L.Karst. and Pinus silvestris L. seedlings

V. Golubovic-Curguz[1], D. Vilotic[2], M. Veselinovic[1];
[1]Institute of forestry, Belgrade, Serbia and Montenegro, [2]Faculty of forestry, Belgrade, Serbia and Montenegro.

For a successful afforestation it is necessary to be used the nursery plants which are with except well developed over ground parts, and also must have quite well developed root system. The well branched root swelling need the lateral roots of first, second and third orders. Significant for operating all of root system are rootlets responsible for water absorption and minerals supply from the soil.
In the study is shown how strong is the influence of the used substratum type to
development of root system of seedlings in the nursery plantation.
The carried out sowing of seed *Picea abies* L. Karst. and *Pinus silvestris* L. in the substratums of peat and humus taken from the natural sources, which were different in the texture and chemical composition.
The experiment applied in the five variations of substratums, pure or in mixed combinations of them. During the fertilization the regular steps of nursering and followed the development of seedlings in all of variants. A morphometric seedling root analysis was done at the end of vegetation.
The results of this study confirmed that the used type of substratum had a very significant influence to the seedling root development.

P0589. Accumulation and intracellular localization of heavy metals in tolerant plants.

M. Nadubinska[1,2], V. Banasova[1], O. Horak[2], M. Ciamporova[1], D. Gruber[2], I. K. Lichtscheidl[2];
[1]Institute of Botany, Bratislava, Slovakia, [2]Institution of Cell Imaging and Ultrastructure Research, Vienna, Austria.

Phytocoenological investigations of former mining and industrial sites in Slovakia and Austria revealed species-poor vegetation with a dominance of some heavy metal tolerant plants. Extreme concentrations of Pb, Zn and Cd in soil were found in Arnoldstein (Austria) and Banská Štiavnica (Slovakia); Cu was abundant in Banská Bystrica (Slovakia).
The total and water soluble metal content of plants and soil was measured by plasma emission or atomic absorption spectroscopy. Heavy metal uptake and accumulation differed substantially between accumulator plants (*Thlaspi caerulescens*, *Arabidopsis halleri*) containing more than 1 % of Zn, and excluders (*Silene vulgaris*).
For plant specific localization, we combined tissue-specific EDX - scanning electron microscopy with fluorescent labeling in live cell. A proper fluorescent marker was selected and its concentration assessed. This new approach allowed to localize zinc to vacuoles of leaf epidermis and also to some mesophyll cells of *T. caerulescens.* This correlates well with the finding that more than 70 % of Zn in plant are water soluble.
Supported by SAIA/ÖAD Aktion #46s5; VEGA #2/5086/25; and HSJS Stadt Wien.

P0590. Comparison of leaf anatomical characters in some CAM plants of the Crassulaceae

T. Rózsavölgyi, E. Mihalik;
University of Szeged, Szeged, Hungary.

The aim of this work was to compare the stomata frequency, the presence/absence and quality of epidermal appendages and the dimensions of the mesophyll cells in five species adapted to different environmental conditions. (Kalanchoe daigremontiana, K. fedtschenkoi, K. tomentosa, Crassula multicava and Cotyledon ladysmithiensis). These plants have leaves with different level of succulence (ratio of leaf area and leaf thickness). The highest succulence level has been detected in Cotyledon plants together with the lowermost stomata number and largest mesophyll cells. The succulence and stomata number of the three Kalanchoe species are different. The less succulent Kalanchoe daigremontiana bears twice as much stomata, than the former plant. Although the succulence of K. tomentosa is near to Cotyledon, the stomata number is the highest among species, indicating that there is no direct relation between the stomata number and the succulence. We also estimated the contribution of the epidermal appendages in the environmental adaptation. The level of the taxonomic relationship is not reflected in the anatomical characters.

P0591. Optimal photosynthetic capacity of nitrogen fixing plants: Is it larger than photosynthetic capacity of nitrogen absorbing plants?

Y. Osone;
Forestry and Forest Products Research Institute, Tsukuba, Japan.

Some higher plants acquire nitrogen (N) needed for the growth by symbiotic associations with microorganisms that fix atmospheric dinitrogen (N_2). The symbiotic N_2 fixation has been considered to be especially important for plants inhabited in the environments where N severely limits plant growth. However, as do the systems that absorb nitrogen from soil solutions, symbiotic N_2 fixing systems require a great carbon input for constructing and maintaining the specific apparatuses and assimilating N_2. Thus, too much carbon allocation to N_2 fixation decreases plant growth rates, while it could increase N concentration in plants and hence photosynthetic capacity (P_{max}). We presented a model analysis of optimal photosynthate allocation to N fixation and optimal photosynthetic capacity that maximize the growth rate of N_2 fixing plants. The model predicts that optimal photosynthetic capacity of symbiotic N_2 fixing plants is smaller than that of N absorbing plants under a wide range of nitrogen availability. However, this result contrasts to the general observation, which reason is also discussed.

P0592. Morphological and anatomical adaptations of some species of aquatic macrophytes to sazonality of Pantanal Mato Grossense, Brazil.

E. Scremin-Dias;
Universidade Federal de Mato Grosso do Sul, Campo Grande, Brazil.

Pantanal Mato-Grossense, the biggest flooded plain in South America, is located in middle west of Brazil. In this ecosystem there is a great diversity of macrophyte species belonging to different botanical families. These plants present peculiar morphological and anatomical adaptations, large phenotypic plasticity and, most of them, are amphibian species, occurring even in aquatic environment as in soil free of flood. Species of Onagraceae, Alismataceae, Pontederiaceae and Polygonaceae were collected and prepared to Light Microscopy and Scanning Electron Microscopy. Avoiding species to stress imposed by aquatic environment present frequently typical aerenchyma, heterophylly, submerse thin leaves, bright cuticule, characteristics observed in several species of these families. Some species of Onagraceae and Pontederiaceae are tolerating to stress imposed by aquatic environment. Quantitative and qualitative analysis of morphological and anatomical variations related to flood and dry seasons in Pantanal, and the peculiar aspects of some species are presented.

P0593. Study of quantitative and qualitative changes of proteins and polyphenol oxidase in several plucking from Iranian tea leaves

H. Sobhanian, H. Ebrahimzadeh, V. Niknam, S. Safarian, M. Habibi, A. Bagheri;
Tehran University, Tehran, Islamic Republic of Iran.

Polyphenol oxidases (PPO) can hydroxylate monophenols to o-diphenols and oxidate o-diphenols to o-quinones. The oxidative and hydrolytic enzymes endogenous to tea shoots are crucial for generation of various characteristic quality attributes of black tea. Plant materials of Iranian fresh tea leaves plucked from a farm located in the north of Iran. Protein was determined by the method of Lowry et al. (1951), and Bradford (1976). PPO activity was determined at 410 nm. Electrophoresis, pH optima, thermal stability, Substrate specificity, effect of inhibitors and optimum temperature also studied. We found optimum temperature for sample 1 to 3, 35,40 and 30 °C respectively. Optimum pH was 8.6 for sample 1 and two pH for either sample 2 and 3, 5.2 and 7.2 for 2 where as, 4.8 and 7.9 for 3. In thermal stability sample 2 showed higher thermal sensibility than the others. We found some substrates with no activity with sample 2 but with a high activity in the others. The effect of five inhibitors, namely NaCl, glycin, ascorbic acid, L-cysteine and sodium azide on crude Iranian tea PPO activity were studied. We found all by inhibitory effect with different inhibitory potential.

P0594. Stress-induced flowering in *Arabidopsis thaliana*? Effects of mineral nutrition deficiency on *A. thaliana* flowering.

J. Kolar;
Institute of Experimental Botany, Prague 6, Czech Republic.

Flowering is regulated by many cues (e.g. photoperiod). In some species, it is accelerated by abiotic stresses. This may enable plants to “escape” severe stress by producing seeds. We studied how nutritional stress affects flowering of *Arabidopsis thaliana*.
Ecotypes Col and Ler were supplied with 1% or 100% Hoagland solution (H). In one experiment, plants were continuously grown in these solutions in 2 daylengths (8 h, 12 h). When compared to 100% H, Ler grown in 1% H had fewer leaves at anthesis but flower bud appearance and anthesis were delayed. All these parameters were strongly affected by photoperiod in 100% H but much less in 1% H. Similar results were found in Col.
We also tested the response of Col to a change in nutrient supply. Plants were initially grown in 100% H and the solution was then changed to 1% H. These plants developed flower buds and opened flowers earlier and after making fewer leaves than controls kept in 100% H.
Continuously poor mineral nutrition appears to delay *Arabidopsis* flowering and reduce its sensitivity to photoperiod. In contrast, flowering is accelerated by a sudden decrease of nutrient levels.
Supported by grant KJB600380510 from GAAV CR.

P0595. Structure and ultrastructure of stigmatic papillae of *Datura stramonium* L. during its development

H. ghasempour, M. Aliasgharpoor, A. Movafeghi, M. Dadpoor;
University of Tabriz, Iran, Tabriz, Islamic Republic of Iran.

Structure and ultrastructure of papillae at the surface of stigma of *Datura stramonium* L. (Solanaceae) were investigated using light and transmission electron microscopy. In the course of development, papillae progressively covered the stigma as unicellular structures, then lysed and detached from its surface. Papillae as well as underlying stigmatic cells showed high secretory activity. Secretion began very early in the 20-25 mm long buds. In this stage, electron dense droplets were observed at the surface of the endoplasmic reticulum, in the cytoplasm and in the vacuoles. Electron density of these components after post-fixation with OsO4 and their capacity for staining with Sudan Black B and Auramine O revealed their lipoid nature. In the mature stigma droplets increased in number and formed large lipoid bodies under the cuticle and on the stigma surface. This procedure caused the cuticle to rupture and become distanced from the cell wall. It seemed that a part of lipoid exudates passed through the ruptures and reached the stigma surface. The existence of these ruptures may facilitate the passage of the lipoid material that occurs also through the thin cuticle.

P0596. Sterile mutant of Verbena hybrida induced by heavy-ion beam irradiation and wild species V. peruviana exhibit self-incompatible phenotype.

H. Saito[1], Y. Hayashi[1], T. Kanaya[2], K. Suzuki[2], T. Abe[1];
[1]RIKEN, Wako, Japan, [2]Suntory Flowers Ltd., Higashiomi, Japan.

Garden verbenas (Verbena hybrida) belonging to the Verbenaceae family are originated from interspecific hybridization among several species, many cultivars frequently produce seeds. Recently, a sterile mutant has been isolated in the verbena cultivar ‘Coral Pink’ of Temari series (Suntory Flowers Ltd., Tokyo, Japan) by mutation induction using heavy-ion beams at RIKEN Accelarator Research Facility (RARF, Saitama, Japan). We investigated pollen and ovule fertility assessed by acetocarmin staining, seed-set following controlled-pollination tests and behavior of pollen tubes in pistils with the sterile mutant of ‘Coral Pink’ (SC) and its original fertile one (FC). As the results, although SC has functional male and female gametes, few self-pollinated flowers carry out seed-set, leading to sterile phenotype. Additionally, the sterile mechanism of SC was compared with the wild species V. peruviana (VP) which is one of origin of Temari series and exhibits sterility. Interestingly, similar phenotype was observed in PV. We further investigated, therefore, whether there are differences on self-incompatible reaction between SC and VP.

P0597. An investigation on pollen tube growth and embryo development of tomato (*Lycopersicon esculentum* Mill.)

N. -. Ercan;
Faculty of Agriculture, Antalya, Turkey.

In this study the development of the pollen tubes into the styles was investigated using the fluorescence method according to Kho and Baer (1968). For this study, flower buds were emasculated before anther dehiscence and pollinated by hand on the day of anthesis.Ten tagged flowers were collected 3, 6, 12, 24, 48, 72 h after pollination and scored pollen tube growth according to a method by Henny (1981).

For embryo development, flower specimens were taken at daily intervals starting one day after pollination up to ten days. Flowers were fixed in FAA for 24 hours, dehydrated in a graded ethanol series and embeded in paraffin. Sections of ovary in 5-8 µm thickness were stained with Haematoxylen according to Brooks (1950).

After germination on the stigma, pollen tubes developed into callose plugs inside the styles and kept moving in bundles until they reached the carpels.

During the ovule-related experiment, pseudoembryo formation was observed beside normal embryo development.

Detailed results and illustrations will be presented in the text.

P0598. Sperm-Biased Mutation Transmission in Plants: Discovery and Explanatory Models

M. O. Johnston[1], C. Whittle[2,1];
[1]Dalhousie University, Halifax, NS, Canada, [2]University of British Columbia, Vancouver, BC, Canada.

Here we report results of two separate studies showing that sperm carry more mutations than eggs in both gymnosperms and angiosperms, and then we present simple models of optimal allocation to repair of sperm versus egg. In the first study, we compared the substitution rates at neutral sites of maternally and paternally inherited organellar DNA in gymnosperms. Sperm were found to transmit a greater number of mutations in both mitochondrial and chloroplastidial DNA. Second, we used UV-B and UV-C to induce deleterious mutations in A. thaliana. Analysis of grand-offspring (F2) showed that a successful sperm on average carried more deleterious mutations than a successful egg. These mutations were induced in somatic tissues and were passed to the gametes. Finally, simple models are constructed to study the effects of several factors on the optimal allocation to repair of sperm versus eggs. When benefit-cost curves differ, optimal allocation to repair is lower for the gamete type having the more-efficient repair. In addition, optimal investment in repair of sperm is lower with increased levels of self-fertilization and with decreased levels of inbreeding depression.

P0599. Neogene Plant Cuticles and Environmental Changes from Yunnan, Southwest China

B. SUN, D. Yan, S. Xie, L. Xiao, L. Wei;
College of Earth and Environmental Science,Lanzhou University, Lanzhou, China.

Neogene and Paleogene plant fossils in China are mostly impression and seldom compression fossils. Recently, abundant plant fossils were found in the Neogene from Tengchong and Baoshan in Yunnan Province, Southwest China. These fossils were collected from the Nanlin Fromation (Miocene) and Mangbang Formation (Pliocene). It is noticeable that a lot specimens have good cuticles owing to conserving condition and fine lithologic character. Among them. Some angiosperm cuticles (*Carpinus subcordata* Nathorst, *Ulmus harutoriensis* Oishi et Huzioka, *Quercus pannosa* Hand-Mazz, *Nothaphoebe cavaleviei* Yang and so on) were anatomized. The stomatal parameter of *Carpinus subcordata,* which indicates that atmospheric CO_2 concentration in Neogene, is higher than that of today. By comparing the cuticular characteristic of *C. subcordata* with that of its NLR, *C. cordata*, we conclude that Neogene climate in western Yunnan is warm and humid, belonging to torrid zone to sub-torrid zone or warm temperate zone. This work was supported by the NSFC (40372012), Key Project of Science and Technology of Educational Ministry of China (104177), NSF of Gansu, China (ZS031-A25-002-Z).

P0600. Seed dispersal in the pre-Mediterranean, relict Coriaria myrtifolia: an evolutionary interpretation

J. L. Medina-Gavilán[1], N. Gassó[2], R. Salguero Gomez[3];
[1]Universidad de Cádiz, Puerto Real (Cádiz), Spain, [2]CREAF-Universitat Autònoma de Barcelona, Barcelona, Spain, [3]Universidad de Sevilla, Sevilla, Spain.

The evolutionary history of the plant-disperser mutualism has been rarely examined. In particular, few studies have explicitly examined seed dispersal systems of plant species known to be relict taxa in their present-day environment. Moreover, seed-dispersal biology in the genus Coriaria is virtually unknown. Here, dispersal system of Coriaria myrtifolia L., a fleshy-fruited shrub, were explored. It is a typical representative of relict plant taxa of Tertiary origin that make up a great part of the present-day Mediterranean flora.

Current relationships between C. myrtifolia and its vertebrate dispersers in NE Spain, for summer 2004, were analysed. The main dispersers were found to be mammals, specially Martes foina. Seeds were dispersed in apparently unfavourable microhabitats, rarely more than 2-3 m from mother plant.

A primary adaptative role of its infrutescence to endozoochory versus a possible defensive role of fruit pulp is also discussed. Besides, a relationship between fruit-size and dispersers were examined to genus level, on the basis of that fruit size appears to be more sensitive to dispersers-driven selection than other fruit traits

P0601. The *Glyptostrobus europaeus* whole-plant in the Pliocene fossil forests of Italy

E. Martinetto[1], A. Cerutti[1], J. Van der Burgh[2];
[1]Dipartimento di Scienze della Terra, Torino, Italy, [2]2Laboratory of Palaeobotany, Budapestlaan 4, NL-3584 CD, Utrecht, The Netherlands.

Foliage, seeds and cones of *Glyptostrobus europaeus* (Taxodiaceae, or Cupressaceae s. l.) are very common within muddy sediments in several Pliocene fossil forests of northern and central Italy. Recent investigations in the Stura di Lanzo site showed that the plant bearing the *Glyptostrobus europaeus* foliage, also produced stumps and logs with the recently defined *Glyptostroboxylon rudolphii* wood-type, which is diagnostic for the genus *Glyptostrobus.* Also in the spectacular fossil forest of Dunarobba (central Italy) conifer foliage, seeds and cones belong uniquely to *Glyptostrobus europaeus.* The wood-type, formerly identified as *Taxodioxylon gypsaceum*, has been re-assigned to *Glyptostroboxylon rudolphii*. A third analogous example concerns a fossil forest preserved in the Pliocene succession of the Upper Valdarno basin. The numerous and huge upright trunks of these three sites provide a good example of what was the habit of the *Glyptostrobus europaeus* whole-plant, the more common and largest tree growing in the local swamps at that time.

P0602. Yakima Canyon permineralized plants: a lens into the Miocene

M. Tcherepova, **K. B. Pigg**;
Arizona State University, Tempe, AZ, United States.

The Yakima Canyon of central Washington state, USA contains a diverse middle Miocene permineralized "bog" flora of fruits, seeds, leaves and other remains. The suite of taxa occurring at the different florules within the flora represent a wetland (swamp) community and elements from the adjacent slopes. Our studies of the past decade have provided highly detailed systematic information about several genera at Yakima, including Woodwardia, Liquidambar, Quercus and Taxoduim. Also present are Vitis, Nyssa, Paliurus, Pinus, Osmunda, Meliaceae and the newly described lythraceous fruit Shirleya. We now wish to use the plants from the Yakima flora as a focal point for interpreting the diversity of genera that are also known as compressions, pollen and petrified wood in the Columbia River Basin. From this study we will gain a better understanding of the Neogene fossil record of several important taxa and their critical taxonomic characters.

P0603. Diversity and dynamics of Holocene mangroves of the western Ganga Brahmaputra Delta, India.

A. K. Hait[1], H. Behling[2];
[1]City College, Calcutta, India, [2]Geowissenchaften, Universitat Bremen, Bremen, Germany.

The coastal areas of western GB Delta are covered by extensive mangrove forest, the Sundarbans. The forest is considered as the world’s largest single continuous tract of mangrove forest. *Avicennia* is the dominant forest type followed by *Excoecaria, Phoenix* and *Ceriops*.

Pollen analytical studies on sediment deposits collected from different parts of the western GB delta also reveals the presence of a mangrove ecosystem in the area since the last 9000 years. Palynological data indicates rapid sea level change during the early to mid Holocene limited mangrove ecosystems on the southernmost plain of the GB Delta. From the mid-Holocene onward, mangrove forests spread south eastward. The development of mangrove forest during this time has been in response to altered sedimentation rates as sea level rise decelerated and increased rate of sediment accumulation came into balance with the rate of subsidence. As a result of these factors, along with high fresh water influx after the mid Holocene, progressively more luxuriant growth of mangrove began to inhabit the southern and south eastern Sundarban region to along what is now the present day coast.

P0604. History of formation of forests in the plain part of Ukraine in the Holocene

L. G. Bezusko[1], A. G. Bezusko[2], S. L. Mosyakin[1], Z. M. Tsymbalyuk[1];
[1]M. G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv (Kiev), Ukraine, [2]National University Kyiv-Mohyla Academy, Kyiv (Kiev), Ukraine.

The authors analyzed and generalized the results of palynological and radiocarbon-dating studies of Holocene deposits of the forest, forest-steppe and steppe zones of Ukraine. Based on the obtained data, we reconstructed the pattern of main changes of vegetation and climate starting from 10,300 years BP. We consider changes in forest vegetation of the studied area in the Early (PB-1, PB-2, BO-1, BO-2, BO-3), Middle (AT-1, AT-2, AT-3, SB-1, SB-2, SB-3) and Late Holocene. For most important forest-forming trees (species of *Pinus*, *Betula*, *Alnus*, *Quercus*, *Tilia*, *Carpinus*, *Fagus* etc.), the main periods of their maximum participation in Ukrainian forest vegetation were identified. Broadleaf forests and mixed forests with participation of broadleaf trees were most widespread in Ukraine 4,500-6,200 years BP. During the second phase of the Atlantic time of the Holocene the northern border of the steppe zone in Ukraine was stable. Expansion of forest communities in the steppe zone progressed through gradual increase of forest areas that originally occurred in floodplains and ravines.

P0605. The Late Pleistocene/Holocene record of environmental history from the Bulgarian Black Sea coast

M. V. Filipova-Marinova[1], E. Bozilova[2];
[1]Museum of Natural History, Varna, Bulgaria, [2]Biological Faculty of Sofia University, Sofia, Bulgaria.

Lacustrine sediments of eight coastal lakes and marine sediments of 17 cores from the shelf, continental slope and deep-water area were subjected to pollen and dinoflagellate analysis and provide Late Pleistocene/Holocene record of vegetation dynamics, human impact, and climatic changes along the Bulgarian Black Sea coast. According to pollen record open steppe communities dominated by cold resistant and heliophillous taxa such as Artemisia, Chenopodiaceae and Poaceae prevailed during the Pleniglacial and during the Stadials of the Late Glacial. Climate must have been cold and dry. Only during the Bølling/Allerød Interstadials of the Late Glacial the increase of Pinus diploxylon indicates certain improvement of climate. Two lines of vegetation dynamics during the Holocene could be distinguished. Along the Northern coast xerophytic communities dominated. Only during the climatic optimum (Atlantic) steppe-forest communities occured. Along the Southern coast the migration of arboreal taxa started after 9945±160 BP from their Late Glacial refugia. Human impact from the Eneolithic and Early Bronze Age is also registered.

P0606. Evolution of plastid genomes within the parasitic flowering plant genus *Cuscuta*

K. Krause, S. Berg, K. Krupinska;
Institute of Botany, Kiel, Germany.

The holoparasitic plant genus Cuscuta comprises species with full photosynthetic capacity, and functional chloroplasts, achlorophyllous species and intermediate forms with restricted photosynthetic activity and degenerated chloroplasts. Compared to nonparasitic plants, extensive deletions have taken place in the plastid DNA of achlorophyllous species encompassing photosynthetic as well as regulative genes, while green species like *C. reflexa* have retained most of the plastid genome. Transcription of the *C. reflexa* ptDNA resembles that of nonparasitic higher plants regarding promoter structure and transcription patterns but shows marked differences in the steady state RNA profiles. In intermediate species, genes for the photosynthetic apparatus were retained while the *rpo* genes coding for the plastid-encoded RNA polymerase that is responsible for their transcription were lost. Concomitantly, adaptations within the plastid genome have occurred that enable transcription mediated exclusively by a nuclear-encoded plastid RNA polymerase. Thus, Cuscuta is an interesting model for the evolution of reduced organellar genomes.

P0607. Phylogenetic relationships among algal streptophyte and embryophyte lineages based on chloroplast genome evolution

J. Lee[1], J. R. Manhart[2];
[1]Seoul National University, Seoul, Republic of Korea, [2]Texas A&M University, College Station, TX, United States.

Our understanding of chloroplast genomic evolution has expanded by the increased availability of complete genomic sequences in green plants. The known embryophyte introns and five operons in about 30 genera from all major lineages of algal streptophytes were surveyed and analyzed. The survey indicates that Streptophyta sensu lato cpDNAs contain psbB and rpl23 operons, and that derived charophytes are distinguished from primitive charophytes by the presence of introns previously only found in embryophyte cpDNAs. Derived charophytes have similar operon structures involving clpP and 3' rps12 operons that are not found in primitive charophytes. In addition, the complete sequences of two charophyte chloroplast genomes suggest that the five operons and all embryophyte introns are of a charophyte origin. However, some algal streptophyte lineages experienced gene transfer, intron loss, and/or genomic rearrangement possibly associated with the loss of inverted repeats. Phylogenetic relationships of algal streptophytes and embryophytes were constructed using genomic changes including the gain/loss of matK and the loss of chloroplast rpl5, chlI, and tufA.

P0608. The chloroplast genome of the charophycean green alga *Chara vulgaris*

C. Lemieux, C. Otis, M. Turmel;
Universite Laval, Quebec, PQ, Canada.

It is well recognized that land plants arose from green algae belonging to the Charophyceae. Of the five orders recognized in this class, the Charales and Coleochaetales are thought to be the closest relatives of land plants. We compared the chloroplast DNA (cpDNA) sequence of *Chara vulgaris* (Charales) with those of *Chaetosphaeridium* (Coleochaetales) and the liverwort *Marchantia*. Like the latter cpDNAs, *Chara* cpDNA features a quadripartite structure with two copies of a rRNA-containing inverted repeat separating large and small single-copy regions. At 184,933 bp, *Chara* cpDNA is substantially larger than *Chaetosphaeridium* and *Marchantia* cpDNAs. Considering that all three genomes share a very similar gene repertoire, the lowest density of coding sequences is found in *Chara* cpDNA. Gene order is highly conserved in the three genomes. Two group I and 16 group II introns reside in *Chara* cpDNA; 13 of these introns share homologs at identical positions in both *Chaetosphaeridium* and *Marchantia* cpDNAs. Overall, our results support the idea that the typical features of land plant chloroplast genomes were gained in the green algal ancestors of all terrestrial plants.

P0609. Complete structure of the chloroplast genome of the duckweed, Lemna minor

A. V. Mardanov, N. V. Ravin, B. B. Kuznetsov, T. V. Kolganova, K. G. Skryabin;
Center “Bioengineering”, Moscow, Russian Federation.

We determined the complete nucleotide sequence of the chloroplast genome of the duckweed, Lemna minor(araceae, monocots). It is a circular DNA molecule, 157 kb in size, and is composed of a large single copy region of 17 kb, and a pair of inverted repeats regions of 26 kb each. we compared the sequence to other published chloroplast genomes to infer the location of putative genes. When the inverted repeat is considered only once, we assigned 115 genes, of which 81 could encode proteins, 30 encode tRNAs and 4 encode rRNAs. Most putative protein coding genes appear to start with on ATG codon, but we also detected other possible start codons, some of which, as well as appasrent stop codons in the putative genes, suggest RNA editing. A comporative analysis among angiosperms showed that the Lemna minor chloroplast genome was more similar to that of some dicots(Calycantus floridins, Panax schinseng, Nymphea albe, etc) then to chloroplast genomes of monocots belonging to the grass family (rice, maize, wheat and sugarcane). This work was supported by a grant from the Russian Academy of Sciences.

P0610. Comparative phylogenetic analyses of cryptophyte nuclear, nucleomorph and plastid genes

K. Hoef-Emden, D. H. Tran, M. Melkonian;
Universität zu Köln, Botanisches Institut, Köln, Germany.

The ancestor to the plastid-bearing Cryptophyceae obtained its plastid by engulfment of a red alga. The reduced former red algal nucleus, the nucleomorph, was retained in the cryptophyte cells between the two outer and inner plastid membranes. Thus, cryptophytes are chimaeras with four genomes in a cell.

In this study, genes of the nuclear and nucleomorph ribosomal operons and the plastid gene *rbc*L of several cryptophyte taxa were sequenced and their evolutionary rates and phylogenies compared. In the DNA sequences of *rbc*L, the trees were best resolved with data sets including third codon positions despite of an obvious bias. Seemingly codon biases may support molecular phylogenies in highly conserved sequences of closely related taxa. Whereas the phylogenies were largely congruent in nuclear, nucleomorph and plastid gene phylogenies, differences were found in evolutionary rates of the genes predominantly in clades containing leukoplast-bearing taxa. Possibly nucleomorph and plastid genes of the cryptophytes coevolve as a unit under similar evolutionary constraints.

P0611. Palynological characteristic of the Middle and the Upper Jurassic of the Russian Platform

J. Rostovtseva;
Lomonosov Moscow State University, Moscow, Russian Federation.

The Bathonian, Callovian, Oxfordian palynological assemblages from central region of the Russian Platform are described. The Lower Bathonian assemblage is characterized by predominance of spores (69%), mainly Cyatheaceae (30%) and Gleicheniaceae (8%). The pollen of *Classopollis* occurs only in minor quantity (1,2%) in the Lower Bathonian assemblage and up to 4% in the Upper Bathonian one. The various ancient spores (*Neorastickia rotundiformis, Toroisporites* sp., *Sterisporites incertus*) separate the Lower Bathonian assemblage from others. Five palynological assemblages are distinguished in Callovian deposits. The amount of *Classopollis* is increased up to 33-51% which reflects in warming of climate. Two abundance peaks of marine dinocysts and acritarchs occur in ammonite zones *Proplanulites koenigi* and *Quenstedtoceras lamberti* that indicate two transgressive events during the Early and the Late Callovian Ages. The Oxfordian assemblage is also dominated by dinocysts and green algae (up to 60%). The marine basin had been getting more deep-water for the Oxfordian time.

P0612. Meristem development and dichotomous branching in Selaginella martensii

P. Lu, **J. Jernstedt**;
Department of Plant Sciences, University of California, Davis, CA, United States.

Dichotomous branching is ancestral in vascular plants, and persists in both lycophytes and euphyllophytes. Shoot branching in *Selaginella martensii* was analyzed over time, using sections and a non-destructive sequential replica technique. *Selaginella martensii* exhibits anisotomous dichotomous branching in which the shoot apical cell (AC) is short-lived, determinate, and not directly involved in the formation of either leaf primordia or new branch shoot apical meristems (SAMs). Early growth of new branch SAMs occurs by the activity of a group of apical initials, rather than a single AC, which forms later. The number of cutting faces of an AC (2, 3 or 4) and the direction of AC segmentation (clockwise or counterclockwise) are unrelated to each other and to these attributes of the AC of preceding or successive dichotomies. AC presence and activity in this species varies with the cycle of dichotomous branching.

P0613. The first finding of a new lycopod cone from the Lower Carboniferous of Moscow Region (Russia)

O. A. Orlova[1], A. L. Jurina[1], S. V. Naugolnykh[2];
[1]Moscow State University, Moscow, Russian Federation, [2]Geological Institute, Russian Academy of Sciences, Moscow, Russian Federation.

A new lycopod cone found in a clay shale of the Serpukhovian deposits of Moscow Region. It is attached to a shoot, on which short subtriangular leaves are helically disposed. A lower lateral branch of the shoot bears a spherical strobilus, which is very unusual for Carboniferous lycopod cones. Its apex is a rounded and its base - a wedge-shaped. The strobilus reaches a length of 116 mm and a width of 92 mm. Lanceolate sporophylls with acuminate tops are in the upper part of the strobilus. The strobilus is heterosporous. Mega- and microsporangia are not arranged regularly respect to each other. Numerous microspores of *Lycospora*-type are seen in the distal part of ovoid microsporangia. They have rounded outlines and reach 20-25 µm in diameter. More than one tetrad of the megaspores of the genus *Sublagenicula* are present in megasporangia. Each megaspore has a top shaped as a subgula. Several isolate megaspores and their tetrads are seen in different areas of the strobilus. Megaspores from the strobilus largely vary in their sizes. The research was supported by Russian Foundation for Basic Researches No 03-04-49351.

P0614. Mycorrhizae and Land Plant Evolution

B. Wang, Y. Qiu;
University of Michigan, Ann Arbor, MI, United States.

The successful colonization of the land by plants (embryophytes) is an intriguing subject for plant and evolutionary biologists. The mycorrhizal symbiosis between plants and fungi has been suggested to play an important role in this process. We have conducted a literature survey of distribution of mycorrhizae and mutualistic plant-fungus symbiosis in most families of land plants and mapped these data onto a land plant phylogeny reconstructed using molecular data. This analysis allows assessment of phylogenetic depth and frequency of evolution of mutualistic plant-fungus symbiosis and mycorrhizae. We are also investigating evolution of several plant genes, DMI 1, DMI 2, and DMI 3, which are involved in mycorrhizal symbiosis. We aim to determine their time and mode of origin possibly in charophytes and bryophytes, and to examine their patterns of evolution throughout land plants. These data will help to shed light on evolution of genetic basis of this important ecological trait that enabled plants to invade the land.

P0615. Ashicaulis(Osmundaceae) from the Middle Jurassic, northern China

M. Matsumoto[1], S. Ken'ichi[2], W. Zhang[3], S. Zheng[3], Y. Wang[4];
[1]Chiba University, Chiba, Japan, [2]Natural History Museum and Institute, Chiba, Chiba, Japan, [3]Shenyang Institute of Geology and Mineral Resources, Shenyang, China, [4]Nanjing Institute of Geology and Palaeontology, Nanjing, China.

Ashicaulis(Osmundaceae) is described on the basis of one small-silicified rhizome collected from the Middle Jurassic Tiaojishan Formation in Hebei, China. This specimen consists of a small, upright stem surrounded by frond bases, and adventitious roots. In cross section, the stem ranges from 8.5 to 10.5 mm in diameter with a dictyoxylic xylem cylinder composed of 24-32 xylem strands separated by many leaf gaps. The stem consists of parenchymatous, and a two-layered cortex. Stipular wings have one large sclerotic mass. This is the third structurally preserved rhizome of Ashicaulis from the Mesozoic in northern China. Two fossil species of the genus Ashicaulis, A. hebeiensis and A. liaoningensis, have been described from China and more than 20 species have been found in the higher latitudes of the southern hemisphere, India, and USA, from the Triassic to Early Cretaceous. New species of Ashicaulis adds the further evidence for reconstructing past diversity and geographic distribution of the Osmundaceae, especially in Eastern Asia.

P0616. Origin and evolution of *Ephedra* (Ephedraceae, Gnetales)

Y. Yang;
Institute of Botany, Chinese Academy of Sciences, Beijing, China.

Ephedraceae include a single genus (*Ephedra* L.) and ca. 50 species worldwide. Huang and Price (2003) believe that extant *Ephedra* originated approximately 8-32 Myr ago, but fossil evidence from our study clearly suggests a much older origin. We recently described a new fossil species of *Ephedra* from the Jianshangou Bed in the lower part of the Yixian Formation at Huangbanjigou village, Shangyuan district of Beipiao City, western Liaoning Province, northeast China, which is aged about 126-145 Myr. This new species is closely related to the extant *Ephedra rhytidosperma* Pachomova because they share some reproductive characters, e.g. ovulate cones bearing 2 pairs of bracts and the unique ovules/seeds surface sculptural characters. This finding coupled with other recent discoveries clearly suggests that *Ephedra* has a much older age than previous estimation from molecular studies, and the family Ephedraceae may be more diverse in the Lower Cretaceous/Upper Jurassic.

P0617. Genetic variation and SNP analysis of modern melons compared to a medieval sample

Z. Szabó[1], G. Gyulai[1], R. Lágler[1], A. Bittsánszky[1], J. Kiss[1], L. Horváth[2], L. Heszky[1];
[1]St. Stephanus University, GödöllR, Hungary, [2]Institute of Agrobotany, Tápiószele, Hungary.

aDNA of medieval (15th cent.) melon (*Cucumis melo*) were analyzed and compared to modern melon cultivars (47) with a final attempt to reconstruct the extinct melon. SNPs (single nucleotide polymorphism) were detected in the transcribed spacers (ITS1 and ITS2) of ribosomal DNA (rDNA). Eight of the twenty microsatellite markers amplified a total of 485 SSR alleles. The number of alleles per marker ranged from 2 to 7 with an average of 5.7 including CMCT44 (2 alleles), CMAG59 (5 alleles), CMGA104 (5 alleles), CMCT134 (4 alleles), CMTA134 (6 alleles), CMCTT144 (7 alleles), CMTC168 (6 alleles) and CMCT170 (5 alleles). Sequence analysis of SSRs showed different fragment lengths depending on changes in the number of unit of core sequences. Dendrogram (SPSS11) based on the presence versus absence of SSR and ITS alleles revealed that medieval melon had characters of *inodorus* type melons. *Source of grants: OTKA-M-04563,* OECD-JA00018642, USA-Hungarian Fulbright Commission, and SzÖ-4/2003.

P0618. Cap analysis of common millet cultivars compared to a 15th century sample

R. Lágler[1], G. Gyulai[1], M. Humphreys[2], Z. Szabó[1], J. Sándor[3], A. Bittsánszky[1], J. Kiss[1], L. Horváth[4], L. Heszky[1];
[1]St. Stephanus University, HAS-SIU Research Group, Department of Genetics and Plant Breeding, GödöllR, Hungary, [2]IGER, Aberystwyth, United Kingdom, [3]University of Nitra, Nitra, Slovakia, [4]Institute of Agrobotany, Tápiószele, Hungary.

Common millet (*Panicum miliaceum*) seed remains were excavated from the 15th CENT. layer (King's Palace, Budapest, Hungary). The extracted aDNA was analyzed by ISSR and SSR marker and compared to twenty modern c. millet varieties. SSR sequences at *gln*4, *sh*1, *rps*28 and *rps*15 loci; and a mitochondrial (mtDNA) fragment (*Mbo*I) at 18S-5S-rDNA locus was recovered and sequenced from the medieval millet. Four (*gln*4, *sh*1, *rps*28 and *rps*15) SSR markers amplified orthologous alleles in the 15th CENT. millet. After sequencing the SSR allelles showed identical alignment to modern millet with only one SNP at the 6th position (A to G) at *rps*28 locus. CAP analysis revealed no any SNPs in the restriction sites of six endonucleases *Taq*I, *Bsu*RI, *Hinf*I, *Mbo*I, *Alu*I and *Rsa*I. After cluster analysis, middle age millet showed the closest genetic similarity to a Russian registered modern variety '*Omskoje-9'. Source of grants: OTKA-M-04563, OECD-JA00018642,* USA-Hungarian Fulbright Commission, and SzÖ-4/2003.

P0619. The Preservation of Cytoplasm in Fossil Plants

X. Wang[1], D. L. Dilcher[2];
[1]Nanjing Institute of Geology and Palaeontology, Nanjing, China,
[2]Florida Museum of Natural History, Gainesville, FL, United States.

Cytoplasm is a rare object for paleobiological research. The cytoplasm in extant plants usually is decayed shortly after death. However, this decay process needs to be re-examined in light of new data. The decay of cytoplasm is an organic reaction that needs time and the action of enzymes that are very sensitive to temperature changes. Wildfires are not rare at all geological history. High temperatures of forest fires can stop the decay of cytoplasm and the right combination of temperature and occurrence of the fire can charcoalify plant bodies, including cytoplasm. Charcoal is an inert material frequently seen in the sediments. Based on these knowledge, it is conceivable that cytoplasm fossils should be more common objects for research than previously thought. The never-seen-before fine preservation and ultrastructures of cytoplasm in charcoalified plant debris from the early Cretaceous in Kansas, USA are presented in this paper. Different preservation patterns suggest that at least lightning and wildfires are related to the production of fossil cytoplasm. This conclusion is favored by the experiments with modern plant materials.

P0620. Mitochondrial DNA of early land plants: introns, exons, and spacer evolution in bryophytes

M. Groth-Malonek, T. Rein, V. Knoop;
IZMB - Institute for Cellular and Molecular Botany, Bonn, Germany.

Bryophytes as the basalmost embryophytes play a crucial role in the understanding of mitochondrial evolution in land plants. Intron conservation in the mitochondrial genes nad2, nad4, nad5 and nad7 corroborates the distinctness of the bryophyte classes mosses, liverworts, and hornworts. Positionally conserved introns then provide variable nucleotide sequences which are a useful tool for phylogenetic analyses on lower taxonomic ranks. Few is known so far about conserved gene arrangements in bryophyte mitochondrial DNA.
The gene cluster nad5-nad4-nad2 is known to be co-transcribed in Marchantia polymorpha (liverwort) and conserved in the alga Chara. We have investigated this gene continuity in all three bryophyte classes and observe striking differences in the modes of evolution of the two closely located gene spacers flanking nad4. Analyses of this and other gene arrangements such as the trnA-trnT-nad7 cluster give further insights into evolutionary processes in early land plants.

P0621. Micromorphology of trichomes of *Thymus bracteosus* (Lamiaceae)

M. A. Marin, S. N. Duletic-Lausevic, P. D. Marin, P. Janackovic;
Inst. Botany, Fac. Biology, Studentski trg 16, Belgrade, Serbia and Montenegro.

Thymus bracteosus Vis. ex Bentham (Lamiaceae) is an endemic species distributed at Dinarides. Morphology and distribution of trichomes on the vegetative and reproductive plant parts were investigated using light microscopy and scanning electron microscopy. The plant material was collected during summer 2004. The leaves of *T. bracteosus* bore an indumentum of unicellular papillae, unbranched nonglandular trichomes and glandular peltate trichomes on different stages of development. Numerous juvenile and rare mature peltate trichomes were distributed in epidermal depressions on both leaf sides and on the outer calyx surface. Nonglandular, unbranched, elongated trichomes are especially densely distributed on stem and calyx, while on the leaves were distributed only on leaf margins. Unicellular papillae are distributed on both leaf sides and on the outer calyx surface. The characteristic feature for this species were numerous unicellular papillae which were present on both leaf sides. Distribution and taxonomic significance of various trichomes on vegetative and reproductive parts of this and related, previously investigated species, is discussed.

P0622. Epicuticular secretions on seed surfaces of Massonieae (Hyacinthaceae)

W. Wetschnig[1], G. Prenner[1], E. Stabentheiner[1], M. Pfosser[2];
[1]Institute of Plant Sciences, Graz, Austria, [2]Biologiezentrum d. OÖ Landesmuseum, Linz, Austria.

The Massonieae Baker is a medium sized tribe of Hyacinthaceae subfam. Hyacinthoideae comprising about 16 genera and 230 species distributed from Africa south of the Sahara to Madagascar and India. In the course of our SEM studies we found different types of epicuticular wax cristalloids on the seed coat surfaces in 6 of 14 investigated genera. Wax cristalloids are a common feature of shoot and leave surfaces of angiosperms. But on seed coat surfaces they only have been reported in Orchidaceae and in five families of non monocotyledonous lineages. Analysis of non-coding and coding plastid sequences and of intron structure yielded a monophyletic group only when the genus *Pseudoprospero* was excluded from Massonieae. The remaining taxa can be grouped into 9 highly supported clades (bootstrap support value >90%) and thus present a robust framework for mapping of morphological characters onto a phylogenetic tree. The combination of micromorphological character states with molecular data allowed us to discuss the evolution of such traits in a phylogenetic framework and could be a further step towards a better understanding of Massonieae.

P0623. Morphological variability of leaves in some artificial Birch hybrids.

I. Y. Isakov;
Voronezh State Forest Technical Academy, Institute of Forest Genetics and Breeding, Voronezh, Russian Federation.

The aim of the study was to compare the shape of leaves in artificial hybrids. We studied hybrids from silver birch (Betula pendula Roth, diploid 2n = 28) and downy birch (B. pubescens Ehrh., tetraploid 2n = 56) crossing. We examined this progeny on the basis a 22 - year - old field trial. Mother trees of this two species were chosen in Voronezh State Nature Reserve. The choice was random. Seed progeny of the 1st and 2nd generation received by hybridization, self- and spontaneous pollination are grown in experimental stands. The leaves of hybrids were further examined using morphological method. Ten the leaf characters and pollen size were observed. The leaf characters were scored from 15 randomly collected leaves of one hybrid. Some of the hybrids had B. pubescens morphology as it was expected and some - B. pendula leaf morphology. Only one tree showed continuous morphological variation connecting parent plants. Endogenitic variability of the leaves is not connected with variability of pollen size in this tree.

P0624. Transport-dependent evolution of leaf structure in dicots

Y. V. Gamalei, M. V. Pakhomova, D. R. Batashev, O. V. Voitsekhovskaja;
V.L. Komarov Botanical Institute RAS, St. Petersburg, Russian Federation.

Comparative studies of minor veins and their adjacent tissues in leaves of dicotyledonous plants have resulted in the development of a structural and functional typology and a database on phloem structure in dicots. Two main lineages of evolution of leaf structure correspond to woody and herbaceous dicot species, respectively. The structural characteristics of the phloem are specific for families, sometimes even for orders. With respect to minor vein phloem, an ancestral type (combining traits of both symplastic and apoplastic loading mechanisms), and four specialized types - symplastic (primitive and advanced) and apoplastic (primitive and advanced) - were described. The combination of symplastic and apoplastic features is typical for the Prodicots. Specialized types appear in phylogenetically advanced taxa of the Eudicots: symplastic types in species inhabiting forest ecosystems, and apoplastic types in inhabitants of herbaceous ecosystems. An influence of compartmentation of water flux on the organization of leaf tissues has been demonstrated. The basis for the transport-dependent characteristics of leaf structure has been elucidated.

P0625. Characterization of a blueberry hybrid progeny (*Vaccinium corymbosum* L. x *V. ashei* Reade) in SW Spain by using molecular (ISSR) and morphological traits: congruence between both evidences.

R. Parra Martín[1], Z. M. Díaz Lifante[1], J. P. Martín Clemente[2], B. Valdés[1];
[1]Universidad de Sevilla, Sevilla, Spain, [2]Universidad Politécnica de Madrid, Madrid, Spain.

A first step in a blueberry breeding program currently developed in SW Spain, has been the characterization of the initial germplasm, 38 blueberry hybrid plants produced in EEUU by hybridization between commercial highbush (*Vaccinium corymbosum* L.) and rabbiteye (*V. ashei* Reade) cultivars, with “Misty”, “O’Neal” and “Sharpblue” cultivars as control. Morphological and molecular evidences have been examined. In morphological characterization 30 quantitative and 13 qualitative traits have been considered. Multivariate ordination analyses (Principal Component and Correspondence Analyses) and classification (Cluster Analysis) have been performed, and a dendrogram was obtained from the distance matrix. Molecular characterization has been investigated by using the Inter Simple Sequence Repeat (ISSR) technique. The 10 most informative primers of UBC set 9 were selected and generated 151 ISSR polymorphic bands; a dendrogram was obtained based on the similarity matrix. Classification schemes generated by morphologic ISSR data are not coincident. Nevertheless, certain congruence was found in the identification of the most distant groups.

P0626. Development of novel low copy nuclear markers for phylogenetic reconstructions at both genus and species level

M. Li[1], J. Wunder[1], G. Bissoli[1], H. Saedler[2], **C. Varotto**[1];
[1]CSBT, Center for the Study of Biodiversity – Trentino, San Michele all'Adige, Italy, [2]Max-Planck-Institut for Plant Breeding Research, Cologne, Germany.

At the species level, the resolving power of both traditional sequential markers (e.g. *rbcL*) and anonymous multilocus markers (e.g. AFLP) frequently becomes limited. Especially when using a low number of sequential markers, problems connected to incongruence can significantly decrease the robustness of the phylogenetic reconstruction.

We developed novel low copy nuclear markers able to allow amplification from a wide array of angiosperm families. Their application to solve phylogenetic relationships is shown for some genera belonging to Lamiales and in particular for species belonging to the *Melampyrum* genus as an example of closely related species within genera. The phylogeny of seven *Melampyrum* species, never determined before, was obtained by means of 8 newly developed nuclear markers in addition to traditional ones, like *ITS*, *matK* and *rbcL*. The possibility to increase robustness of the phylogenetic reconstruction by using a higher number of sequential markers is discussed.

P0627. Towards embryology of *Campanulaceae* in connection with family systematics

N. A. Zhinkina;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

Campanulaceae is one of the families with unclear systematic position. The typical genus *Campanula* is of special interest; it is heterogeneous, distributes in almost all Holarctic zones and also in mountain regions where the evolution of *Campanulaceae* mainly occurred. Embryology of different genera members was researched on light level. Taking into consideration Linneaus statement on significance of frutification and seed structure as important features for definition of systematic position of species and genera within the family, we paid attention to the study of seed structure in fruit (scanning microscopy). Ultrastructure of seed surface is closely connected with the structure of seed coat and is a reprint of outer epidermal and inner spermoderm layers. The most heterogeneity in seed surface ultrastructure is observed in the members of *Campanulaceae*. Great differences in shape and seed sizes were noted that could be also used as the important morphological feature in species description. Resemblance and differences in some embryological features and data on seed surface structure contribute much in systematics and phylogeny of *Campanulaceae*.

P0628. Azolla: Phylogenetic History, Divergence Times, and Character Evolution

J. Metzgar[1], K. M. Pryer[1], H. Schneider[2];
[1]Duke University, Durham, NC, United States, [2]Albrecht-von-Haller Institute of Plant Sciences, Goettingen, Germany.

The economically important fern genus *Azolla* (Salviniaceae) comprises a small (seven species) but distinct lineage within the morphologically diverse heterosporous water ferns (Salviniaceae + Marsileaceae) - one of the three major clades of core leptosporangiate ferns. The five extant genera of heterosporous ferns have been largely ignored in systematics studies and infrageneric relationships are virtually unknown. Here, we present results from the phylogenetic analysis of a six-locus data set of coding and non-coding regions from the plastid and nuclear genomes of *Azolla*. By integrating critical heterosporous fern microfossils as age constraints, we are able to determine divergence time estimates for extant *Azolla* species and for the *Salvinia-Azolla* split using our molecular data set. Within an explicit phylogenetic context we also investigate morphological character state transitions that may have been associated with the ecological specialization of these ferns to aquatic habitats.

P0629. Micromorphological anlalysis of *Stachys scardica* trichomes

S. M. Grujic Jovanovic, S. Duletic Lausevic, P. D. Marin, A. Simic;
Faculty of Biology, Belgrade, Serbia and Montenegro.

Micromorphology and distribution of trichomes on stem, leaves and calyx of *Stachys scardica* (Griseb.) Hayek were investigated using light microscopy and scanning electron microscopy. This species is widely distributed in Balkan peninsula. The investigated material was collected during summer 2004, from Zlatibor mountain. On the stems two types of trichomes were found: nonglandular 3-armed elongated trichomes were densely distributed, and glandular peltate trichomes with 4-celled heads. Abaxial and adaxial leaf surfaces were covered with numerous multi-branched and elongated nonglandular trichomes and glandular peltate trichomes with 4-celled heads. The outher surface of calyx was densely covered with numerous multi-branched nonglandular trichomes, among which the peltate glandular trichomes were distributed. From inner side very long simple trichomes were observed to emerge. The genus *Stachys* shows wide range of variability within some species. Usefulness of trichome microcharacters taxonomical treatment an related species is discussed.

P0630. Are all phylogenetic problems possible to resolve if long enough sequences are used?

P. Erixon, B. Oxelman;
Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden.

It is well known that when the internal branch lengths are short relative to the terminal branches, phylogenetic inference is a very difficult problem. Most real examples of this have focused on deep phylogenetic relationships as the major eukaryot groups, plastids of different phyla, etc. Here, we study the plastid phylogeny of a subset of 8 closely related taxa in *Silene* (Caryophyllaceae). An aligned matrix of 24000 chloroplast DNA characters was analyzed. Despite the low overall variability (>90% constant sites) and the long sequences, some of the internal branches cannot be resolved confidently. This indicates saturation among the few variable sites and/or extremely short internal branches. The amount of homoplasy is very high for a chloroplast data set of 8 taxa (CI=0.6). We have partitioned the data into synonymous/non-synonymous sites, coding/non-coding regions, indels/substitutions, and stem/loop regions of self-splicing introns, to investigate this further. We also evaluate the possibility of recombination between plastid lineages.

P0630. On the modes of neotenical divergence in limens of genus Gagea (Liliaceae)

I. G. Levichev, L. S. Krasovskaya;
Komarov Botanical Institute of the Russian Academy of Sciences, Sankt-Petersburg, Russian Federation.

In the genus Gagea of the laws of age-related variation of radical leafs permits identification with manifestation of the neoteny phenomenon. The neoteny has been the leading evolutionary trend of this phylon. Intrageneric neotenical divergence generated the large genus (about 250 species) with many morphological features of juvenilization, are presented at the definitive stage. The degree of neotenization are determined by the correspondence with the empirical standard series of neotenization, which reflects: age-related leaf blade variation during ontogenesis, degree of neotenization, and sequence of the individual morphogenesis of the basipetally developing leaf. Besides the 10 stages, the phytomer in the end of its neotenization, creates two more states: a rudiment stage and the category of «silent» phytomers, when its function begins to be carried out by the next below-located axial phytomer. The algorithm of basal neoteny, of the leads historically to the oligomerization, explains of the localization of «silent» phytomers at the infrabasal, and the suprabasal levels, and evolution of polycyclicity in the direction of monocyclicity of ephemers.

P0631. The PBI Solanum project - an international collaboration to monograph Solanum

L. Bohs[1], **M. Nee**[2], S. Knapp[3], D. Spooner[4], J. R. Bennett[3], J. Clarke[5], L. Walley[3];
[1]University of Utah, Salt Lake City, UT, United States, [2]New York Botanic Garden, Bronx, NY, United States, [3]Natural History Museum, London, United Kingdom, [4]University of Wisconsin, Madison, WI, United States, [5]Smithsonian Institution, Washington, DC, United States.

Large plant genera typically lack up to date, critical monographic treatments due to the practical difficulties of studying them in their entirety. The most recent comprehensive worldwide monograph of *Solanum* (Solanaceae) was completed over 150 years ago, and accounts for only a small proportion of the estimated 1500 species currently recognised. The PBI Solanum project is one of four major monographic projects funded by the US National Science Foundation and the All Species Foundation and aims to provide a complete species-level taxonomic monograph of the genus. It is a collaboration between the University of Utah, the Natural History Museum, London, the New York Botanical Garden and the University of Wisconsin-Madison, as well as a number of Solanaceae specialists worldwide. Advances in the dissemination of information via the internet are being harnessed to provide a web-accessible database of species names, plant descriptions and literature, interactive identification keys, digital images and a database of herbarium collections, as well as providing links to Solanaceae resources in the fields of molecular biology and genomics.

P0632. Flow cytometric analysis of nuclear genome size - the problematic effect of cytosolic compounds

J. Loureiro[1], E. Rodriguez[1], J. Doležel[2], C. Santos[1];
[1]Department of Biology, Aveiro, Portugal, [2]Institute of Experimental Botant, Olomouc, Czech Republic.

In plant sciences, flow cytometry is mostly focused on ploidy and nuclear DNA content analysis. Although considered the most reliable technique for this type of analyses, recent studies revealed some problems associated with the methodologies used to isolate and stain plant nuclei. These studies alerted to the presence of cytosolic compounds that can bias genome size estimates. It is therefore important to identify these compounds and develop strategies to overcome this problem.

Until the moment the effect of caffeine and tannic acid was tested in nuclei isolated from *P. sativum*, a usual plant DNA standard, using four of the most popular buffers used for preparation of nuclei suspensions. Caffeine decreased propidium iodide fluorescence in the analysed buffers and tannic acid besides that also affected nuclei morphology. The effect of tannic acid in isolated nuclei was very similar to the effect observed when problematic species, as *Quercus suber*, were analysed.

Further studies with other cytosolic compounds and plant species are in preparation in order to clarify this problem and obtain truly reliable procedures to analyse nuclear DNA content of plant cells.

P0633. Genome variation in the plastid DNA of the mycotrophic orchid *Neottia nidus-avis*

D. Cafasso[1], G. Chinali[2], S. Cozzolino[1];
[1]Dipartimento delle Scienze Biologiche, Napoli, Italy, [2]Dipartimento di Medicina Clinica e Sperimentale, Napoli, Italy.

Chloroplast structure and function, as plastid DNA (cpDNA) sequence, have, with few exceptions, remained highly conserved within plant kingdom. Parasitic plants represent a remarkable exception to this general trend, because much of their plastid genome is under relaxed functional constraint. In this contest, the presence of different trophic modes in Orchidaceae, from autotrophic to holoparasitic, makes this group ideal for investigating molecular changes in cpDNA that accompany the evolution of heterotrophy.We investigated nucleotide sequence of a cpDNA region of the mycoparasitic *Neottia nidus-avis* and of its sister species *Listera ovata* in order to detect patterns of evolutionary changes in the genome of a non-photosyntetic plant compared to the corresponding closest photosynthetic taxon. In *Neottia* cpDNA we detected many deletions but we also found the contemporary presence of three non-functional copies of the *rbc*L maintained as pseudogenes. These results indicate that cpDNA in non-photosyntetic plants can easily evolve when functional selection is relaxed and that multiple deletions are not the only main mechanism of structural changes.

P0634. Genome size in Dahlia (Asteraceae - Heliantheae)

E. M. Temsch[1], J. Greilhuber[1], K. R. W. Hammett[2], B. G. Murray[3];
[1]Department of Systematic and Evolutionary Botany, University of Vienna, Vienna, Austria, [2]Hammett Plant Breeding Ltd., Auckland, New Zealand, [3]School of Biological Sciences, The University of Auckland, Auckland, New Zealand.

Dahlia is a monophyletic genus classified into 4 sections, which are not monophyletic according to a recent DNA phylogeny (ITS of 18S-26S rDNA). We studied variation of genome size (DNA C-values) with regard to taxonomy, polyploidy, crossability, and technical difficulties of measurement in flow cytometry and Feulgen densitometry caused by secondary metabolites. DNA 2C-values ranged from 3.3 pg in D. dissecta (2n = 34) to ca 8.9 pg in D. variabilis cultivars (2n = 64), which had fairly stable C-values. The highest 2Cx-value occurred in D. imperialis (5.1 pg, 2n = 32). Tetraploid D. coccinea (2n = 64) shows somewhat reduced Cx-values compared to D. coccinea, 2n = 32, but resembles its probable derivative D. variabilis (2n = 64). Hybrids correspond to expectation from parental C-values (D. coccinea x D. rudis, 2n = 32; D. apiculata x D. tenuicaulis, 2n = 32). Secondary compounds occasionally caused problems with the Feulgen method, but floral pigments were found relatively inert.

P0635. No DNA Loss in Autotetraploids of *Arabidopsis thaliana* and *Aegilops longissima*

H. Ozkan[1], M. Tuna[2], R. Elumalai[3], B. Ulker[4], D. Galbraith[3];
[1]University of Cukurova, Adana, Turkey, [2]University of Tekirdag, Tekirdag, Turkey, [3]University of Arizona, Tucson, AZ, United States, [4]Max-Planck Institute for Plant Breeding Research, Cologne, Germany.

To address the issue of genome evolution in autopolyploids, and particularly to investigate whether rapid sequence elimination also occurs in autopolyploids as in allopolyploids, we employed AFLP fingerprinting to examine small number of genomic loci in F1 hybrids between two different autopolyploids of *Arabidopsis* ecotypes. Using this approach, we found perfect additivity in the F1 hybrids between the newly formed autopolyploids when compared to their parental lines. Using flow cytometry, we extended our study in a quantitative manner, in which the nuclear DNA contents in two newly formed autopolyploids, namely *Arabidopsis thaliana* and *Aegilops longissima*, were determined. The increase in genome size of the two different autopolyploid lines was additive. Taken together, we found no evidence for genome size reduction due to autopolyploidization of studied species.

P0636. Limited genome size variation in four subspecies of *Pinus nigra* s.l.

F. Bogunic[1,2], E. Muratovic[2], D. Ballian[1], S. Siljak-Yakovlev[3,2], S. C. Brown[4];
[1]Faculty of Forestry, Zagrebacka 20, University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [2]Laboratory for research and protection of endemic genofond, Department of Biology, Faculty of Science, Zmaja od Bosne 35, University of Sarajevo, Sarajevo, Bosnia and Herzegovina, [3]Ecologie, Evolution, Systématique, UMR CNRS 8079, Universite Paris-Sud, Bat. 360, 91450 Orsay Cedex, France, [4]Institut des Sciences du Végétal, UPR 2355 CNRS, Gif-sur-Yvette, France.

Despite the fact that genome size should be constant at species level, many reports of intraspecific variations exist. Thus we carried out "ad hoc" analysis to determine the possible existence of nuclear DNA content variation in European black pine (*Pinus nigra* s.l.), a good model for a such study given its karyological uniformity, morphological polymorphism, broad geographical distribution and ecological plasticity. The panel comprised 18 populations across the natural range of *P. nigra* from Europe including four subspecies: subsp. *nigra*, *salzmanni*, *dalmatica* and *pallasiana*. Mean 1C DNA content was 23.65 pg (±0.203) assessed by flow cytometry. The coefficients of variation within and between populations did not exceed 2%. We have already reported the existence of significant differences for three Black pine populations. Slight intraspecific variation was also confirmed in the present study dealing with many more populations. There were no relationships between 1C DNA content and taxon affiliation of *P. nigra* subspecies. We conclude that intraspecific variation was not taxonomically important in our case.

P0637. Genome Size in Mediterranean Malvaceae: Karyological, Ecological and Evolutionary Implications.

P. Escobar García[1], J. Greilhuber[2], E. Temsch[2], J. Fuertes Aguilar[1];
[1]Real Jardín Botánico, CSIC, Madrid, Spain, [2]Institute of Botany, University of Vienna, Vienna, Austria.

This karyological study of subtribe *Malvinae* comprises 33 species from *Althaea*, *Lavatera*, *Malope* and *Malva*, genera displaying their maximum diversity in the Western Mediterranean Basin. The patterns of variation in DNA amounts measured show coherence with other sources of evidence (ITS data, fruit morphology), being of high utility for the systematic study of Mediterranean *Malvinae*. DNA amounts ranged from 2*C* = 1.25 pg in *Malva parviflora* to 2*C* = 10.94 pg in *M. alcea*. This means a 8.7-fold overall range of variation. Chromosome numbers vary from 2n = 14 in *L. trimestris*, the only diploid of the group (x = 7), to 112 in *L. cretica*, which corresponds to 16-ploid. Well defined, both evolutionary and ecological trends are observed in the distribution of DNA amounts. Strong differences in DNA amounts among types of life cycles appear. The average DNA amount for ephemerals is 2*C* = 1.79 pg, less than the average for annuals, *2C* = 2.93 pg. This value is similar to the DNA content of facultative perennials, 2*C* = 2.85 pg. The obligate perennials display the largest value, 2*C* = 6.32.

P0638. Genome size in Cirsium and its relation to natural hybridization

P. Bureš[1], L. Horová[1], J. Suda[2];
[1]Masaryk University, Brno, Czech Republic, [2]Charles University, Prague, Czech Republic.

Nuclear DNA amounts of 12 diploid and one tetraploid taxa and 12 natural interspecific hybrids of *Cirsium* from 102 populations in the Czech Republic, Austria, Slovakia and Hungary were estimated using DAPI and PI flow cytometry. 2C-values of diploid (2n=34) species varied from 2.14 pg in *C. heterophyllum* to 3.60 pg in *C. eriophorum* (1.68-fold difference); the 2C value for the tetraploid *C. vulgare* was 5.54 pg. AT frequency ranged from 48.38 % in *C. eriophorum* to 51.75 % in *C. arvense*. Biennial species of *Cirsium* possessed larger nuclear DNA amounts than their perennial relatives. Genome size was negatively correlated with Ellenberg´s indicator values for continentality and moisture and with eastern limits of distribution. C-values positively corresponded with the spinyness (degree of spinosity). The hybrids of diploid species remain diploid, and their DNA content was smaller than the mean of the parents'. Species with smaller genomes produce interspecific hybrids more frequently. Negative correlation is between frequency of natural hybridization and the genome size difference between parental taxa in the most frequently hybridizing *Cirsium* species pairs.

P0639. Karyological study of SE Alpine and Central European taxa of *Luzula* sect. *Luzula*

T. Baļ iļ , N. Jogan, J. Dolenc Koce;
Biotechnical Faculty, Ljubljana, Slovenia.

Luzula sect. *Luzula* is the most taxonomically diverse group within the genus. It displays a wide range of chromosome numbers due to polyploidization and chromosome fragmentation (agmatoploidy). In several taxa from Slovenia, NE Italy and S Austria genome size (C-value) was measured in root tip cells densitometrically with interphase-peak DNA image cytometry. Chromosome number was determined on the same slides. Since agmatoploid and peculiar partial agmatoploid karyotypes are confined to higher altitudes, a special effort was made to include all the SE Alpine taxa.
As expected, C-value proved to be the same in diploid (12 AL: *L. campestris*) and agmatotetraploid (24 BL: *L.* cf. *sudetica*, *L.* cf. *divulgata* and 48 CL: *L. sudetica*) taxa and approximately doubled in true tetraploid (24 AL: *L. divulgata, L. multiflora*1) and tripled in true hexaploids (36 AL: *L. multiflora*2). C-value of partial agmatoploid (12 AL+24 BL: *L. alpina*) approximately equals the DNA amount in tetraploids. Karyological variability of *L. multiflora* (24 AL and 36 AL) and taxonomic status of Alpine *L.* cf. *sudetica* and Submediterranean *L.* cf. *divulgata* require further study.

P0640. Why is it so difficult to obtain high quality AFLP profiles in *Argyranthemum*?

L. Borgen[1], M. Jørgensen[1], R. Obermayer[2];
[1]National Centre for Biosystematics, Natural History Museum, Oslo, Norway, [2]Department of Systematic and Evolutionary Botany, University of Vienna, Vienna, Austria.

Argyranthemum (Asteraceae: Anthemideae) is the largest genus endemic to the Atlantic oceanic islands in Macaronesia. Its diversification has been studied by morphometrics as well as crossing experiments, isozymes, cpDNA restriction sites, ITS sequences, and FISH/GISH. All species are diploid (2n=18), suffrutescent, and interfertile. To investigate the genetic structure of two species of reciprocal hybrid origin, *A. lemsii* and *A. sundingii*, and their progenitors, *A. broussonetii* and *A. frutescens*, we tried to develop AFLP fingerprinting markers. Several AFLP protocols were tested. We increased the number of selective bases in one or both of the primers, and used a third restriction enzyme (TE-AFLPs). All protocols gave a multitude of fragments but no high quality AFLP profiles and only a few fragments that could be reliably scored. The genome sizes (1C) of the progenitor species are 7.07 and 7.21 pg, which should be workable genome sizes for normal AFLP protocols. Our AFLP problems might then be related to strongly amplified fragments that represent repetitive, high copy loci or parts of transposable elements.

P0641. Genome size of desiccation-tolerant *Ramonda serbica* and *R. nathaliae* (*Gesneriaceae*)

T. Zivkovic[1], S. Siljak-Yakovlev[2], O. Catrice[3], B. Stevanovic[1], V. Stevanovic[1];
[1]Faculty of Biology, Institute of Botany, Belgrade, Serbia and

Montenegro, [2]Ecologie, Evolution et Systématique, UMR CNRS 8079, Université Paris-Sud, Orsay Cedex, France, [3]Institut des Sciences du Végétal, CNRS UPR 2355, Gif-sur-Yvette, France.

Ramonda serbica and *Ramonda nathaliae* are extremely rare representatives of resurrection plants among Holarctic phanerogamic flora. Both species are endemics of Balkan peninsula and Tertiary relicts. The sample concerns two populations of *R. serbica* (one from Serbia and one from Montenegro) and one population of *R. nathaliae* from Serbia. Nuclear DNA content and GC percentage were assessed by flow cytometry. The 2C DNA values for *R. nathaliae* and *R. serbica* were 2.38 pg and 7.77 pg, respectively. These results were in accordance with different ploidy levels of these species. The base composition for *R. nathaliae* was found to be 42.06% GC. The significant intra-population variation of DNA amount was observed in *R. serbica* from Montenegro. The 2C DNA content ranged from 2C=7.62 pg to 11.31 pg and revealed existence of different ploidy levels between individuals of this population.

P0642. Ploidy level variation in *Lythrum salicaria* L. (Lythraceae) at large spatial scale

B. Kubátová[1], P. Trávníļek[2,3], J. Suda[2,3], D. Bastlová[4], V. Ļurn[1];
[1]University of South Bohemia, Faculty of Agriculture, Biotechnological centre, Ļeské BudŊjovice, Czech Republic, [2]Academy of Sciences of the Czech Republic, Institute of Botany, PrŢhonice, Czech Republic, [3]Charles University, Department of Botany, Prague, Czech Republic, [4]University of South Bohemia, Faculty of Biological Sciences, Ļeské BudŊjovice, Czech Republic.

Purple loosestrife (*Lythrum salicaria* L.), a native Eurasian species, belongs among highly invasive angiosperms in North American wetlands. Ploidy level of numerous progenies rising from nearly 600 mother plants sampled at both primary and secondary areas of distribution was screened using flow cytometry. Large cytotype variation (2x, 3x, 4x, and 6x) was found across the native range (76 populations covering 14 European and Middle East countries) DNA-tetraploids prevailed in the area studied, while DNA-diploids and DNA-hexaploids were recorded only in Israel and Turkey, respectively. DNA-triploid progenies occurred in one population from Hungary. Sympatric growth of tetraploid and hexaploid individuals was encountered in Turkey. On the contrary, cytotype uniformity is a typical feature for the non-native American material (77 populations covering 13 states of the U.S.A. and Canada) where only DNA-tetraploids were revealed.

P0643. Genome size variation and evolution among diploid *Gossypium* species

J. S. Hawkins[1], H. Kim[2], J. D. Nason[1], R. J. Percifield[1], R. A. Wing[2], J. F. Wendel[1];
[1]Iowa State University, Department of Ecology, Evolution and Organismal Biology, Ames, IA, United States, [2]University of Arizona Genomics Institute and Computational Laboratory, Tucson, AZ, United States.

Although genomes of eukaryotic organisms vary approximately 80,000-fold in size, there is only a 20-fold variation in the number of protein-coding genes. Based on comparisons of orthologous regions among several taxa, it is generally agreed that the majority of this genome size variation can be ascribed to the repetitive fraction. Therefore it is of interest to determine the components of DNA that contribute to genome size variation, and its relevance to organismal fitness and evolution. Although all diploid members of *Gossypium* have a haploid complement of 13 chromosomes, genome sizes range 3.0-fold, from 885 to 2572 Mb per 1C nucleus**.** This wide range in genome size, in addition to a well-established phylogeny, makes *Gossypium* an excellent system for the study of genome size evolution. Genomic shotgun libraries were constructed from three members of *Gossypium* and one outgroup species. Approximately 0.14% of each haploid genome was sequenced for each of the species. The results suggest that a major fraction of the genome is composed of repetitive *gypsy*-type retrotransposons and that these sequences are responsible for much of the observed genome size variation.

P0644. Genome size variation in the endemic sagebrushes and their allies (*Artemisia*, Anthemideae, Asteraceae) of North America.

S. Garcia[1], T. Garnatje[2], S. C. Sanderson[3], E. D. McArthur[3], J. Vallès[1];
[1]Laboratori de Botànica, Facultat de Farmàcia, Universitat de Barcelona, Barcelona, Spain, [2]Institut Botànic de Barcelona (CSIC-Ajuntament de Barcelona), Barcelona, Spain, [3]Shrub Sciences Laboratory, Rocky Mountain Research Station, USDA., Provo, UT, United States.

Genome size of around 30 taxa belonging to the North American sagebrushes and related species (mainly from subgenus *Tridentatae* of the genus *Artemisia*) has been assessed by flow cytometry, including all the most common sagebrushes as well as some narrow endemics. The higher nuclear DNA amount per basic chromosome set of the *Tridentatae* compared with that of the other sections and subgenera of the genus is confirmed. The possibility of finding any connection between genome size data and morphological, physiological or environmental traits of the studied species has been tested. However, little interspecific variation has been found, the most notable being the differences in C-value with taxa of doubtful taxonomic position in the section, namely *A. bigelovii* or *A. pygmaea*. It is suggested that such homogeneity in nuclear DNA amount (together with the high morphological, chemical and karyological affinities) supports the hypotheses of a recent diversification process in this restricted group of the genus. Additionally, low values of intraspecific and intrahybrid nuclear genome size variation have been detected for most taxa.

P0645. Genome size estimation in herbarium vouchers by DAPI flow cytometry

P. Trávníļek[1,2], J. Suda[2,1];
[1]Institute of Botany, Academy of Sciences, PrŢhonice, Czech Republic, [2]Charles University, Department of Botany, Prague, Czech Republic.

DAPI flow cytometry was applied for genome size (ploidy level) estimation in herbarium vouchers of vascular plants. Effect of different drying methods, storage conditions, and the age of herbarium vouchers (1-36 months) on peak attributes was tested using model taxon *Vaccinium* subg. *Oxycoccus* comprising four cytotypes (2x, 4x, 5x, 6x). While mode of desiccation had little impact on histogram quality, material stored in deep freezer showed longer lifetime and yielded significantly lower CVs than samples stored at room temperature. Subsequent investigation of 20-month old herbarium vouchers of various vascular plants (pteridophytes, gymnosperms, and angiosperms) gave reproducible signals in 43 out of 60 taxa. In comparison with the fresh material, certain decrease in relative fluorescence intensity (0.2 - 11.7%, mean 4.6%) occurred in most dry samples, being negatively correlated with genome size. Demonstrated feasibility of ploidy estimation in herbarium vouchers further broadens the versatility of flow cytometry and opens new prospects in plant biosystematics.

P0646. Genome size evolution among *Gossypium* species

C. E. Grover[1], H. Kim[2], R. A. Wing[2], A. H. Paterson[3], J. F. Wendel[1];
[1]Iowa State University, Ames, IA, United States, [2]University of Arizona, Tucson, AZ, United States, [3]University of Georgia, Athens, GA, United States.

Plant genomes range in size over three orders of magnitude. Mechanisms of genome expansion and contraction likely have contributed to this disparity, but the relative role played by each in shaping modern genomes is unclear. Comparative sequencing of large, homologous regions of genomic DNA from organisms that differ in genome size provides an opportunity to reveal mechanisms of genome size change. We present results from an ongoing analysis based on comparative sequencing of homologous BACs in *Gossypium*. Despite the relatively young age of the genus (5-10 mya) and its conserved complement of chromosomes (n = 13) and genes, 1C values for the genus range over 3-fold, from 885 to 2572 Mbp. Aligned BACs from interspecific comparisons suggest that the primary cause of genome size expansion is transposable element proliferation, whereas small scale deletional processes may counterbalance genome growth via mechanisms such as illegitimate recombination. Furthermore, the data indicate that the mechanisms that lead to genome size differences do not affect all genomic constituents equally.

P0647. Appendages matter, again: Phylogenetics and the classification of *Curcuma* L.

T. M. Rehse[1], W. J. Kress[2,1], P. S. Manos[1];
[1]Duke University, Durham, NC, United States, [2]Smithsonian Institution, Washington, DC, United States.

The genus *Curcuma* L. (Zingiberaceae) is an important part of tropical Asian floras and many Asian cultures, yet the identification of the vast majority of species has been fraught with difficulty due to possible hybridization and polyploidization. Here we take a phylogenetic approach to understand the basic evolutionary pattern of *Curcuma*, using the nuclear ribosomal ITS and chloroplast matK/trnK. A broad representation of taxa was sampled, including morphological and geographic extremes of the genus. Also included are five unusual genera: *Hitchenia glauca*, *Laosanthus graminifolius*, *Smithatris supraneeana*, *S. myanmarensis*, *Stahlianthus involucratus*, and *Paracautleya bhatii*. A paraphyletic *Curcuma* including these genera was found, creating a monophyletic 'Curcuma clade', and the generic definition therefore expanded to include them. The three major clades in the phylogeny are used to subdivide the genus for the first time into three subgenera. The significance of hybridization and polyploidy in the genus is discussed.

P0648. Microsatellite markers for *Tragopogon dubius*

M. E. Studstill, J. A. Tate, D. E. Soltis, P. S. Soltis;
University of Florida, Gainesville, FL, United States.

Microsatellite markers are dispersed throughout the nuclear genome and consist of tandemly-duplicated di- or trinucleotide repeats. Because they evolve rapidly, microsatellite loci are useful to compare genetic diversity at the species or population level. We have developed a microsatellite library for *Tragopogon dubius*. This diploid species served as the common parent of the allotetraploid species *T. mirus* and *T. miscellus*, both of which formed multiple times in the Pacific Northwest of the U.S. within the last 80 years. Interrupted and continuous microsatellite loci were examined, with the expectation of higher diversity among alleles with continuous tandem repeats. Using these microsatellites, we compared genetic diversity between North American and Eurasian populations of *T.dubius*. These markers will also be used in the construction of a genetic map for *T. dubius* and will contribute to ongoing work to improve our understanding of recurrent polyploidy using *Tragopogon* as a model.

P0649. Molecular phylogeny and origin of polyploid gorses (*Ulex*, Fabaceae).

A. Ainouche, M. Affagard, M. Misset;
UMR-CNRS 6553, Rennes, France.

Ulex (Fabaceae) is a small euploid series, which occurs in western Europe, mainly in the Iberian Peninsula. The hexaploid *U. europaeus* subsp. e*uropaeus* is notorious for being now an invasive weed in different continents, following introductions during the last two centuries. The use of ETS nrDNA, ITS nrDNA and *trn*L-*trn*F cpDNA data to investigate the evolutionary history of *Ulex* provided insights to elucidate most relationships among the diploid taxa native from either the *atlantic* or the *mediterranean* areas and allowed inference on the origins of the polyploids. *Ulex breoganii* (4*x*) and *U. gallii* (6*x*) share a single ETS genotype identical to that of the Atlantic diploid *U. minor,* suggesting their probable autopolyploid origin. *U. argenteus* subsp*. erinaceus* (4x) and *U. argenteus* subsp. *subcericeus* (6*x*) appear to derive from a common Atlantic ancestor, while *U. latebracteatus* (4*x*) is most probably deriving from the Mediterranean *U. parviflorus* (2*x*) genotype. Additivity of ETS sequences from both the Atlantic and the Mediterranean genomes in the invasive hexaploid *U. europaeus* subsp*. europaeus* supports the hypothesis of its recent allopolyploid origin.

P0650. Molecular phylogeny and the role of hybridization in the diversification of Polygonum section Persicaria (Polygonaceae)

S. Kim, M. J. Donoghue;
Yale University, New Haven, CT, United States.

Polygonum sect. *Persicaria* (Mill.) Meisn. consists of ca. 70 species of weedy herbs found in moist or disturbed areas. Phylogenetic analayses were conducted using nuclear (ITS and *LEAFY* first and second intron and second exon) and chloroplast (*mat*K and noncoding regions of *psb*A-*trn*H and *trn*L-F) DNA sequences from 45 species (10 outgroups). Our ITS trees suggest that sect. *Persicaria* is polyphyletic, with *P. amphibium* linked with sect. *Tovara* and the universally distributed *P. lapathifolium* complex basal. In our combined chloroplast trees the basal lineage is not fully resolved and the *P. lapathifolium* complex is allied with South American species, suggesting cytoplasmic introgression or recent diversification of the South American species. The number of *LEAFY* copies is generally consistent with ploidy level. Not all species share a common *LEAFY* copy, indicating possible lineage sorting, but our gene trees support the hybrid origin of several species as hypothesized based on incongruent nuclear and chloroplast gene trees.

P0651. Ploidy patterns in the arctic-alpine polyploid *Draba lactea* Adams (Brassicaceae) and its low-ploid relatives

R. E. A. Obermayer[1], H. H. Grundt[2], L. Borgen[2];
[1]Department of Systematic and Evolutionary Botany, Univ. of Vienna, Austria, [2]National Centre for Biosystematics, Univ. of Oslo, Norway.

Ploidal level information is of particular importance in intricate polyploid complexes such as in arctic-alpine *Draba*. Relative DNA content and reference chromosome numbers were determined for the tetra- and hexaploid *D. lactea* and seven of its low-ploid relatives. Absolute DNA content was measured by internally standardised Feulgen densitometry. The plants grouped into diploids (*D. altaica, D. fladnizensis*, *D. lonchocarpa*, *D. nivalis*, *D. palanderiana* and *D. subcapitata*; 2*n* = 16), tetraploids (*D. lactea*, *D. turczaninovii*; 2*n* = 32), hexaploids (*D. lactea;* 2*n* = 48), and two odd triploids. *Draba palanderiana,* reported as di-, tetra- and octoploid, was diploid in all investigated accessions. Hexa- and tetraploids were observed in *D. lactea*, in approximately the same ratio (8:1) as previously reported. The ploidal levels of the Central Asian *D. altaica* and *D. turczaninovii* were reported for the first time. In the present study, the DNA amounts of the polyploids increased in direct proportion to ploidal level. In combination with molecular data, these results are pointing to a relatively recent polyploid origin.

P0652. Evolutionary dynamics of nuclear genes and origin of polyploid annual bromes (Poaceae).

P. FortunÃ©, M. Ainouche, K. Ainouche;
UMR CNRS 6553 Ecobio, Rennes, France.

Gene and genome duplications are important evolutionary features of nuclear plant genomes. They represent a critical source of functional diversification and speciation (in both plant and animals). However, these phenomena can be responsible for a series of problem in phylogenetic reconstruction. They may also be misleading in analyses of polyploid species based on molecular data. Indeed, orthology, homeology (in allopolyploid species) and paralogy of the sequences that are used have to be unambiguously ascertained before any analysis. This will be discussed in the context of phylogenetic reconstruction of diploid and polyploid annual *Bromus* species (Poaceae) originating from Eurasia and the Mediterranean region. Data sets from repetitive ribosomal DNA sequences (*ITS*) and low-copy nuclear genes (*Waxy* gene encoding the Granule Bound Starch Synthase I) will be compared.

P0653. Genome origins, recombination, and diversity in a complex polyploid, *Sorghum halepense* (Poaceae)

C. D. Kellogg[1,2], J. J. Doyle[1], S. Kresovich[2];
[1]L.H. Bailey Hortorium, Cornell University, Ithaca, NY, United States, [2]Institute for Genomic Diversity, Cornell University, Ithaca, NY, United States.

The origins and subsequent evolution of the polyploid *Sorghum halepense* (L.) Pers. (2*n* = 4*x* = 40) have not been well characterized, despite its significance as one of the world's most noxious weeds. We have constructed haplotype networks from several unlinked nuclear loci for individuals of the *S. halepense* species complex. These haplotype networks are used to infer the origins of the genomes of *S. halepense*. Complex patterns are seen in the haplotype networks for individual loci, as well as in comparisons between loci. The evidence supports *Sorghum bicolor* (L.) Moench (2*n* = 2*x* = 20) as a putative diploid progenitor of *S. halepense*. The contribution of *Sorghum propinquum* (Kunth) Hitch. (2*n* = 2*x* = 20) is less clear. Introgression, genomic changes accompanying the polyploid event, and tetrasomic inheritance in the polyploid may be responsible for the differing patterns seen between loci. Low levels of nucleotide diversity suggest that *S. halepense* may be of recent origin; however, recombination between the diploid progenitors has created high levels of allelic diversity, which may be contributing to the invasive ability of *S. halepense*.

P0654. Allozyme diversity in the tetraploid endemic Oxytropis chankaensis (Fabaceae)

A. Kholina;
Institute of Biology and Soil Science FEB RAS, Vladivostok, Russian Federation.

Oxytropis chankaensis Jurtz. (Fabaceae) is a herbaceous perennial plant endemic of the sand dunes of the west shore of Khanka Lake (Far East of Russia), which is included in the Rare Plant Species Book of Far East of Russia. It is a tetraploid with 2n = 32. Using starch gel electrophoresis, we examined 16 enzyme systems presumably controlled by 28 loci. Twelve loci were shown be polymorphic. Banding pattern exhibited no evidence of fixed heterozygosity and showed both balanced and unbalanced heterozygotes at all polymorphic loci, with some individuals exhibiting a pattern consistent with the presence of three or four alleles at a single locus. High levels of genetic variability were found at population level (P_{95} = 37.1%, A = 1.95, H_{ob} = 0.261). The results support an autotetraploid origin for tetraploid *O. chankaensis*, and the high number of alleles at some loci may be due to repeated polyploidization events. The high values of genetic variation agree with those expected for tetraploids.

P0655. Uncovering the origin of the wheat B genome

H. Özkan[1], **B. Kilian**[2,3], C. Yücel[1], W. Martin[3], F. Salamini[2,4];
[1]Department of Field Crops, Faculty of Agriculture, University of Cukurova, Adana, Turkey, [2]Max-Planck-Institute for Plant Breeding Research, Koeln, Germany, [3]Institute for Botany III, Heinrich-Heine-Universität Düsseldorf, Germany, Duesseldorf, Germany, [4]Fondazione Parco Tecnologico Padano, Lodi, Italy.

Bread wheat has a polyploid origin from three ancestral genomes. In the past, extensive studies have been carried out to resolve the phylogenetic relationship of genome B to species among the Sitopsis section of Aegilops. In spite of intensive efforts, clear evidence for the B genome origin is still lacking. Identification of the B genome origin may open unexpected possibilities for wheat breeding.

To identify the B genome donor, we characterized 520 accessions of Ae. sect. Sitopsis, using AFLPs at 80 loci. Based on this, 10 lines from each species were selected and compared with B genome from nulli-tetraploid Chinese Spring. We found that some Ae. speltoides are promissing B genome donor candidates. To solve this mystery, we extended our analysis by SNP-haplotype studies. Eight loci were amplified for the A and the B genome from 40 T. dicoccoides and six Ae. speltoides lines. For each locus, clearly defind haplotypes were identified. Comparing nucleotide diversity and haplotype structure it is now evident that the B genome of modern wheats arose from an apparently outbreeding Ae. speltoides line, the ancient allelic diversity of which is conserved in modern wheats.

P0656. Allopolyploid speciation in *Senecio*: changes to transcriptome in wild and synthetic hybrids.

M. J. Hegarty[1], J. M. Jones[1], I. D. Wilson[1], G. L. Barker[1], J. A. Coghill[1], G. Liu[2], R. J. Abbott[2], K. J. Edwards[1], S. J. Hiscock[1];
[1]University of Bristol, Bristol, United Kingdom, [2]University of St. Andrews, St. Andrews, United Kingdom.

Hybridisation between plant species is one of the best-known mechanisms by which abrupt speciation can occur. The genus *Senecio* provides examples of both homoploid and allopolyploid speciation, though we focus here on the latter. Since its introduction to the UK in the 18th Century, the invasive species *Senecio squalidus* (diploid) has hybridised on at least two occasions to the native *S. vulgaris* (tetraploid) to produce the sterile triploid *S. x baxteri*. This has then undergone a chromosome doubling event to produce the fertile allohexaploid *S. cambrensis*. As an example of recent speciation, *S. cambrensis* is a valuable model for studying changes to gene expression resulting from hybridisation and polyploidy. Here, we describe the construction and use of custom cDNA microarrays from the *Senecio* taxa involved in the allopolyploid formation of *S. cambrensis* to study gene expression between the hybrid and parental taxa. We describe dramatic changes to the transcriptome of the hybrids, with evidence from resynthesised allopolyploids indicating that such changes occur rapidly following hybrid formation.

P0657. Simple technique for determination of ploidy level using chloroplast number in stomatal guard cells of*Trifolium* plants

N. Enayatmehr;
Azad University, Tehran, Islamic Republic of Iran.

Trifolium is a major crop plant. Determination of ploidy level is requierd for studying interspecific relationships, genetic studying of transgenic plants and plant breeding programes. All species of this genus have small chromosomes. Therefore an efficient alternative ploidy determination technique is requierd for this group of plants. The relationship between ploidy level and the number of chloroplasts in stomatal guard cells, was studied in 24 populations of 8 species of *Trifolium*. Three randomly selected middle leaves of greenhouse grown plants were used for chloroplast counting in twenty pairs of stomatal guard cells per each leaf. Chromosome number were also determined in root tip of studied plants. The ploidy level was highly correlated with the number of chloroplasts in stomatal guard cells. Number of chloroplasts in tetraploid population of *T. fragiferum* was approximately twice as many diploid species : *T. spumosum, T. campestre* and *T. physodes*. These results suggested that counting chloroplast number in the leaf stomatal guard cells is an efficient alternative technique for determination of ploidy level in the genus *Trifolium*.

P0658. The copy numbers of the *Leafy/Floricaula* gene in the family Chenopodiaceae

H. Storchova[1], J. Veit[2];
[1]Institute of Experimental Botany AS CR, Prague, Czech Republic,
[2]Institute of Biology II, University of Freiburg, Freiburg, Germany.

The *LEAFY/FLORICAULA* (*LFY/FLO)* gene is a key regulator responsible for the transition from vegetative to reproductive development in angiosperms. A single copy of *LFY/FLO* is supposed to exist in diploid plant species. In contrast, polyploids contain several copies of this gene, some of them with modified function. As *LFY/FLO* copy number may reflect ancient polyploidisation events, it does not always correspond to the currently estimated ploidy level.

We analysed the copy number of *LFY/FLO* in 14 representatives of the family Chenopodiaceae, focusing on *Chenopodium* and *Atriplex*. We applied Southern hybridisation of digested genomic DNA with digoxigenin labelled *LFY/FLO* probe. In some species, the number of *LFY/FLO* copies did not correspond to the ploidy level. We sequenced the second intron and its flanking regions and discussed the nature of additional copies. We have performed the comparative analysis of partial *LFY/FLO* sequences in the phylogenetic context of Chenopodiaceae.

Ackowledgement: This project was supported by the grant GACR 522/05/0300

P0659. *Allium oleraceum* L. polyploid complex in the Czech Republic: geographical and ecological pattern

M. Duchoslav[1], L. afáŚová[1], F. Krahulec[2];
[1]Department of Botany, Palacký University, Olomouc, Czech Republic,
[2]Institute of Botany, Academy of Sciences of the Czech Republic, PrŢhonice, Czech Republic.

Allium oleraceum L. represents polyploid complex (2n = 3x-6x) of common European geophytes, probably of allopolyploid origin. We examined the population frequencies and distribution of cytotypes in the area of the Czech Republic. Ploidy was inferred from estimates of DNA contents, using flow cytometry, for 4347 plants sampled from 327 populations. We further tested for habitat differentiation among cytotypes by comparing many environmental variables of their respective habitats. Across the entire sampling area, pentaploids were most abundant (53% of individuals) while hexaploids and tetraploids were least abundant (33% and 14%, respectively). We did not find any triploid plant. Most populations contained only one cytotype (77%), 24% contained two and 1% had a three cytotypes. Populations with two cytotypes occurred in all possible cytotype combinations. We found significant differences in geographical pattern among cytotypes. Tetraploids and hexaploids showed partially vicariant pattern of distribution while pentaploids were distributed evenly over the whole study area. The results provide evidence for habitat differentiation among cytotypes.

P0660. Molecular phylogenetic analysis of *Oryza* L. (Poaceae) and its consequences for historical biogeography, cytogenetics and morphological evolution.

G. C. X. Oliveira[1], B. A. Schaal[2];
[1]University of São Paulo, Piracicaba, Brazil, [2]Washington University, Saint Louis, MO, United States.

Oryza L. is a small, pantropical grass genus with species generally occurring in flooded grasslands. The genus comprises 23 species with a skewed distribution among infrageneric taxa and ten genomic groups (determined by meiotic chromosome behavior in hybrids): A, B, C, E, F, G, BC, CD and HJ. Both parsimony and maximum-likelihood phylogenetic analyses were applied, based on chloroplast DNA *trnTLF* noncoding sequences. The phylogenies showed that the small complexes are basal and the large apical complexes are of relatively recent origin, with many poorly differentiated species displaying the ability for rapid intercontinental dispersal. Both the diploid and tetraploid genomes CD and HJ are monophyletic, but the Asian and African BC species seem to have originated from distinct polyploidization events. The Neotropical CD genome may have evolved anagenetically from the African BC. Spikelet morphology assessed from center-to-outline distances separated by constant angles seems to have diverged in an approximately linear way in relation to phylogenetic distance, except for the mainly insular species *O. minuta*, whose spikelets are smaller than predicted.

P0661. DNA rearrangement and progressive diploidization of the paleopolyploid maize genome

J. Bennetzen[1], J. Ma[1], R. Liu[1], P. San Miguel[2], K. Ilic[3], Z. Swigonova[4], J. Lai[4], J. Messing[4];
[1]University of Georgia, Athens, GA, United States, [2]Purdue University, West Lafayette, IN, United States, [3]Stanford University, Stanford, CA, United States, [4]Rutgers University, Piscataway, NJ, United States.

Sequence analyses of orthologous regions from several cereal genomes have indicated the natures and rates of genome change in these lineages. Since the origin of maize from a tetraploid formed less than 12 mya, ~25% of the tetraploid's genes have been lost, mostly through a progressive accumulation of small deletions. The gene losses usually have not removed both orthologues, so that the number of gene families has not changed dramatically. Gene losses appear to be equally likely from both "homoeologues" in most regions, suggesting that epigenetic silencing of long chromosomal stretches on one homoeologue did not commonly occur after polyploidization. Recent tandem gene amplifications and deletions are observed, many associated with unequal recombination. In addition, transposable elements (TEs) have acquired, transposed and thereby amplified numerous genes or gene fragments. The regions between genes show almost no conservation between the two maize homoeologues, sorghum and rice. This is largely because intergene TE amplification and subsequent removal by unequal homologous and illegitimate recombination make these regions exceptionally dynamic.

P0662. A comparative study of chromosome morphology among the some cultivars of Cicer arietinum L.

f. -. mahmoodi .k;
Teacher Training university, Tehran, Islamic Republic of Iran.

Eleven cultivars(desi and kabuli types) were subjected to karyotype analysis for their potential use in determination of genetic relationships in chickpea cultivars. Somaticchromosome number 2n =16 confirmed in all the cultivars.Within cultivars interchromosomal size variation was observed to be quite large in some cultivars but not in the remaining rest cultivars.Significant differences in haploid genome length among the cultivars were observed(18-25µ) .The cultivars were classified in two groups based on karyotypic similarity,with the first group comprising inter crossable,while the remaining cultivars forming second group.The first group are also genetically close to eachother as deduced by other Morphological, Biochemical and DNA based studies circumstuntial evidence has lead to the speculation that perhaps karyotypic similarity and intervariety crossability are positively related to eachother .

P0663. Karyological and taxonomic notes on *Odontites vernus* group (Scrophulariaceae s.l., tribu Rhinantheae) in the Iberian Peninsula.

L. Delgado, M. Santos, M. Martínez-Ortega, F. Gallego, E. Rico;
University of Salamanca, Salamanca, Spain.

The *Odontites vernus* group is the most widely distributed and probably the most complex from a taxonomical point of view within the genus *Odontites* Ludwig. According to the traditional treatments, it is represented in the Iberian Peninsula for two taxa: *O. vulgaris* Moench, 2n=20, and *O. vernus* (Bellardi) Dumort., 2n=40. With the purpose of clarifying the taxonomical status of both species in the Iberian Peninsula, morphological and karyological studies from Iberian material were made. The most repeated ploidy level in the about 50 populations studied is the tetraploid level.Recognizing the individuals of both ploidy levels by morphological characters does not seem to be possible according to the results obtained from this study. Neither the geographical distribution of the morphological variants nor that of the ploidy levels support the taxa separation. It is possible that both taxa behave here like cryptospecies or that, as a whole, it is a polyploid complex with two ploidy levels (2n=20,40); in this case, *O. vernus* should be considered as a unique taxon in the Iberian Peninsula.

P0664. Comparative assessment of induced mutants from *Solanum macrocarpon* L.

O. A. Oyalana, K. O. Ogunwenmo;
Babcock University, Lagos, Nigeria.

Three mutants (M1, M2, M3) consistently expressed cytological and morphological variations among eight seedlings growth lines treated with 0.6% aqueous solution of colchine. The five others resumed normal growth after the tenth leaf stage. The mutants experienced delayed germination (8-12 days) and tumour swellings, tip twisted or rolled radicles. M1 and M2 plants had three cotyledons while M3 and controls had two cotyledons each. Leaves were smaller and slightly folding in the mutants. Mutants were procumbent to prostrate with short and fewer internodes than erect control plants. Epidermal cells were extensively wavy in M3 plants, stomata characterised by one guard cell in M1 and closed pores in M2. M2 plants did not produced flower while M1 and M3 produced fewer flowers than controls. M1 contained fewer seeds while fruit ripening was delayed in M3. M1, M3 and control plants exhibited diploid chromosome complement (2n) of 24 but doubled in M2. M1 and M3 showed somatic instability, 2n = 28, 32 and 42. Meotic irregularities in M1 and M3 include clumps, laggards and bridges.

P0665. Karyotype Analysis of Chilean Taxa of *Alstroemeria* L. (Alstroemeriaceae)

E. Bayer[1,2], J. F. Zoller[3];
[1]Botanischer Garten München-Nymphenburg, München, Germany, [2]Zentrum für Geobiologie und Biodiversitätsforschung an der Ludwig-Maximilians-Universität München (GeoBio-Center at LMU), München, Germany, [3]Ludwig-Maximilians-Universität München, Fakultät für Biologie, Department Biologie I, Bereich Botanik, München, Germany.

The Chilean taxa of *Alstroemeria* L. are already profoundly described by classical systematic methods, but relationship is not yet completely resolved. Morphometric and C-banding analysis were applied and proved to be useful for identification of individual chromosomes and species-specific characteristics. Differences in chromosome size are observed on inter- and infraspecific level. Despite of variation in size, chromosomes can be grouped into a typical karyotype with a formula of 2n=16: 1 (m) + 3 (m-sm) + 4 (st-t), valid for more than 20 taxa (species and subspecies) examined. Our data show that one chromosome is conserved while others are submitted to the dynamic process of rearrangement during speciation. Additionally FISH-analysis was applied for physical mapping of rDNA sequences (18S-5,8S-28S). The relationship of four Chilean taxa, *A. ligtu* L.(three subspecies) and *A. pulchra* Sims, based on systematic characters, is now confirmed by cytogenetic methods and discussed in detail.

P0666. Contribution to the Cytotaxonomy of the Georgian Flora

M. T. Davlianidze[1], M. Bokeria[2];
[1]Institute of Botany of the Academy of Georgia, Tbilisi, Georgia, [2]Georgian State Museum, Tbilisi, Georgia.

Cytological research of high mountain species of Caucasus was made. Descriptions of the karyotypes and chromosomes number of 100 species (40 endemics and subendemics) were analyzed. It was shown, that these species belonged to the mono- and olygotypic genera or sections: Brunnera macrofilla 2n=12; Sobolewskia caucasica 2n=16; Cladochaeta candissima 2n=18; Primula farinifolia 2n=18; P.bayernii 2n=22; Merendera raddeana 2n=18; Colchicum szovitsii 2n=18; C.bifolium 2n=18; C.zangezurum 2n=18; C.woronowii 2n=42,48; C.speciosum 2n = 38; Gagea joannis 2n=24; G.sulfurea 2n=72; Crocus suvorovianus 2n=8; Colpodium versicolor 2n=4; Zingeria trichopoda 2n=8. The subnival belt vegetation spreading in the upper limit has been investigated. The origin and differentiation of the subnival floristic complexes were analyzed. The diploids makes up 76%, polyploidy - 24% . Subnival belt contains an ancient oreophits. Phylogeny for the major species based on the cytotaxonomycal investigation is discussed.

P0667. A karyosystematic study of some endemic, rare and interesting weeds of Crete (Greece)

P. Bareka[1], G. Kamari[1], N. Turland[2], D. Phitos[1];
[1]Botanical Institute, Patras, Greece, [2]Missouri Botanical Garden, Saint Louis, MO, United States.

In Spring of 2003, a research project entitled “Threatened weeds in the traditional agriculture of Crete”, financially supported by the National Geographic Society, took place. The project was a collaboration between the Missouri Botanical Garden, St. Louis U.S.A. (MO) and the Botanical Institute of the University of Patras, Greece (UPA). The goal of this project was to carry out a thorough floristic survey of weeds in sites of traditional agriculture of the South Aegean island of Crete, Greece. During this project, living material was also collected for cytological investigation.

As preliminary results of this karyosystematic study, the chromosome number, karyotype morphology and geographical distribution of some endemic, rare and interesting weeds of Crete are presented here. Further issues of taxonomy, phytogeography and conservation of some Cretan weeds are briefly discussed.

P0668. Strasburgeria robusta (Strasburgeriaceae) survives as a high-polyploid species in New Caledonia

K. Oginuma[1], J. Munzinger[2], H. Tobe[3];
[1]Human Life & Enviromental Science, Kochi, Japan, [2]IRD BP A5, Noumea, New Caledonia, [3]Graduate School of Science, Kyoto, Japan.

Strasburgeria robusta, the only species of the family of its own, is a tree of 3-15 m tall that grows at elevation of (300-)700-1200 m, mainly in Nothofagus and/or Araucaria humid forest. It is strictly located on ultramafic soil, in the south part of the main island in New Caledonia. Recently Strasburgeriaceae are placed in rosids (APG II 2003), but its relationship is still uncertain. Morphological and vegetative anatomical characters are relatively well known about S. robusta, but its cytology is not known yet. We investigated its somatic chromosome number using cells collected from young leaves and flowers buds, and found that the species has as many as about 500 chromosomes. To our knowledge, 2n = ca. 500 represents the highest number in angiosperms except for several particular species of Crepis, Kalanchoe, Spinach, etc. Although the base number is unclear, there is no doubt that such a chromosome number represents an extremely high-polyploid. While Strasburgeria probably had lost its relatives at lower ploidy levels in its history, it descendant has survived only as the extremely high-polyploid adapted to nickel-rich soils in New Caledonia.

P0669. Karyosystematics and molecular phylogeny of *Trilliaceae*

E. O. Punina, E. M. Machs, E. S. Kim, Y. A. Myakoshina, V. S. Chupov, A. V. Rodionov;
Komarov Botanical Institute RAS, Saint Petersburg, Russian Federation.

All species of Trilliaceae carry giant chromosomes, the mean size of which is about 9 Mbp, that is 3 times more that all human genome. Karyotypes of Trilliaceae have revealed high interspecies variability of heterochromatin banding patterns. We have studied the Q- and CMA-chromosome banding patterns of *Paris incompleta, P. quadrifolia, Daiswa hajnanensis, Trillium recurvatum, T. erectum, T. grandiflorum, T. tschonoskii* and *T. camschatcense*. Then we compare p-distance between these species through ITS1-5.8S-ITS2 sequence analysis. It was shown that all *Paris* chromosomes have multiple small AT-rich heterochromatic bands. On the other hand, there are large both AT- and GC-enriched heterochromatic bands on a part chromosomes of *Daiswa* karyotype. The chromosomes of all *Trillium* species, with except of *T. tschonoskii*, carry large AT-enriched heterochromatic bands. Our results of ITS1 and ITS2 sequences analysis support the position of *T. tschonoskii* on the branch of *Paris* species in spite of morphology analysis and chloroplast gene matK sequence of this species are clustered *T. tschonoskii* with *T. camschatcense.* Grants RFBR 03-04-49477 and 02-04-49896.

P0670. Citotaxonomy of the subtribe Lychnophorinae (Vernonieae: Asteraceae)

E. R. Forni-Martins[1,2], M. E. Mansanares[3,4], J. Semir[1], A. L. L. Vanzela[5];
[1]Universidade Estadual de Campinas, Campinas, SP, Brazil, [2]CNPq, Brasilia, Brazil, [3]Curso de Pós-graduação em Biologia Vegetal, Universidade Estadual de Campinas, Campinas, SP, Brazil, [4]FAPESP, São Paulo, Brazil, [5]Universidade Estadual de Londrina, Londrina, PR, Brazil.

Lychnophorinae is composed by 9 genera, most of them endemic to the Brazilian *campos rupestres*. In the genus *Lychnophora* there is disagreement between different authors regarding the limit and number of species. The difference is based on sinonimization and transference of several species to related genera. There are also difficulties in the delimitation of other genera (*Minasia*, *Proteopsis* and *Heterocoma*). Aiming a better understanding of the taxonomy of the group as a whole, chromosome numbers of about 49 species were determined. The numbers 2n=34, 36 or 38 were distributed among species of several sections of *Lychnophora* and also closely related genera. Chromosomes size (1.0 to 2.58µm) and morphology (mainly metacentric, with some submetacentric) were analyzed in 7 species and showed relative constancy. The use of FISH, with 45S rDNA probe, have demonstrated great diversity, with 4 to 10 hybridization sites among 16 species. Although karyotype characters can't be used to segregate genera and sections of *Lychnophora*, they are very useful for the differentiation between some species, wich taxonomic limits have been previously questioned.

P0671. Origin and evolution of sweet potato (*Ipomoea batatas*) and its wild relatives

S. Srisuwan, D. Sihachakr, S. Siljak-Yakovlev;
Ecologie, Systématique, Evolution, UMR CNRS 8079, Orsay, France.

Sweet potato (*Ipomoea batatas*), a hexaploid species (2n=6x=90), is an important food crop. The origin of its polyploidy and the genome evolution are still being discussed. The relationship among closely related species, or diploid (2n=2x=30) parental candidates (*I. trifida, I. triloba, I. leucantha, I. tiliacea* and *I. setosa*) has been investigated by using molecular markers. However, molecular-cytogenetic analysis is lacking through those investigations. In this study, the new data concerning karyotype and genome size of those species are reported. The genome size of hexaploid *I. batatas* (3.45 pg) was about three times as high as that of diploid species (1.17pg). The fluorochrome banding was used to determine GC rich DNA regions, the fluorescence in situ hybridization (FISH), the number and position of 18S-26S and 5S rDNA loci, and the silver staining, to study NORs activity. Those chromosome markers were found effective to distinguish the karyotype of 5 diploid species and two varieties of *I. batatas*. Moreover, the close relationship between *I. trifida* and *I. batatas* has been demonstrated upon analysis of molecular-cytogenetic characteristics.

P0672. Characterizing polyploidy in the Caribbean Consolea Lem. (Cactaceae): chromosomes, cytomixis and pollen grain size.

V. Negron-Ortiz[1,2], L. I. Strittmatter[1];
[1]Miami University, Oxford, OH, United States, [2]Smithsonian, Botany Department, Washington, DC, United States.

Chromosome counts within the Cactaceae have indicated the presence of euploid and polyploid species, and it has been suggested that both

polyploidy and hybridization events have led to speciation in this family. We studied the ploidy level and chromosome number of Consolea, a genus of nine species endemic to the Caribbean. Consolea is sub-dioecious with male, female and, in a few species, hermaphroditic plants. Mitotic

chromosome counts on root tips were determined for eight species, resulting in 6x, 7x and 9x ploidy levels. Neither diploids (2x=22) nor dodecaploids were found as formerly reported. Flow cytometry is being used to confirm the chromosome counts, and test for presence of sex chromosomes. Cytomixis and variable sized pollen grains were noticed in

several species. Cytomixis, the migration of nuclear material through cytoplasmic channels, has often been observed during microsporogenesis of genetically unbalanced, and seldom, diploid plants.

We detected cytomixis in male-fertile and male-sterile anthers of microspore mother cells, and between a tapetal cell and a microspore

mother cell. Pollen sizes will be compared among the polyploid species.

P0673. A taxonomic study in section *Sacculiferum* of *Allium* from Korea

B. U. Oh[1], **C. G. Jang**[2];
[1]School of Life Sciences, Chungbuk National University, Cheongju, Republic of Korea, [2]Biotechonology Research Institute, Cheongju, Republic of Korea.

The sect. Sacculiferum is one of the members of subgenus Rhizirideum that is restricted in Northeastern Asia. This section has morphological characters such as ovate bulb, longer filaments than perianth, purplish flower, and subglobular umbel in common. There are known 9 taxa of the section with 4 endemics in Korea. Although each taxon of the section is mainly delimitated by leaf shape, growing pattern, the size of umbel, the shape of perianth, and chromosome number, taxonomy of this section is not an easy matter. The main problems of taxonomy is the classification between A. sacculiferum and thunbergii complex. The most part of members in this section have 2n = 16 (x = 8) in their basic chromosome number. As A. sacculiferum and pseudojaponicum were tetraploidy of 2n = 32, they were well separated from other taxa. The karyotype of A. thunbergii complex was little bit different features from other taxa of the section. The sect. Sacculiferum was defined 3 different groups with cytological data. Giemsa C-banding data will be also used to investigate relationships within the section and discriminate the taxa in A. thunbergii complex.

P0674. A tale of two parasitic lianas :Cassytha and Cuscuta [The comparative karyology]

P. K. Bhattacharyya;
The University of Burdwan, Burdwan, India.

The karyotype study of two native, parasitic lianas, Cassytha filiformis L. (2n = 24) and Cuscuta reflexa Roxb. (2n = 32) revealed five types of chromosome groups based on centromeric index (F%). Type A: Chromosomes C.12.5µm long with two constrictions, one nearly terminal (F% = 8%) and the other nearly submedian (F% = 36%). Type B: Chromosomes (6.6 - 24.2µm) with nearly median constriciton (F% = 38.8 - 47.9%). Type C: Chromosomes (3.4 - 16.1µm) with nearly submedian constriction (F% = 22.8 - 37.4%). Type D: Chromosomes (9.3 - 9.7µm) with two constrictions, one nearly subterminal (F% = 14.8%) and the other nearly submedian (F% = 37%). Type E: Chromosomes (7.2 - 14.6µm) with nearly subterminal (F% = 18.3%) to nearly terminal (F% = 6.5%) constriction. The population of Cassytha revealed symmetric karyotype with range of chromosome length 6.3 - 12.6µm, disparity index, 33.33% and karyotype formula A2B4C18 while the population of Cuscuta revealed asymmetric karyotype with range of chromosome length 3.4 - 24.2µm, disparity index, 84%, and karyotype formula B14C6D2E10. The meiosis of Cuscuta revealed pericentric inversion bridge and secondary origin of long chromosome.

P0675. Chromosome numbers in selected species of Hypericum L. in Lithuania

E. Bagdonaitǟ, J. Labokas;
Institute of Botany, Vilnius, Lithuania.

Hypericum perforatum and *H. maculatum* are known as species producing a wide range of pharmaceutically important secondary metabolites. As indicated by previous studies, the wild populations of the species is rich primary source of genotypes for the plant breeding and cultivation. Seeds were collected from the natural habitats and field collection and germinated in Petri dishes on wet filter papers. Seedlings with the roots of ca. 5 mm in length were chosen for the karyological studies. These studies confirmed that *H. perforatum* is characterized by a tetraploid chromosome number (2n = 4x = 32), but morphologically inconspicuous hexaploids (2n = 6x = 48) also occur. Variability of the number of chromosomes in this species is associated with specific way of its reproduction, a facultative apomixis. The main reasons for the selection and breeding of the polyploids might be higher contents of secondary metabolites. *H. maculatum* is a diploid (2n = 2x = 16) and it reproduces sexually. The chromosome counts reported here also facilitates distinguishing between species and their natural hybrids.

P0676. Characterization and chromosome location of repetitive DNA in *Anemone hortensis* L.

J. Mlinarec, D. Papes, V. Besendorfer;
Department of Molecular Biology, Division of Biology, Faculty of Science, University of Zagreb, Zagreb, Croatia.

Karyotype of the Mediterranean species *Anemone hortensis* L. consists of three acrocentrics (chromosomes 1, 2 and 3), one meta-submetacentric (chromosome 4) and four metacentrics (chromosomes 5, 6, 7 and 8). In *A. hortensis*, large AT-rich heterochromatic bands are located intercalary and terminally on long arm of all acrocentrics and terminally on chromosomes 4 and 5. In this study, we report the nucleotide sequences and chromosomal organization of repetitive elements. The tandem repeats isolated after digestion of genomic DNA with *Eco*RV (JME) and *Hind*III (JMH2) were 567 bp and 743 bp long, respectively. The JME satellite sequence family was located in all intercalary DAPI bands, while the JMH2 satellite sequence family coincided to terminal DAPI bands. After digestion of genomic DNA with *Hind*III, 945 bp long JMH1 repeat sequence was isolated. FISH revealed dispersed organization of JMH1 on all chromosomes of *A. hortensis*. JMH1 exhibited partial homology to the *Ty*3/*gypsy*-like retroelement and has to be confirmed as a part of a retrotransposon.

P0677. Caryological Study of Some High-Mountain Rare and Endemic Species of the Caucasus

T. Gviniashvili[1], R. Gagnidze[1,2];
[1]N. Ketskhoveli Institute of Botany, Tbilisi, Georgia, [2]I. Javakhishvili Tbilisi State University, Tbilisi, Georgia.

The aim of the study was to investigate caryology of rare and endemic species of the Caucasus high mountains. For number of years the authors studied the main components of floristic complexes and different taxons of the Caucasus high mountain flora. The methods used in the study were taxonomical, areological, ecotopological and caryogeographical. Endemism is an especially common phenomenon for the Caucasus high mountain rocky-scree-cobble ecotypes. Most of the species of these ecotypes are appear to be diploids. The results of our study confirm that diploid species of the Caucasus high mountain flora are autochthonous. They are of the relatively ancient age. However, polyploids, species with high chromosome numbers, are the result of a further selection process. These species overcame different inconvenient climatic barriers during the long time of the evolution and thus, they might be considered as palaeopolyploids. One of the most important factors in the evolution of the Caucasus endemics is geographical isolation.

P0678. Chromosome number and meiotic behaviour studies in *Hoffmannseggella* H.G.Jones (Laeliinae, Orchidaceae)

J. Y. Costa[1,2], E. R. Forni-Martins[3,4];
[1]Curso de Pós Graduação em Biologia Vegetal, UNICAMP, Campinas, Brazil, [2]FAPESP, São Paulo, Brazil, [3]Universidade Estadual de Campinas (UNICAMP), Campinas, Brazil, [4]CNPq, Brasília, Brazil.

Hoffmannseggella is a Brazilian endemic genus of rupiculous orchids, previously assigned to the *Parviflorae* section of *Laelia*, distributed all over the Espinhaço Range, mainly in Southeast region. We analysed mitotic and meiotic chromosome numbers of 9 *Hoffmannseggella* species: 6 presented n=20/2n=40 and 2 presented 2n=80 with aneusomatic root tissues. *H. rupestris*, one of the polyploid species, presented two cytotypes (2n=40 and 2n=80). A new species, found in a parallel study, presented 2n=44 chromosomes, being the first documentation of a *Hoffmannseggella* species originated by aneuploidy. Meiotic abnormalities are observed in several species, like one extra bivalent, tetravalents, chromosome laggards in anaphase and tetrads with micronucleous. However, all species presented high normality of tetrads (86.4 - 100%). Polyploidy, aneusomaty and most of the meiotic abnormalities were found in species distributed on the Diamantina Plateau, one specific region of the Espinhaço Range, where species usually presented sympatry and flowering period overlapping, suggesting that this region could represent a hot spot for speciation inside the genus.

P0679. Chromosome analysis of the genus *Skimmia* (Rutaceae) in East Asia

T. Fukuda[1], H. Nagamasu[2];
[1]Graduate School of Science, Kyoto University, Kyoto, Japan, [2]Kyoto University Museum, Kyoto, Japan.

Chromosome analysis was performed for three species of *Skimmia* in East Asia; *S. japonica, S. reevesiana* and *S. arisanensis.* Chromosome counts revealed that *S. japonica* was diploid (2n=30) over its entire distribution, and the other two species were tetraploid (2n=60). This result does not contradict the report of Johnson & Taylor (1989). All species had five large pairs and 10 rather small pairs of chromosomes. *S. japonica* var. *lutchuensis* in Ryukyu, which grows as large trees, was also found to be diploid, which indicates that plant size and form are not related to ploidy level in *S. japonica*. Karyotype analysis revealed some differences, which can be represented as four karyotypic formulae. In *S. japonica* three karyotypes were found. A-type had the widest distribution, but the chromosome pair with the lowest long/short arm length ratio showed geographical variation; lower than 1.2 in Honshu and further north, and more than 1.2 for southern Kyushu to Taiwan. C-type and D-type were found only in Yaku Island and Taiwan respectively. Karyotype of the two tetraploid species (B-type) differ from *S. japonica* in having only one subterminal pair.

P0680. Cytotaxonomy of some species of *Cousinia* (Asteraceae) from Iran

S. Ghaffari;
Tehran university institute of biochemistry and biophysics, Tehran, Islamic Republic of Iran.

Cousinia with a total of c. 662 species , of which 379 are endemic within the Flora Iranica area, is remarkable in various respects.In the recent years some new species or new records of Cousinia are added to the Flora of Iran. The generic distribution area of Cousinia is nearly identical with the Irano-Turanian region. In this study original observations on meiotic cells in twenty eight species of the genus Cousinia are reported. Of these, the chromosome numbers for Sixteen endemic species viz, C. aitchisonii C. Winkl. (n=13), C. alexenkoana Bornm. (n=13), C. behboudiana Rech.f. & Esfand.(n=12), C. boissier Buhse (2n=24), C. canolleana Jaub.& Spach. (n=9), C. gmelini C. Winki. (n=12), C. irritans Rech.f. (n=13),C. kerejensis Bronm. & Gauba. (n=12), C. lasiandra Bunge (n=13), C. meshhedensis Bronm.&Rech. f. (n=13), C. pichlorina Bronm.&Rech. f. (n=12), C. pinarocephala Boiss. (n=12), C .raphiostegia Rech.f. (n=13), C. trachylepis Bunge (n=13), C. turkmenorum Bornm. (n=11), C. wilhelminae Rech. f. are reported for the first time. Twelve species provide confirmation of scarce or disputable previous data.

P0681. Giemsa C-banding and karyological studies in species of *Rhinopetalum* (*Liliaceae*)

G. Bakhshi Khaniki;
Payame Noor University, Tehran, Islamic Republic of Iran.

C-band patterns and karyology are described for three Old World *Rhinopetalum* species. All species have a similar basic karyotype (n=12), consisting of large symmetric (m, sm) and smaller asymmetric (t, st) chromosomes, but C-bands differ between them. The bands are rather few, located at intercalary, telomeric, centromeric and rarely secondary constriction regions. The genus *Rhinopetalum*, is comparatively richer in heterochromatin. The patterns are characterized by the occurrence of thick telomeric/subtelomeric heteromorphic bands in the second pair of m-chromosomes. Presence of a distinct centromeric band in the short arms of these m-chromosomes in *Rh. bucharicum* discriminate it from the two allied species. A certain level of banding heteromorphy was observed mostly in term of bands size. It is obvious from this study that diversity exists between individual species studied both in the dispersion and quantity of detectable heterochromatin and chromosome morphology. Further aspects of banding patterns, band heteromorphy, chromocenters, equilocal position of bands and the role of C-banding in taxonomy are discussed.

P0682. A critical review and a new proposal of karyotype asymmetry indices

B. Paszko;
W. Szafer Institute of Botany, Polish Academy of Sciences, Krakow, Poland.

In the literature nine different methods (the karyotype classification of Stebbins, the TF%, the Rec, the As K%, the Syi, the A_1, the A_2, the AsI and the DI) of evaluation of the karyotype asymmetry were found, that are used to delineate the the direction of phylogenetic changes among and within different taxa. Expanded investigation of these nine methods reveals that qualitative classification of Stebbins is a less sensible and only one parameter, the A_2 index, correctly describes the variation of chromosome length in a complement. A new asymmetry index (the AI) is proposed to measure the karyotype asymmetry and a new parameter, the CV_{CI}, is offered, that precisely assess relative variation of centromeric position. The AI index, the CV_{CI} and the CV_{CL} (=A_2 index) have the potential to display even minor karyotypic variations. Thus, these three indices together increase precision of results in comparison with other existing methods. All of them can be used to test evolutionary hypotheses and may be included in multivariate analysis. All this has important consequences in the interpretation of results of karyological studies, especially in evolutionary context.

P0683. FISH of tandemly repeated DNA sequences and RAPD analysis for characterization of geographically isolated populations in five species of *Alstroemeria* (Chile)

O. Schrader[1], C. M. Baeza[2], H. Budahn[1];
[1]Federal Centre for Breeding Research on Cultivated Plants, Institute of Horticultural Crops, Quedlinburg, Germany, [2]Departamento de Botánica, Universidad de Concepción, Concepción, Chile.

In fifteen geographically isolated populations of five species of *Alstroemeria* (*A. aurea*, *A. ligtu*, *A. hookeri, A. pelegrina* and *A. presliana*), collected in Chile, were investigated the karyotypes and variation of RAPD markers. Tandemly repeated DNA sequences - 5S and 18/25S rDNA genes and the sequence A001-I (De Jeu et al. 1997) were used in characterizations of karyotypes carried out by fluorescence *in situ* hybridization (FISH). For measurements of chromosomes was used 10 somatic metaphases per population. Differences in 550 RAPD marker bands were used for characterization of populations creating an index of similarity. The FISH with all three DNA probes had shown a high degree of polymorphism between and sometimes also within the populations of *A. aurea, A. hookeri* and *A. ligtu*. Furthermore, comparing the 4 populations of *A. hookeri* between themselves, the population 4181 was different in their arm length of chromosome 3, showing a higher difference in relationship to the other 3 populations. In the same comparison the RAPD markers (index of similarity) showed a lower value. The possible evolutionary mechanisms providing these polymorphisms were discussed.

P0684. Structure and evolution of centromere satellite sequences in Arabidopsis halleri spp. gemmifera

A. Kawabe[1], S. Nasuda[2];
[1]Institute of Evolutionary Biology, Edinburgh, Scotland, United Kingdom, [2]Kyoto University, Kyoto, Japan.

Centromeric tandem repetitive sequences were isolated from Arabidopsis halleri ssp. gemmifera. Two novel repeats families, pAge1 and pAge2 were found. The repeat units are about 180 bp and are arranged in head to tail organization. The repeats are similar to the pAL1 180-bp repeat of A. thaliana and pAa of A. arenosa. A. gemmifera also has the sequences of the pAa family. Sequence divergence between A. gemmifera and A. thaliana is about 30%, about twice that estimated for protein coding gene regions. One region including Box B showed high conservation among the different centromeric repeat families, while several regions differ mainly between the three families. The sequences from different species could not be distinguished. FISH analysis showed that the three 180-bp repeat families have chromosome-specific locations, though some chromosomes have two repeat families. The chromosome specificity of the three repeat families differs among A. gemmifera strains, and in a related species A. lyrata ssp. kawasakiana.

P0685. Comparative karyotype analysis in *Chaetanthera chilensis* (Willd.) DC. and *Chaetanthera ciliata* Ruiz et Pavón (Asteraceae) by double fluorescence *in situ* hybridization

C. M. Baeza[1], O. Schrader[2];
[1]University of Concepción, Department of Botany, Concepción, Chile, [2]Federal Centre for Breeding Research on Cultivated Plants, Institute of Horticultural Crops, Quedlinburg, Germany.

Karyotypes of *Chaetanthera ciliata* and *C. chilensis* from Chile were examined using the location of the 5S and 18S/25S rDNA gene sequences. Signals of 5S and 18/25S rDNA are seen in 4 and 5 of the 11 chromosome pairs in *C. ciliata* and *C. chilensis*, respectively. The reported karyotypes are symmetric with small chromosomes and a great similarity among them. Chromosome asymmetry indexes (AsI % and A_1) were similar for both species. This report is the first on chromosome number and karyotype analysis of *Chaetanthera ciliata* and *C. chilensis*. One of the remarkable differences between the karyotypes of *C. ciliata* and *C. chilensis* is that *C. ciliata* has only metacentric chromosomes, whereas *C. chilensis* has a submetacentric chromosome pair. These differences in the karyotype suggest that structural changes or rearrangements may have contributed to the diversification of the genus. Using the FISH technique, notable differences can be observed with respect to the position and number of rDNA sequences depending on the chromosome.

P0686. Genome organization of some *Iris* species assessed by molecular cytogenetics

S. Siljak-Yakovlev[1], F. Bogunic[2], E. Muratovic[3], M. E. Solic[4], D. Pavlovic[5], S. Medjedovic[2];
[1]Ecologie, Systématique, Evolution, UMR CNRS 8079, Orsay, France, [2]Faculty of Forestry, Sarajevo, Bosnia and Herzegovina, [3]Faculty of Sciences, Sarajevo, Bosnia and Herzegovina, [4]Institute Mountain and Sea, Makarska, Croatia, [5]Faculty of Science, Kragujevac, Serbia and Montenegro.

DNA content of 8 *Iris* species (*I. bosniaca*, *I. germanica, I. illyrica*, *I. pallida*, *I. pseudopallida, I. pseudopumila*, *I. reichenbachii* and *I. variegata*), was assessed by flow cytometry. The 2C DNA value ranged from 11.48 to 14.01 pg. The significant variations of DNA amount were observed among three populations of *I. bosniaca* (from 11.66 to 12.34 pg), and 4 populations of *I. pseudopallida* (from 12.17 to 14.01 pg), from different geographical origins and ecologically contrasting habitats. Genome organisation and chromosome complements for certain species were characterised by molecular cytogenetic techniques: 1) chromomycin fluorochrome banding for detection of GC rich DNA regions, 2) fluorescence *in situ* hybridization (FISH) with rDNA probes to determine the number and position of rDNA loci, 3) DAPI after FISH experiment revealing number and position of heterochromatic bands and 4) silver staining to study NORs activity. This work presents the first report on genome size and physical mapping of 5S and 18S-5,8S-26S rDNA gene clusters for these species. Some considerations concerning the chromosomal evolution of the endemic Balkan irises are also presented.

P0687. The Cytotaxonomic Studies on the Properties of Species of Origanum leptocladum Boiss. and Origanum micranthum Vogel

A. G. -. Balim, T. -. -. Kesercioglu;
Dokuz Eylul University, Izmir, Turkey.

The flora of Turkey, in terms of medical plants, are too rich. Among these plants, the species of Origanum L. which is one of the medicinal plants with high commercial value has occupied an important place. Approximately 70 % of the species of Origanum L. are endemic either on an island or in a mountain. When Turkey's flora is examined, it is known that there are 21 Origanum L. species which belong to eight sections. 13 of these species are endemic. In this research,the cytotaxonomic properties of two endemic species, Origanum leptocladum Boiss and Origanum micranthum Vogel which belong to Origanum L. genus and show the spread in the East Mediterranean Area of Turkey are examined.The cytotaxonomic properties of these two Origanum L. species are first dealt with and by doing their chromosomes counting,they have been given in their original scheme. The numbers of the chromosome of both species have been determined as 2n=30.

P0688. Genetic, morphological, physiological and taxonomic studies in the Chilean endemic genus *Leucocoryne* Lindley

L. M. Mansur, G. Verdugo, O. Zoellner, P. Salas, C. de la Cuadra, L. Araneda, L. Arriagada;
Universidad Catolica de Valparaiso, Quillota, Chile.

The genus *Leucocoryne* (*Alliacea*) is endemic to Chile and is distributed from Iquique (26º 13´ S) in the Atacama dessert to Concepción (36º S) in the South. It has conservation problems. Genetic, morphological, physiological and taxonomic findings of research in Chile since 1996 are presented. Half of *Leucocoryne* are either 2n=10 or 2n=18. Gene flow occurs between ploidy levels. It is largely self-incompatible. We developed morphological descriptors to characterize 15 species in the germplasm collection. Morphological and molecular (AFLP) variation is found. *L. narcissoides* and as *L. appendiculata,* the two northernmost species, are different at the molecular and flower morphology levels. They are the only ones with six stamens or with fertile staminoids. Seeds store for up to three years at room temperature and germinate at 10-15 ºC. The first cycle is completed in approximately 100 days. *Leucocoryne* bulbs break dormancy in 4.5 months at 20ºC, but there is variation. Nutrients are remobilized efficiently to the bulb at maturity. Tissue culture and commercial varieties have been developed. *Leucocoryne talinensis* a new species has been described and published.

P0689. Cytological and molecular approach to analyse Patagonian *Bromus* species

A. M. García[1], G. E. Schrauf[2], G. González[1], **L. Poggio**[3,1], C. A. Naranjo[1], M. P. Dupal[4], J. W. Forster[4], G. Spangenberg[4];
[1]CIGEN -CONICET, Llavallol, Argentina, [2]Facultad de Agronomía UBA, Buenos Aires, Argentina, [3]Facultad de Ciencias Exactas y Naturales UBA, Buenos Aires, Argentina, [4]Plant Biotechnology Centre, Bundoora, Australia.

Bromus pictus, *B.setifolius* and *B.brevifolius* are taxa of the section *Pnigma,* native from the Patagonia. It is believed that they constitute a specific complex whose morphological trait variation did not permit a clear delineation between the taxa. Variation within this group was detected using AFLP´s and RAPD´s. *B.brevifolius* has a close affinity with *B. pictus* and both taxa are relatively more distantly related to *B.setifolius*. Cytogenetic analysis revealed that *B. setifolius is*: $2n=28$; *B. pictus:* $2n=70$; and *B.brevifolius:* $2n=70$. The genomic *in situ* hybridization (GISH) of labelled DNA of *B.setifolius* over the 70 mitotic chromosomes of *B.pictus* reveals that the probe hybridized 28 chromosomes, morphologically similar to those of *B. setifolius*. This result confirms that *B pictus* must be separated from *B.setifolius* and given full specific status. Moreover, GISH confirms the allopolyploid origin of *B pictus* and the relationship with its putative progenitor *B.setifolius*.

P0690. The relation of the Scrophulariaceae tribes Buddlejeae and Teedieae as inferred from nuclear RPB2-d and chloroplast DNA sequences.

K. Kainulainen, B. Oxelman;
Evolutionary Biology Centre, Uppsala, Sweden.

The phylogeny of Scrophulariaceae as inferred from the nuclear low copy gene RPB2-d and the chlorplast DNA regions trnL/F and ndhF is presented focusing on the relations of the tribes *Buddlejeae* and *Teedieae* as well as the taxonomically unplaced genus *Camptoloma*. Two RPB2-d paralogues are present in both diploid (2n=38) and tetraploid *Buddleja* species, as well as some putative pseudogenes. The basic chromosome number of *Buddleja* is X=19, and it has been hypothesized that the origin of the genus is a result of a hybridization event between two lower chromosome numbers, most probably X=7 and X=12, of which *Gomphostigma* (X=7) has been suggested to represent one of the ancestral lineages. *Gomphostigma* is here shown to be nested within the *Buddleja* clade, and hence more likely derived from a *Buddleja* ancestor. Inclusion of the genera *Nicodemia*, *Chilianthus* and *Emorya* into *Buddleja* is supported, and a South African origin of Buddlejeae is indicated. *Camptoloma* appears closely related to *Teedieae*.

P0691. Species-level Phylogeny, Biogeography, and Ecology of *Elegia* (Restionaceae, South Africa)

P. M. Moline, H. P. Linder;
Institute of Systematic Botany, Zurich, Switzerland.

Restionaceae are Southern Hemisphere graminoids, most diverse in the Cape Floristic Region (CFR, South Africa) and SW Australia. We inferred the phylogeny of the *Elegia* group, which comprises 60 African species, from a cladistic analysis of sequence data from four chloroplast markers (*trnL-F* region, *atpB-rbcL* spacer, *trnK* intron, *matK*, and *rbcL*) for all 60 species. Based on the cladogram we proposed an expanded circumscription of the genus *Elegia*. The biogeographical pattern in *Elegia* was assessed by applying four recently published methods to delimit areas of endemism, and by contrasting a grid overlay with eco-geographical areas to test the influence of the input data. All methods retrieved with varying resolution the same areas of endemism in the CFR. Our results show that eco-geographical areas should be preferred over a grid overlay in the study of biogeographic patterns. Contrasting the overlap of distribution areas with the ecological distance between all sister-species pairs in *Elegia* showed that all sister-species are separated in eco-geographical space.

P0692. An example of species radiation and convergence on a piece of Pacific Gondwana: New Zealand gnaphalioid Asteraceae

J. M. Ward[1], I. Breitwieser[2], R. D. Smissen[2];
[1]University of Canterbury, Christchurch, New Zealand, [2]Landcare Research, Lincoln, New Zealand.

Most of the 70-80 species of gnaphalioid Asteraceae in New Zealand constitute a single lineage that is entirely endemic except for two species in New Guinea. Members of this lineage show poor phylogenetic signals from ITS sequence data but a remarkable morphological and ecological diversity. This is consistent with results from an increasing number of New Zealand’s plant groups. These have led researchers to infer rapid and recent species radiation associated with geological and climatic instability in New Zealand in the late Tertiary and early Quaternary. Curiously striking morphological similarities exist between this endemic gnaphalioid lineage and other Asteraceae lineages both in New Zealand and elsewhere. Such morphological convergences can cause taxonomic confusion if they are misinterpreted as synapomorphies. Currently we are using multilocus fingerprinting and sequencing of anonymous nuclear DNA to gain insight into the complex interrelationships of New Zealand’s Gnaphalieae.

P0693. Achene evolution in the genus *Ranunculus* L.

C. A. Lehnebach[1], P. J. Lockhart[1], P. Garnock-Jones[2], E. Hörandl[3], O. Paun[3], C. Ezcurra[4], M. Rivero[5];
[1]Allan Wilson Centre, Palmerston North, New Zealand, [2]Victoria University, Wellington, New Zealand, [3]University of Vienna, Vienna, Austria, [4]Universidad Nacional del Comahue, Bariloche, Argentina, [5]Universidad Austral de Chile, Valdivia, Chile.

With over 600 species, *Ranunculus* L. is the largest genus in the Ranunculaceae. Modern taxonomic studies have divided this genus into 7 subgenera and about 26 sections. This has been done primarily based on achene morphology, which has been considered the most important source of characters for any infra-generic classifications. Recent molecular studies using nrITS and *mat*K data have shown that only some of these sections are monophyletic. This incongruence between molecular and morphological classifications has been attributed to the parallel evolution of morphological characters including achene types. An aim of this study has been to assess the extent of morphological convergence in *Ranunculus* achene morphology and investigate its relationship to habitat. To do this, numerous anatomical and morphological characters have been studied directly and/or under SEM and LM. The patterns of evolution of key characters and reconstruction of ancestral states have been assessed using McClade on a large scale phylogeny derived from nrITS and matk sequences.

P0694. Teaching Botany in Aotearoa: Taking the Phlylogenetic Approach

L. Baxter;
CBER, University of Waikato, Hamilton, New Zealand.

The flora of New Zealand is rich in biodiversity, exhibiting a unique variety of plants including a high proportion of endemic species and distinctive plant forms. As such, the flora provides great opportunities for students of Botany to gain an extensive knowledge of the different plants groups. Because we at University of Waikato are committed to training future plant systematists, our approach is to draw on the most current phylogenetic framework when looking at plant diversity, with an emphasis on examples from the New Zealand flora. This is especially important as most textbooks available focus almost exclusively on Northern hemisphere taxa. The Angiosperm phylogeny tree modified from APG II (2003) and Judd and Olmstead (2004) underpins the phylogenetic scaffold we employ to aid students comprehension of how groups are evolved. This poster is one example of how we are integrating examples from the New Zealand flora into the current understanding of plant systematics.

P0695. DNA sequences reveal unexpected complexity in the evolution of the New Zealand edelweiss genus *Leucogenes*

R. D. Smissen, I. Breitwieser;
Manaaki Whenua Landcare Research, Lincoln 8152, New Zealand.

Nuclear and chloroplast sequences signal complex interactions between lineages in the evolution of New Zealand edelweiss species. Two clearly divergent nuclear ribosomal ITS sequence types are found in the genus. One sequence type occurs exclusively in *Leucogens grandiceps* but some specimens of this species show extensive heteroplasmy in sequences. The other three species of *Leucogenes* (*L. leontopodium, L. neglecta* and *L. tarahaoa*) display ITS sequence types similar to a group of pulvinate *Raoulia* species. In contrast to ITS sequences, *Leucogenes* are united by their chloroplast sequences, except for one geographically isolated population. Preliminary sequencing of a novel nuclear marker provides some support for the monophyly of *Leucogenes.* We propose that introgression or hybrid speciation has affected both chloroplast and nuclear ribosomal DNA sequence distribution in *Leucogenes*. Further, the polyploids *L. neglecta* and *L. tarahaoa* appear to have independent origins, and are linked on one hand by their chloroplast sequences to diploid *L. grandiceps* and on the other hand to *L. leontopodium* by their morphology and ITS sequences.

P0696. Assessing genetic variability of New Zealand sea grass (*Zostera muelleri*, Zosteraceae) at multiple spatial scales

T. C. Jones, **C. Gemmill**, C. Pilditch;
University of Waikato, Hamilton, New Zealand.

Both the extent and quality of New Zealand’s estuarine sea grasses (*Zostera muelleri*) are rapidly declining and are now the focus of ecological and physiological investigations. To contribute to the conservation efforts of this marine angiosperm we surveyed genetic diversity within eight estuaries using Random Amplified Polymorphic DNA (RAPD) markers. Broad scale sampling covered nearly the complete latitudinal gradient of New Zealand. Intensive sampling was conducted within two isolated estuaries along five 10m transects, located on the East and West coasts of the North Island, to assess genetic variation at progressively finer scales. UPGMA, AMOVA, and PCA analyses together confirm that inter-estuary variation was low, while intra-estuary variation was high, with most individuals having a different RAPD profile. This implies that conservation efforts need to be directed towards conserving populations in as many estuaries as possible to retain a high degree of buffering against environmental change and translocation of specimens need to be harvested/ecosourced locally.

P0697. Consensus networks: A tool for studying hybridisation

B. R. Holland[1], K. Huber[2], V. Moulton[2], P. J. Lockhart[1];
[1]Allan Wilson Centre, Palmerston North, New Zealand, [2]University of East Anglia, Norwich, United Kingdom.

Reticulate evolution is a common theme of plant evolution and species radiation. However, when analysing DNA sequences, plant molecular systematists usually depict species relationships on bifurcating trees. Like evolutionary trees, phylogenetic networks provide a means to visualize species relationships, but unlike trees they can also show reticulate relationships. One problem in using networks, is that molecular markers in plants can be characterised by heteroplasmy, recombination, partial gene conversion and paralogy - this can result in networks that are complex and difficult to interpret.

Consensus networks are a new approach that provide a means for combining the strongest phylogenetic signals from different gene loci without losing information (Holland et al, Mol. Biol. Evol. 2004. 21:1459-1461). They also provide a natural way for distinguishing patterns that arise from phylogenetic error and lineage sorting from patterns that arise through hybridisation. Here we report observations from empirical and analytical studies that illustrate the usefulness of consensus networks for studying hybridisation and plant species radiation.

P0698. Biogeography of endemic New Zealand *Isoëtes*

D. E. Hofstra[1], C. E. C. Gemmill[2], M. D. de Winton[1];
[1]National Institute of Water & Atmospheric Research Ltd. (NIWA), Hamilton, New Zealand, [2]Centre of Biodiversity and Ecology Research, Department of Biological Sciences, University of Waikato, Hamilton, New Zealand.

Isoëtes in New Zealand has been determined as two species, *I. kirkii* A. Braun and *I. alpinus* Kirk, alternatively as three varieties or subspecies, and includes diploid and tetraploid plants. Based on morphology and cytology there remains uncertain delineation and taxonomy of endemic *Isoëtes*.

Endemic *Isoëtes* form a major plant community in South Island lakes, yet have declined in North Island lakes as populations face dual threats from invasive alien weeds and from deteriorating water quality. Although protection of native biodiversity is a goal of lead conservation agencies, for *Isoëtes,* suitable selection criteria are needed to identify those lakes, species and populations to target for conservation effort.

Current research seeks to determine the biogeographic scales of genetic variation for *Isoëtes* taxa. We used DNA sequences (ITS, cpDNA) and RAPDs to assess the genetic variation amongst numerous populations. The results from this study support the separation of South Island material from North Island tetraploids, and also distinguish a variety described from one lake (Lake Omapere) from which extant populations have already been lost.

P0699. Relationships of model plants in the phylogenetic neighbourhood of Arabidopsis

K. McBreen[1], D. Huson[2], P. McLenachan[1], O. Kardailsky[1], P. Heenan[3], M. Lysak[4], P. Lockhart[1];
[1]Allan Wilson Centre, Palmerston North, New Zealand, [2]University of Tübingen, Tübingen, Germany, [3]Landcare Research, Lincoln, New Zealand, [4]Royal Botanical Gardens, Kew, Richmond, United Kingdom.

The model represented by *Arabidopsis thaliana* (Brassicaceae) and its close relatives is becoming increasingly valuable as the already vast array of genetic and biological resources and information available expands. Defining the phylogenetic neighbourhood of *A. thaliana* is an important complement to these resources. Previous treatments of the Brassicaceae have analysed single or concatenated genes. The Z-closure super network method combines trees from genes that are analysed individually to form a “species network”. Sets of taxa for each gene need only be partially overlapping and each gene may be described by a different evolutionary model. We present a Z-closure species phylogeny that combines gene trees reconstructed from seven loci. It includes taxa from close relatives of *A. thaliana* that are currently being studied as model species. The resulting network is largely congruent with previously published phylogenies, but identifies incongruence among some datasests. Possible explanations for this are discussed.

P0700. Phylogeny and adaptive radiation in Australasian genus Celmisia (Astereae, Asteraceae)

M. Ito[1], S. Wagstaff[2], I. Breitwieser[2], D. R. Given[3];
[1]University of Tokyo, Tokyo, Japan, [2]Landcare Research, Lincoln, New Zealand, [3]Christchurch Botanic Gardens, Christchurch, New Zealand.

New Zealand is regarded as fragments of the Gondwana Continent, but is presently located far from the continent. Some genera include a lot of species, and it shows the characteristics like Oceanic Islands. Celmisia belongs to Asteraceae, and is endemic to New Zealand and Australia, consisting of ca. 70 species. In especially New Zealand ca. 60 species are distributed. Most of New Zealand species of Celmisia are an alpine plant, but some species are the coastal plant. They vary from 1 cm to 1 m in size, and from a small shrub to herbaceous plant in habit, showing speciation with adaptative radiatiton. The preliminary analysis using the trnL-F region of the chloroplast DNA showed very little mutation in this genus, suggesting that the speciation have occurred relatively recently. Here, we report the result of phylogenetic analysis using sequences of ITS and ETS regions of nrDNA, having faster rate of molecular evolution. In the obtained phylogenetic tree, two major monophyletic clades have been recognized in Celmisia. The Australian species located at distal position in one of the clade, suggesting that they had migrated from New Zealand to Australia in recent.

P0701. Phylogeny and biogeography of *Craspedia* (Asteraceae : Gnaphalieae) based on ITS, ETS and *psb*A-*trn*H sequence data

K. A. Ford[1], J. M. Ward[2], R. D. Smissen[1], S. J. Wagstaff[1], I. Breitwieser[1];
[1]Allan Herbarium, Landcare Research, Lincoln, New Zealand,
[2]University of Canterbury, Christchurch, New Zealand.

Craspedia (Asteraceae: Gnaphalieae) is a genus of 23 species found only in Australia and New Zealand. Its species have confusing and continuous character variation and indistinct boundaries, which makes their relationships difficult to elucidate. Phylogenetic analyses of ITS, ETS and *psb*A-*trn*H non-coding spacers resolved three lineages within *Craspedia*, two in Australia and one in New Zealand. The Australian lineages suggest two species radiations into the alpine areas of south-east Australia. *Craspedia* in Tasmania is polyphyletic, with most species closely related to an Australian mainland species. The New Zealand lineage is sister to one of the two Australian lineages. This is consistent with the hypothesis that New Zealand *Craspedia* is derived from a single dispersal event over the Tasman Sea from south-east Australia. *Craspedia* has arrived on Campbell Island and the Chatham Islands by dispersal events from mainland New Zealand. There is low sequence divergence in New Zealand *Craspedia* compared with that in Australia despite more morphological divergence, suggesting a recent and rapid species radiation.

P0702. Molecular dating in the Orchidaceae: inferences about transcontinental disjunctions and explosive diversification in a species rich group with little fossil information

C. van den Berg[1], K. M. Cameron[2], M. W. Chase[3];
[1]Universidade Estadual de Feira de Santana, Feira de Santana, Brazil, [2]The New York Botanical Gardens, Bronx, NY, United States, [3]Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

Orchidaceae is probably the largest family of flowering plants, and practically absent from the fossil record. It has been traditionally considered of young diversification among the monocots, with several transcontinental disjunctions generally explained by long-distance dispersal events. In this study, we used a large (>200) tree compiled from many phylogenetic studies in the family, and optimized *rbcL* sequences with ML. Several different calibrations and NPRS were applied to obtain chronogram estimates for dating the family and selected internal nodes. The crown node was estimated to the boundaries of the Upper Cretaceous to Paleocene, and an early diversification for the main lineages in the family. However, diversification of epiphytic tribes, which account for over 70% of genera and species in the family appears to have occurred in the Eocene. The most important disjunction events are analysed, and indicate overlooked vicariance events, and a new calibration for future studies is proposed at 34 mya with basis in a Boreotropical pair *Phragmipedium/Paphiopedilum.* Inferences with other gene regions are presented to check similar patterns.

P0703. Dating the Asterid tree: Where do Asteridae fossils go?

M. Martínez-Millán;
L. H. Bailey Hortorium, Cornell University, Ithaca, NY, United States.

The Asteridae represents about 1/3-1/4 of all angiosperms, it includes around a hundred families in ten orders. However, the fossil record of the clade is not reflective of their existing diversity, especially in the two bigger clades; the lamiids (euasterid I) and the campanulids (euasterid II) where most of the diversity of the group is found (42.91% of all eudicots). Different attempts to date the time of origin of the clades that compose this group have resulted in very discrepant estimates, even for the same node (i.e. 29.3 vs. 112 million years for the Asterales). Even when this difference could be due in part to the use of different methodological tools, a great part of it is most likely due to the fossils used for the initial calibration. Reliability of fossils involves a critical evaluation and placement of the fossils into the phylogeny. Here some of the oldest asterid fossils ever reported are re-evaluated and placed into the asterid phylogeny so a minimum age dating was attempted. Preliminary results indicate that the Asteridae (Cornales, Ericales, Lamiids and Campanulids) are at least 90 million years old, dating back to the Late Cretaceous (Turonian).

P0704. Diversification of Tofieldiaceae (Alismatales)

M. N. Tamura[1], S. Fuse[2], N. S. Lee[3], J. O. Kim[3], T. Ishii[1];
[1]Botanical Gardens, Graduate School of Science, Osaka City University, Katano, Japan, [2]Museum of Nature and Human Activities, Hyogo, Sanda, Japan, [3]Department of Life Science, Ewha Womans University, Seoul, Republic of Korea.

Tofieldiaceae are often considered as one of the most morphologically primitive plant groups among the monocots. First, we estimated the divergence time of Tofieldiaceae based on *matK* and *rbcL* gene sequences. The Tofieldiaceae diverged from the Alismataceae complex, which are sister to the Tofieldiaceae, in the Cretaceous. Apart from the Acoraceae, which are most basal among the monocots, the divergence time for the Tofieldiaceae is one of the oldest ones among the living monocot families. Second, we estimated a relationship of infrafamilial taxa of the Tofieldiaceae and their divergence times based on *trnK* (including *matK*), *trnL*, *trnL-F* and ITS data. The genera of Tofieldiaceae (*Triantha*, *Tofieldia* and two monotypic genera) diverged from one another in the Tertiary. In contrast with the recent rapid radiation of the living *Triantha* species, the divergence of *Tofieldia* species began much earlier. In the genus *Tofieldia*, three clades are formed, a clade of *T. calyculata*, a clade of *T. pusilla, T. glabra* and *T. okuboi*, and a clade of *T. coccinea, T. nuda, T. thibetica* and *T. divergens*. *T. coccinea* was rapidly diversified recently into the several varieties.

P0705. The taxonomic and phyllogenetic differentiation of the *Potentilla* L. Genus (*Rosaceae*)

S. Redzic;
Department of Biology, Faculty of Science, University of Sarajevo, Sarajevo, Bosnia and Herzegovina.

One of the most numerous and the most variable genus not only in *Rosaceae* family allready in the Dinaric Alps flora and flora of Europea as well is genus *Potentilla*. The briad range of tolerance and large geographic distribution cause of high level diversity of this genus. A lot of species of this genus are «bad species» and their are numerous hybrids betwen them.

Except of that apomixys is additional endenogenic factor who cause high intraspeci and infracpecis variabilty of this genus. Those factors in combination with very variable egzogenic factors contributed very complex taxonomy of this genus. Namely, many species, in reference to taxa, have questionable and debatable taxonomic status. Some from them of Balkans and Dinaric Alps unfairly «deleted» from modern floras such as a Flora Europea.

In order to it for a long time we paid particular attention on classical taxonomy and phylogeny of the most variable «group of species» of *Potentilla* genus and give their new taxonomy and phylogeny.

P0706. Vegetation and Plant Species Diversity in North East India

P. J. Handique;
Gauhati University, Guwahati, India.

North East India comprising the states of Arunachal Pradesh, Assam, Manipur, Meghalaya, Mizoram, Nagaland and Tripura is a distinct megadiversity hotspot. It is located between 20^0N to $29^0$30`N latitude and $89^0$46` E to $97^0$30` E longitude. The total geographical area is 2,55,161 km^2. The floristic diversity is quite enormous in this area but not explored, quantified and estimated into fuller extent and at the finest scale till date. In this paper the plant diversity in North East India is described and highlighted in terms of the species richness and vegetation diversity. Vegetation of this region embraces 5 types - tropical, sub-tropical, temperate, sub-alpine and alpine vegetation. These are further divided into several sub-groups. Diversity of the plant species embraces certain distinct sub-groups namely mono-species genera, endemic and rare species, large groups, economic and medicinal plants, center of origin, wild relatives of cultivated plants, botanical curiosities and primitive flowering plants. The area is comprises of two biogeographic zones - (a) Eastern Himalayas comprising Arunachal Pradesh, (b) North East India comprising other six states.

P0707. Ludwigia (Onagraceae) in São Paulo State (Southeast Brazil)

A. O. S. Vieira;
Universidade Estadual de Londrina, Londrina, Brazil.

Ludwigia L. occupies a rather position in the family Onagraceae. This genus comprising about 80 species in 23 sections. The most important centre of diversity for the genus is South America. The present project was undertaken to investigate the Ludwigia species that occurs in São Paulo State, Southeast Brazil. The results will be include a monograph for Flora Fanerogâmica do Estado de São Paulo and one digital version. The capsular and seed morphology provides very useful taxonomic characters. There are 22 Ludwigia species known to São Paulo State. L. hyssopifolia is a pantropical weed, all the others species are native. The most frequently species collected is L. octovalvis. The fruits of section Myrtocarpus are obconic capsules with free and pluriseriate seeds. L. nervosa, L. tomentosa and a rare species L. brachyphylla occupy mainly Brazilian savannas localities. L. lagunae has the first citation to São Paulo State.

P0708. Flora Mesoamericana: linking specimens with floristics

B. Klitgaard[1], T. Bilsborrow[2], F. Chiang[3], G. Davidse[2], S. Knapp[1], A. Monro[1], M. Sousa S.[3];
[1]The Natural History Museum, London, United Kingdom, [2]Missouri Botanical Garden, St. Louis, MO, United States, [3]Instituto de Biologia, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico.

Flora Mesoamericana is a Spanish language, long-term, monographic level floristic treatment of the vascular plants of the southern states of Mexico and the republics of Central America. The project combines the revision of the ca. 18,000 vascular plant species of the region with an extensive programme of field collecting in previously uncollected regions, which continues to yield undescribed species and to extend distributions. Planned as a ten volume series, the Flora is also published on-line as W3FM - the first such large-scale floristic project to be presented in this way. The result of a ‘revisionary’ approach and targeted field exploration has been that approximately 10% of the species described in each of the 2 volumes published to date have been new to science. Flora Mesoamericana and projects like it are much more than mere compilation efforts. We will explore impediments to the completion of such projects and how current databasing efforts in large herbaria can help to improve information content of multi-authored projects such as Flora Mesoamericana.

P0709. A DNA library of Hawaiian plants for taxonomic and natural products research

S. F. Dunbar, C. W. Morden;
University of Hawaii, Honolulu, HI, United States.

The Hawaiian flora represents a model system for the study of evolution, ecology, and conservation. Approximately 90% of the angiosperm and 77% of the pteridophyte floras are endemic, with colonists having traveled over 3600 km from the nearest continental source. Further, colonists have arrived through long distance dispersal followed by in situ speciation from remote continental sources including Asia, the Americas, Australia, Africa, and boreal regions. The potential for expanding our knowledge of plant biodiversity on a global scale can therefore be enhanced by phylogeographic and systematic studies. Our research over the past 13 years has included collecting plant material for development of a DNA library to be used for such investigations. This library now holds nearly 5000 accessions representing endemic and indigenous species of ferns and angiosperms, many of which are rare and endangered. Accessions are available for use by all researchers interested in such studies.

P0710. Urban floras of the eastern part of Male Polissya (Ukraine)

L. M. Gubar;
M.G.Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv, Ukraine.

Results of the preliminary comparative floristic investigation of model urban floras of the eastern part of Male Polissya (Forest zone, NW Ukraine) are presented, including their ecological and structural analyses.

The urban flora of Ostrog (515 sp., incl. 27.2% aliens), Netishyn (687, incl. 23%), Slavuta (558, incl. 26.6%), and Shepetivka (509, incl. 28.8%) are presented. Species of the alien fraction dominate in all urban floras over apophytes. Herbaceous polycarpics, hemicryptophytes, mesophytes, heliophytes; meadow and forest plants prevail in the ecological spectrum of the urban floras; kenophytes and epoecophytes prevail in the alien fraction. Most species (80.4% in Shepetivka, and 76.6% in Netishym) are concentrated in urban, and suburban zones; 17.4% in Netishyn, and 12.8% in Shepetivka, occur in suburban zones only; and 6.9% in Shepetivka and 5.8% in Ostrog are present only in urban zones. Detailed maps (500x500 m) of species distribution in the Ostrog and Netishyn urban floras are presented.

The town flora of the forest zone differs from the regional flora in higher xerophytysation; in small towns these processes are less evident.

P0711. Key to Taxa of Taiwan Grasses with Characters of Leaf Anatomy by ActKey at www.efloras.org

C. Kuoh[1,2], H. Song[3];
[1]Institution of Biodiversity, Tainan, Taiwan Republic of China,
[2]Department of Life Sciences, Tainan, Taiwan Republic of China,
[3]Information Technology, Missouri Botanical Garden., St. Louis, MO, United States.

ActKey: an on-line interactive key for identification. It is different from the traditional dichotomous key in their multi-access character. Rather than having to answer questions to key couplets and follow a predefined path, the use of ActKey is able to adopt different strategies in identifying an unknown plant. The program is web-based and supports most popular Internet browsers. It allows visitors to use a key at the www.efloras.org website for identifications. Moreover, ActKey allows taxonomist to create a key and publish it online. The www.efloras.org website designed by Hong Song is used to host taxon- and specimen-based information, ActKey is one of its many features.

We demonstrated with constructing an ActKey with character sets of leaf anatomy for identifying Taiwan grasses. Fifteen characters were used in the character set with pop-up windows showing images illustrating the character states. Data of microscopic examination on sections of grass leaf blades of 176 species in 5 subfamilies in Taiwan were included. It will be useful as an aid for identifying Taiwan grasses especially when the floral material was unavailable in the identification process

P0712. The Bromeliaceae of Oaxaca, Mexico: Richness and Distribution

A. Espejo, A. R. López-Ferrari, V. A. Pulido, N. Martínez-Correa;
Depto. Biología. Div. C. B. S. Universidad Autónoma Metropolitana Iztapalapa, México, D. F., Mexico.

The current knowledge of the Bromeliad flora of the state of Oaxaca, Mexico is presented. Based on the study of 2334 herbarium specimens corresponding to 1331 collections, and a detailed bibliographic revision we conclude that the Bromeliad flora known up to now for Oaxaca comprises 160 species and 15 genera. The 100% of the Mexican species of genera *Fosterella, Greigia, Guzmania, Hohenbergiopsis, Racinaea* and *Vriesea* are represented in the state. 22 species are recorded for the first time for Oaxaca and also there are four new *taxa*, in process of description, represented in the state. Species level endemism reaches 19.37% (31 spp.). Collections of 219 (of 570) municipalities and 29 (of 30) districts of the state were recorded. Among the vegetation types occurring in Oaxaca, *Quercus* forest is the richest with 57 *taxa*, followed by tropical deciduous forest and cloud forest with 49 and 46 species, respectively. Bromeliad species representation and distribution in Oaxaca are analyzed in detail and also we provide a comparison with those of states of Chiapas and Guerrero.

P0713. Vascular Flora of the Marquesas Islands

D. H. Lorence[1], W. L. Wagner[2];
[1]National Tropical Botanical Garden, Kalaheo, HI, United States,
[2]Smithsonian Institution, Washington, DC, United States.

The Marquesas (French Polynesia) are an isolated group of volcanic hot spot islands in the SE Pacific Ocean. These 12 islands range from 61.3 to 330 sq. km in size, from 360 to 1250 m in elevation, and from 1.3 to 6.3 My in age. Steep and rugged, the Marquesas are comparatively botanically unexplored and under-collected. Humans, feral animals, and alien plants have severely impacted the lowland and mid-elevation vegetation. The native vascular flora comprises ca. 360 species (45% endemic and 30% pteridophytes). The Vascular Flora of the Marquesas Islands is a collaborative project between the National Tropical Botanical Garden, Smithsonian Institution, and Délégation à la Recherche (French Polynesia). Four collecting expeditions in 2003-2004 yielded c. 5800 herbarium specimens comprising 714 vascular plant species. Nearly 60 new species were discovered during the project. Results will be an Internet-based resource and two volume book form publication. The Smithsonian-hosted website provides access to a database of specimens, images, checklist, island distributions, and literature.

P0714. Cooperation between botanical societies and academic institutions

L. Svensson[1], **J. Mattsson**[2];
[1]Svenska botaniska föreningen, Uppsala, Sweden, [2]Department of life sciences, Huddinge, Sweden.

Many botanical societies have control of information which is of interest for scientific research. It is often available in electronic form although older data may be recorded in other ways.

In a recent project we have made comparative studies on habitats with presumably high species diversity based on information from botanical societies on the occurrence of *Daphne mezereum*. It usually occurs in semi-open habitats in transitions zones containing species from the surrounding biotopes.

Here, we present the mutually beneficial cooperation that has taken place between the members of the scientific project and members of the botanical societies. The primary benefits for the scientific partner have been the sampling of sites for further studies; site identification; and reliable information about the status of different species in different geographical regions. The botanical societies have benefited from updated information about the occurrence of species on previously studied sites; increased respect and acknowledgement of the societies' efforts leading to higher self esteem; and inspiration for new ideas for new studies.

P0715. The vascular flora of the Douro Valley Region (Northern of Portugal)

A. S. Castro[1], C. P. Fernandes[1], Á. R. Martins[1], S. Bernardos[2], F. Amich[2], J. M. Lameiras[1], A. L. Crespí[1];
[1]Herbarium, Botanical Garden, CETAV, Vila Real, Portugal,
[2]Department of Botany, University of Salamanca, Salamanca, Spain.

The conservation and monitoring of the vascular flora for the Douro Region (Northern of Portugal) is one of the most dramatic problems, specially if we considered the high number of taxa involved (1271 taxa). One methodology is here proposed with the aim of the management of this important natural resource. The physiognomic type, habitat, general distribution, flower-fructification period and common names are used in the analytical matrix, in order to organize the ecological information for this vegetal biodiversity.

The results obtained are pointing out the necessity to adapt the environmental legislation for each region. In this case, the direct application of the environmental directives is one of the most limitative factors faced to the vegetal conservation. The differential behaviour of the taxa, according to the structure of the vegetation per habitat, will be detected from the analysis of the ecological sensibility of the area.

P0716. Digital databasing of type collections from Czech herbaria

J. Stepanek[1,2], J. Chrtek jun.[1], J. Hadinec[2], J. Kirschner[1], J. K. Kroupa[1], O. Sida[3], B. Skocdopolova[3], J. Suda[2], K. Sutory[4], P. Triskova[2];
[1]Institute of Botany, Pruhonice, Czech Republic, [2]Herbarium Universitatis Carolinae Pragensis, Praha, Czech Republic, [3]National Museum, Botanical Department, Pruhonice, Czech Republic,
[4]Moravian Museum, Botanical Department, Brno, Czech Republic.

The purpose of the project started in 2001 is to locate and interpret the type specimens of vascular plants preserved in Czech herbaria, and make them available for further research, which involves a detailed nomenclatural and taxonomic study of the specimens, list the specimens in a database, and document the specimens in digitalized form (a database of digital figures of the specimens) both on Internet and on CD-ROM media. In 2001-2003, the most important collection of the tropical and subtropical flora from herb. PR and PRC were evaluated - Australian plants described by K. Domin (1882-1953), and types from collection of K. Presl (1794-1852) containing e. g. material of Th. Haenke (1761-1816) from South America and the famous fern gatherings used in Presl's monograph of fern genera. Since 2004, types from European collections of F. W. Schmidt (1764-1796), I. F. Tausch (1793-1848), K. Presl, F. W. Wallroth (1792-1857), F. A. Waldstein (1759-1823), and K. K. Münch-Bellinghausen (1752-1838, herb. BRNM) have been digitised.

P0717. Cataloguing the Plant Diversity of Madagascar

P. B. Phillipson, G. E. Schatz, P. P. Lowry;
Missouri Botanical Garden, St Louis, MO, United States.

Madagascar, with its high level of plant species diversity and endemism, and growing threats, is recognised as a global biodiversity hotspot. Madagascar's political will to address its conservation issues is strong, but informed decision-making and priority-setting require reliable data, incl. on the delimitation and distribution of species. Conservation planning has been hampered by the lack of a comprehensive Flora or checklist, and estimates of the total number of species and the level of endemism differ widely. Renewed exploration and taxonomic work in the last 2 decades have led to substantial changes in numerous genera, incl. the description of many new spp., and most other groups are in need of review. The *Catalogue of the Vascular Plants of Madagascar* project is an on-line authoritative source with relevant data on each native species. The project team is reviewing and updating the taxonomy of each group, describing new taxa and making nomenclatural changes as needed.

P0718. Toward a new *Flora of Ukraine*: the concept, progress, and problems

S. L. Mosyakin, **O. M. Kornienko**, M. M. Fedoronchuk;
M. G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv (Kiev), Ukraine.

Vascular plants of Ukraine were treated in several identification manuals, the *Flora of the Ukrainian SSR* (12 vols, 1936-1965), the *Flora of Eastern Europe* (11 vols, 1974-2004), and other floristic publications. However, no modern treatment of the whole vascular flora of Ukraine is available now. Following the publication of a nomenclatural checklist of Ukrainian vascular plants (Mosyakin & Fedoronchuk, 1999; a new extended edition is approaching its completion), botanists of the Kholodny Institute of Botany (Kiev) initiated preparation of a new flora of vascular plants, which will include identification keys, descriptions, and other relevant data. The new *Flora of Ukraine* will complement the ongoing series *Ecoflora of Ukraine* (started in 2000) and current nationwide efforts in biodiversity conservation. The progress of the project and current problems (such as computerization, fundraising, international cooperation, low attention to taxonomy at the national level) are outlined in the presentation. We have to invite more experts in taxonomy, more regional reviewers and editors, and to pay more attention to education of young plant taxonomists.

P0719. An updated commented checklist of the vascular flora of Minorca (Balearic Islands, Spain)

P. Fraga Arguimbau[1], C. Mascaró Sintes[2], D. Carreras Martí[1], Ó. Garcia Febrero[1], X. Pallicer Allès[2], M. Pons Gomila[2], M. Seoane Barber[2], M. Truyol Olives[1];
[1]Institut Menorquí d'Estudis, Maó, Spain, [2]GOB-Menorca, Maó, Spain.

As most Mediterranean islands, Minorca has a rich flora with a significant number of endemic taxa. However, so far the only specific floristic work about the island was the *Flórula de Menorca* (1904) of J.J. Rodríguez Femenias, still the most comprehensive study. An updated commented checklist has been completed to commemorate the first centenary of Rodriguez's main work. This new checklist is not only a list of taxa, but also includes additional information on biogeography, life forms, rareness or vernacular names.

A simple quantitative analysis of the previous data shows an overview of some main features of the vascular flora of the island. This latest report establishes a checklist of 1313 taxa. From this total number, the authors have checked the current presence of 1231.The endemic component is represented by 83 taxa (6.3 %) while the alien flora consists of 161 taxa (12.3 %). As could be expected, the Mediterranean component is the most relevant in the biogeographic spectrum (62.9%). In the same way, the life forms reveal the relative importance of the annuals (44.3%). The analysis of the rareness revealed that up to 30 % of the taxa are very rare (< 5 localities known).

P0720. The pteridophytes of the state of Aguascalientes, México.

G. González-Adame, M. E. Siqueiros-Delgado;
Universidad Autónoma de Aguascalientes, Aguascalientes, Aguascalientes, Mexico.

Within the project of "Flora del Estado de Aguascalientes, Mexico", the ferns and fern allies were studied. Fifty-five localities distributed in all municipios of the state were surveyed. Seventy-eight taxa were found: seventy-one species of ferns, five species of *Selaginella,* one species of *Equisetum,* and one species of *Isoëtes.* Forty-one taxa are new records for Aguascalientes. Among the ferns, *Cheilanthes* and *Polypodium* are the most diverse and abundant genera, with 14 and 6 taxa, respectively, usually occurring as epipetric in xerophytic associations, subtropical areas or dry forests. *Anemia*, *Anogramma* and *Botrychium* have the most restricted distribution with only few populations in the state, the two formers are located in subtropical scrub, and the last one in open high elevations in *Quercus* forest. *Selaginella* is also common in Aguascalientes, and inhabits rocky cliffs and rocky soils in dry environments. *Equisetum* and *Isoëtes* are restricted to subacuatic and marshy places.

P0721. The pteridophytic diversity in Yunnan, China

S. Lu;
Institute of Ecology and Geobotany, Yunnan University, Kunming, China.

This paper deals with the diversity of the pteridophytes of Yunnan, China. Yunnan ranks first among China in its number of pteridophytic taxa. There are 60 families, 198 genera and 1500 species of pteridophytes making up 95.2 percent, 85.7 percent and 57.7 percent of the Chinese totals respectively according to Ching's system. There are also many taxa unique to Yunnan/China, *Phlegmariurus yunnanensis*, *Archangiopteris bipinnata* Ching, *Angiopteris esculenta* Ching, *Angiopteris sparsisora* Ching and *Gymnosphaera austro-yunnanensis* (S. G. Lu) S. G. Lu et C. X. Li are examples. While *Christensenia assamica* (Griff.) Ching and *Platycerium wallichii* Hook. belong to families are only occurrence in Yunnan around China. Yunnan has the richest taxa of pteridophytes in China and this area is one of the richest taxa of pteridophytes in the world. The richest taxa of pteridophytes in Yunnan is a combination of long geological history, complicated geographical environment and sustained biotic evolution. Yunnan's pteridoflora vary from tropical to temperate, in the area exist multiple climate types, it is actually an epitome of Eurasia continent's pteridoflora.

P0722. Importance of conservation of wetland flora: Present scenario of West Bengal State (India)

S. Panda;
Charuchandra college, Kolkata, India.

Abstract:

Wetlands are among the most important natural resources on earth. In 1990, an inventory of the wetlands in India was carried out by the Ministry of Environment and Forests, recorded *ca.* 4.1 mha covered by wetlands. In West Bengal, 476 wetlands of different kinds each exceeding an area of 10 ha have been identified. Of these, macrophytic diversity of 18 large wetlands have been explored for the first time by the present authors. Shoreline morphology, water regime, pH, salinity of water and perceived threats were studied. Altogether 201 species of wetland angiosperms were collected. The best macrophytic growth is noted in neutral to slightly alkaline pH (7.50 - 8.31). Floristic analysis, distribution, frequency, phenology, habit and habitats, and the importance of macrophytic diversity for waterfowl habitats and their conservation were discussed. *Aldrovanda vesiculosa* L. is an almost extinct species in this state. Conservation measures must be initiated in making the wise use of wetlands.

P0723. Flora of Altinbesik Cavern National Park (Ibradi-Akseki/Antalya-Turkey)

I. Cinbilgel, M. Gokceoglu;
Akdeniz University, Faculty of Arts and Sciences, Antalya, Turkey.

In this study, the flora of Altinbesik Cavern National Park were displayed. 1481 plant samples were collected as regards the study between June 2002 and September 2004. As a result of the evaluation of the plant samples collected, 330 genera, 562 species and 578 taxons belonging to 83 different families were identified. 11 taxons are new for the C3 square. Out of the plant samples diagnosed 9 taxons belong to Pteridophyta and 569 taxons belong to Spermatophyta division. 6 Gymnospermae and 563 Angiospermae, which belong to the Spermatophyta division, belong to the subdivision of Angiospermae. From the subdivision of Angiospermae, 480 taxons belong to Magnoliopsida and 83 taxons belong to Liliopsida class. 248 of the total taxons in the field are Mediterranean elements, 28 Irano-Turanian elements, 19 are Euro-Siberian elements and 283 are multi-regional or are taxons whose phytogeographical regions are unknown. Besides, in the area of study 67 endemic taxons were found. 50 of these endemic taxons are Eastern Meditarranean elements, 7 are Irano-Turanian elements, 1 is Mediterranean element and 9 are not included any geographical location.

P0724. Towards a Catalogue of the Plants of Colombia

R. Bernal[1], R. Gradstein[2], M. Celis[1], A. Hernández[1], T. Krömer[2], C. Acebey[2];
[1]Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Bogotá, Colombia, [2]University of Göttingen, Göttingen, Germany.

Colombia, with an estimated 30,000 species of native plants, is the second richest country on earth in terms of plants. A multilateral project is currently underway towards the production of a Catalogue of the Plants of Colombia, a highly needed instrument for research, conservation, and sustainable use of Colombian plants. The Catalogue is compiled at the National Colombian Herbarium, Bogotá, and the Herbarium of the University of Göttingen with support of the Volkswagenfoundation. The work will provide a compendium of all vascular plants, bryophytes, and lichens occurring in the country, with information on habitat, geographical distribution, and conservation status. A first draft of the Catalogue is scheduled to be ready by December 2005. This draft is the basis for specialists to produce family treatments. Preliminary checklists are already avalaible for bryophytes (1,600 spp.), lichens (1,500 spp.), and the largest families of vascular plants (10,848 spp.). These figures represent 45% of the number of species expected in Colombia. We plan to complete the Catalogue by December 2008.

P0725. Some Endemic Plants from Southwestern Turkey

I. G. Deniz, O. Dinç Düкen;
Akdeniz University, Faculty of Arts & Sciences, Biology Department, Antalya, Turkey.

In this study, twenty endemic taxa were investigated. These taxa were *Consolida raveyi* (Boiss.) Schröd., *Papaver spicatum* Boiss. var. *spicatum*, *Hesperis pisidica* Huber-Morath, *Minuartia pestalozzae* (Boiss.) Bornm., *Lathyrus belinensis* N.Maxted & D.J.Goyder, *Ebenus boissieri* Barbey, *Liquidambar orientalis* Miller var. *integriloba* Fiori, *Cephalaria scoparia* Contandr. & Quézel, *Anthemis rosae* Sm. subsp. *carnea* (Boiss.) Grierson, *Centaurea pestalozzae* Boiss., *Erica bocquetii* (Pesmen) P.F.Stevens, *Cyclamen trochopteranthum* O.Schwarz, *Convolvulus galaticus* Rostan ex Choisy, *Onosma strigosissimum* Boiss., *Verbascum nudatum* Murb. var. *nudatum*, *Salvia caespitosa* Montbret & Aucher ex Bentham, *Fritillaria whittallii* Baker, *Colchicum baytopiorum* C.D.Brickell, *Crocus baytopiorum* Mathew, *Ophrys lycia* Renz & Taub. Distribution, habitat and ecology, flowering time, altitude and threatened categories of these plants were given.

P0726. Some New Introduced Endemic Taxa from South Anatolia in the Last Decade

O. Dinç Düкen, I. G. Deniz, H. Sümbül;
Akdeniz University, Faculty of Art & Sciences, Biology Department, Antalya, Turkey.

In this study, some new introduced endemic taxa has been investigated from South Anatolia in the last decade. These taxa are *Silene sumbuliana* I.G. Deniz & O.D. Düsen, *Astragalus inanae* R.S. Göktürk, O.D.Düsen & Sümbül, *Glycyrrhiza flavescens* Boiss. subsp. *antalyensis* Sümbül, Ö. Tufan, O.D. Düsen & R.S. Göktürk, *Potentilla nerimaniae* H Duman, *Tordylium ketenoglui* H. Duman & A. Duran, *Cephalaria ekimiana* R.S. Göktürk & Sümbül, *Helichrysum orbicularifolium* Sümbül, R.S. Göktürk & O.D. Düsen, *Campanula yaltirikii* H. Duman, *Ornithogalum pamphylicum* O.D. Düsen & Sümbül, *Ornithogalum isauricum* O.D. Düsen & Sümbül, *Allium elmaliense* I.G. Deniz & Sümbül, *Colchicum imperatoris-friderici* Siehe ex K.M. Perss., *Colchicum inundatum* K.M. Perss., *Ophyrs climacis* Heimeier & Perschke and *Ophyrs hygrophila* Gügel, Kreutz, D. & U. Rückbrodt. Description, distribution, habitat, ecology and IUCN 2001 threatened categories of these taxa are given.

P0727. Investigation of flora of National Parks located in Smolensk and Kaluga provinces of west of Russia

N. M. Reshetnikova;
Main Botanical Garden, Russian Academy of Sciences, Moscow, Russian Federation.

National park “Smolenskoe Poozer’e” (1462 km2) is the unique large protected natural object in Smolensk province. This park is located to the north-west of Smolensk province and includes 35 lakes. National park “Ugra” (986 km2) is the main protected territory of Kaluga province. This park extends from north-west to south-east of the province along the river valleys of Ugra, Zhizdra, and Oka.

We inspected the territories in 1999-2004 and made separate flora lists for multiple landscape units. We also registered biotope for each species. This information was stored as a database and was used for identification of especially valuable territories of the parks.

890 species and hybrides of vascular plants were registered in “Smolenskoe Poozer’e”. It represents approximately 72% of flora of Smolensk province (native flora - 80%) 1070 species and hydrides were registered in “Ugra”. This number represents 78 % of the flora of Kaluga province (native flora - 80 %). Many species are located closely to its range limits. Only a few of adventive species display wide distribution in natural communities.

This investigation was partly supported by RFFI (project 04-04-49641.).

P0728. Historical estimates of biodiversity and the development of identification keys

S. T. Scharf;
Institute for the History and Philosophy of Science and Technology, University of Toronto, Toronto, ON, Canada.

The number of species of angiosperms estimated to exist has been fairly stable for 50 years and has been of the same order of magnitude as the number of described species throughout this time. But in the 17th to 19th centuries, the number of described plants and the number of plants estimated to exist were increasing exponentially, from around 6000 known plants in the 1660s to more than 200 000 by 1900. Also, until around 1800, the estimated numbers of plant species were almost always an order of magnitude more than those of described plants. Early botanists faced an information overload. They needed tools to identify and describe plants precisely, to communicate that data to others who lacked access to the same specimens, and that could accommodate all plants yet to be discovered. The experimentation with new information management techniques occurring during this period resulted in the development of the "natural method" -- suited to storing information about all plants in relatively uniform groups -- as well as the identification key -- a technique enabling users to find the names of specimens, making it easier to determine whether they were novel or previously described.

P0729. DNA taxonomy of the genus *Galanthus,* species identification and illegal trade

N. Friesen[1], Z. Manvelidze[2], I. Baktir[3], M. Mosulischvili[4];
[1]Botanical Garden, Osnabrueck, Germany, [2]Batumi Botanical Garden, Georgian Academy of Sciences, Batumi, Georgia, [3]Deparment of Horticulture, Akdeniz University, Antalya, Turkey, [4]Central Botanical Garden, Georgian Academy of Sciences, Tbilisi, Georgia.

The genus *Galanthus* L. comprises 19 species and it occurs naturally in Europe, Turkey and in the Caucasus. Snowdrops are popular garden plants and millions of bulbs are sold annually, mainly *G. nivalis*, *G. elwesii* and *G. woronowii*. Most of the bulbs are collected in the wild in Georgia and Turkey. Sometimes other species, such as those for which trade has been banned, are also collected and declared as *G. elwesii*, *G. woronowii* or *G. nivalis*, for which commercial trade is allowed. *Galanthus* species are presently on CITES Appendix II.

The monitoring of trade in *Galanthus* is very difficult, as plants are usually imported as bulbs and only very limited identification can be undertaken at this stage of the life cycle. Before identification of a *Galanthus* species can be undertaken any bulb has to be grown-on at a nursery facility for naming at a later date (2-18 months): a costly and time consuming exercise. The custom-houses are interested in quick species identification methods for the genus based on species specific DNA PCR-Marker. *G. nivalis*, *G. elwesii* and *G. woronowii* are genetically clearly different, allowing us the construction of species specific primers.

P0730. Geobotanical zoning in Zagora ranges of Dalmatia, SW Dinarides

A. Z. Lovric, M. Rac;
Biocenotics Laboratory, R. Boskovic Institute, Zagreb, Croatia.

Among Dalmatian uplands so far one studied vegetation chiefly on major marginal mountains reputed in alpinism (Velebit, Dinara, Biokovo); the interpolated ranges of Zagora were mostly neglected by botanists. This rugged relief of SW Dinaric Alps in Dalmatian inlands includes 6 calcareous ranges, whose phytocenoses and floral diversity is now studied. For Postak 1446m and Promina 1148m the known botanical data were scarce, and on Svilaja 1509m, Kozjak 1206m, Tovarnica 1265m, and Matokit 1314m nothing was published. On their ridges *Fagus* almost predominates there, and in fresh NE slopes are mesotermic belts of *Quercus frainetto* and *Qu. dalechampii* as in near Bosnia. In xeric SW slopes are Submediterranean belts of *Carpinus orientalis* and *Ostrya,* and in SW foot ravines also *Qu. ilex* and *Phillyrea* occur. The most specific vegetation is on their stormy peaks: deciduous scrub at upper ecotone *(Oreoherzogia, Arctostaphylos, Ribes, Berberis),* and apical windswept balds of *Festuca dalmatica* and *Sesleria robusta* culminating by eroded bare rockfields with *Minuartia capillacea, Edraianthus* etc. This zoning of Dalmatian ranges is similar as in Greece and southern Italy.

P0731. Numerical analysis of communities of Classes Asplenietea trichomanis and Thlaspietea rotundifolii in Dinaric Alps region

S. Trakic Juvan, S. Redzic, S. Barudanovic;
Center for Ecology and Natural Resources, Sarajevo, Bosnia and Herzegovina.

Work is based on floristic data, which have been reported over fifty years period of time by eminent researchers in the field of phytosociology in former Yugoslavia. Work also includes results of TWINSPAN, which has been applied to raw data matrix. Analysis of vegetation in rock crevices has been made by investigating of 106 quadrats, which included 31 plant communities with 372 detected plant species. Investigated were six major regions of Dinaric Alps. Analysis of vegetation of scree and rubble has been made by investigating of 51 quadrats, which have included 12 plant communities with 259 detected plant species. Investigated were four regions of Dinaric Alps. Our work proves distinct relic and endemic character of vegetation in rock crevices and on screes in the Dinaric Alps region, which correlates to its specific geological past and present, and it also proves existence of syngenetical linkage of this type of vegetation in the investigated region. Furthere more, it is highlightened importance of canyon ecoclimate for survival of great number of endemic species and distribution of submediterranian floral elements into the main land.

P0732. *In situ* physicochemical measurements of the Cretan endemic genus *Petromarula* evaluate its adaptability to the certain environmental conditions of Crete

N. E. Ioannidis[1,2], E. Navakoudis[1,2], **E. Avramakis**[1], E. Hatzinikolaki[1], K. Kotzabasis[1,2];
[1]Department of Botany, Natural History Museum of Crete, Heraklion, Crete, Greece, [2]Department of Biology, University of Crete, Heraklion, Crete, Greece.

The presence of an endemic plant in an ecosystem strongly depends on its adaptability to the certain environmental conditions of its habitat. The adaptability of the monotypic endemic genus *Petromarula* was studied on the island Crete, by using JIP-test analyses based on fluorescence induction measurements. Photochemical (quantum yield) and non photochemical (photoprotective) processes were estimated from plants grown in habitats under ambient light intensities (10-1900 µmol.m^{-2}.s^{-1}). The results showed that *P. pinnata* prefers habitats with low light intensities and is under excitation pressure and stress in high light intensities. This contradicts with the certain light conditions prevailing in Crete (~1700 µmol.m^{-2}.s^{-1}). The possibility to assess such physicochemical results to answer the question whether the island of Crete has served as refuge rather than an evolutionary laboratory for *Petromarula* is discussed.

P0733. Endemics and rare plants growing on serpentines in the Rhodopes Mts. (Bulgaria)

D. K. Pavlova;
Sofia University, Department of Botany, Sofia, Bulgaria.

The largest serpentine area in Bulgaria is in the Rhodopes Mts. The serpentine bodies are located within the lower montane belt. The flora and vegetation on these terrains show similarities with such areas in other Balkan countries. The high number of endemics indicates the importance of serpentine habitats as centers for floristic differentiation and speciation. The number of the Bulgarian and Balkan plant endemics found on the study area is 38 taxa. In The Red Data Book of Bulgaria 19 plants of category rare are listed. This number is rather low, compared to other serpentine areas on the Balkan peninsula, bearing in mind the low altitude, the relatively uniform climatic conditions and the short biological history of the serpentine areas in Bulgaria.The link between the taxa of the serpentine flora in the Rhodopes Mts. testifies to a refugial character of the processes. Plant speciation on these areas in Bulgaria is relatively young and a specific floristic complex has not yet developed. A conservation strategy has to be developed in order to protect the serpentines as centres of plant biodiversity.

P0734. Trichome types in European *Epilobium* and their use for determination

S. Strgulc Krajšek[1], N. Jogan[1], S. Kreft[2], M. Dermastia[1];
[1]Biotechnical Faculty, Ljubljana, Slovenia, [2]Faculty of Pharmacy, Ljubljana, Slovenia.

Although *Epilobium* has been thoroughly studied by several taxonomists, information on trichome structure as distinguishing tool is very scarce. With light and scanning electron microscopy we have recognised two basic trichome types in 14 studied European taxa. All have simple unicellular trichomes with gradually tapering apex and glabrous to papillose surface. Presumably glandular trichomes with truncate to rounded apex and glabrous surface are of two types: long erect and short appressed ones. The latter occur on upper surface of very young leaves of some species and on calyx and fruit of *E. collinum* and *E. obscurum*. Glandular activity of that trichomes has been confirmed by biochemical analyses (TLC, HPLC, reaction with Naturstoffreagent A) which revealed presence of 2 important flavonoids in trichomes and on their surface.

Lengths of each hair type are statistically significantly different between some species. So only using quantitative and qualitative data of indumentum all 14 taxa can be reliably distinguished, what is important especially if only vegetative parts of plants are available.

P0735. Vegetation diversity at 17 canyon affluents of Kupa, middle Croatia

M. Rac, A. Z. Lovric;
Biocenotics Laboratory, R. Boskovic Institute, Zagreb, Croatia.

The calcareous ranges of Dinaric Alps are rich in numerous abrupt canyons so far studied chiefly in Bosnia and Montenegro; the canyon vegetation in western Dinarides of Croatia was scarcely known. Kupa river confluence with its 17 tributary canyons of middle Croatia is the most complex system of ramified canyons within Balkans; their rocky escarpments are from 120 to 450m tall. After our recent studies on floral diversity and phytocenoses, its western canyons of upper Kupa, Dobra, Susica, Kupcina and tributaries have mostly a similar vegetation as these ones in SE Alps of Slovenia, including *Pinus nigra, Ostrya, Fraxinus ornus, Cerasus mahaleb, Taxus, Erica* etc. Other southern canyons of Korana, Mreznica, Slunjcica, Touncica and near minor ones have more thermophilic vegetation as in Balkan canyons of Bosnia, including *Acer obtusatum, Carpinus orientalis, Sorbus umbellata, Cotinus, Colutea, Ruscus aculeatus, Satureia montana, Ceterach, Adiantum,* and also 6 local endemics. This vegetation is linked with frequent foehn impact of southern Mediterranean winds predominating in these southern canyons.

P0736. Genome size of desiccation-tolerant *Ramonda serbica* and *R. nathaliae* (*Gesneriaceae*)

T. Zivkovic[1], S. Siljak-Yakovlev[2], O. Catrice[3], B. Stevanovic[1], V. Stevanovic[1];

[1]Faculty of Biology, Institute of Botany, Belgrade, Serbia and Montenegro, [2]Ecologie, Evolution et Systématique, UMR CNRS 8079, Université Paris-Sud, 91405 Orsay Cedex, France, [3]Institut des Sciences du Végétal, CNRS UPR 2355, 91198 Gif-sur-Yvette, France.

Ramonda serbica and *Ramonda nathaliae* are extremely rare representatives of resurrection plants among Holarctic phanerogamic flora. Both species are endemics of Balkan peninsula and Tertiary relicts. The sample concerns two populations of *R. serbica* (one from Serbia and one from Montenegro) and one population of *R. nathaliae* from Serbia. Nuclear DNA content and GC percentage were assessed by flow cytometry. The 2C DNA values for *R. nathaliae* and *R. serbica* were 2.38 pg and 7.77 pg, respectively. These results were in accordance with different ploidy levels of these species. The base composition for *R. nathaliae* was found to be 42.06% GC. The significant intra-population variation of DNA amount was observed in *R. serbica* from Montenegro. The 2C DNA content ranged from 2C=7.62 pg to 11.31 pg and revealed existence of different ploidy levels between individuals of this population.

P0737. Sempervivum kopaonikense Pancic (Subgenus Jovibarba (DC. emend Koch) Baker - groupe heuffelii - Crassulaceae) - morhological, chorological and ecological characteristics

D. V. Laku iĺ [1], L. Branislava[2], N. Radoslav[3];
[1]Institute of Botany and Botanical Garden «Jevremovac», Faculty of Biology, Belgrade, Serbia and Montenegro, [2]2Institute of Botany, Faculty of Pharmacy, Belgrade, Serbia and Montenegro, [3]National park Kopaonik, Kopaonik, Serbia and Montenegro.

Josif Pancic published *Sempervivum kopaonikense* in “Botanische Ergebnisse einer i. J. 1866 unternommene Reise in Serbien”, in Oesterreichische Botanische Zeitschrift, Vienne 17: 173 (1867).
This plant was initially misidentified as *Sempervivum soboliferum* Sims, before to be renamed by Pancic as a new taxon. In the recent floristic literature the name *Sempervivum kopaonikense* has been completely suppressed or classified exclusively as a synonym for *Sempervivum heuffelii* Schott Šsyn. *Jovibarba heuffelii* (Schott) LöveC, a species with wide distribution, whose area extends from Dinarides towards Eastern Carpatians, including the main part of Balkan peninsula.
Lectotype of *S. kopanikense* is designated. On the basic of a biometric study, morphological differentiation between population of *S. kopanikense* from locus classicus (“Kopaonik, Suvo Rudište”) and other ecologicaly and biogeographicaly different population of *S. heuffelii* from Balkan peninsula will be disscus. Also, taxonomical, chorological and ecological relations will be analyse.

P0738. Taxonomic revision of genus *Cyanus* (*Compositae*) in Bulgaria

S. Bancheva;
Institute of Botany, Sofia, Bulgaria.

In the Bulgarian flora, genus *Cyanus* is represented by 15 taxa, predominantly distributed in the middle and high mountain belts. The territory of the Balkan Peninsula (including Bulgaria) has an important role as a center of origin and diversity of the genus *Cyanus*. It is the richest of endemic species in the Bulgarian flora - more than the half of the taxa have Bulgarian or Balkan distribution. A critical taxonomic revision of all *Cyanus* representatives in Bulgaria with emphasis on their overall morphology, pollen grains, karyotype, ecology as well as the distribution area is made. The pollen grains are Montana- and Cyanus-types (Wagenitz, 1955). Four basic chromosome numbers, x = 8, 10, 11 and 12, are detected. The main evolutionary mechanisms in the group are discussed. An identification key is included. The conservation status of the taxa with restricted distribution, according to IUCN criteria, is determined.

P0739. *Polypodium interjectum* and *P.* x *mantoniae* (Polypodiaceae: Pteridophyta), new to the Bulgarian flora

D. L. Ivanova;
Institute of Botany - BAS, Sofia, Bulgaria.

Three species of *P. vulgare* complex are known to occur in Europe. These are the diploid *P. cambricum*, the tetraploid *P. vulgare* s. str., and the hexaploid *P. interjectum*. Only *P. vulgare* has been recognized in the Bulgarian botanical literature up to now.
We are reporting one species and one hybrid of *Polypodium* as new to the Bulgarian flora. These are *P. interjectum* Shivas and *P.* x *mantoniae* Rothm. The latter is a natural hybrid between *P. vulgare* L. and *P. interjectum*.
Plants from several sites were subject to morphological, cytological and spore analyses. The mitotic chromosome counts revealed a pentaploid, 2n=185, for the hybrid specimens, and a hexaploid 2n=222 for *P. interjectum*.
A morphological comparison between Bulgarian *P. interjectum* and *P. vulgare* was made. The frond morphology of the hybrid *P.* x *mantoniae* is intermediate between the two parents, and the spores were abortive, greatly varying in shape and size.
A map of distribution of the taxa is given. *P. interjectum* and *P.* x *mantoniae* are known to exist in many European countries. These records for the two taxa in Bulgaria extend our knowledge of their distribution.

P0740. Taxonomic relations between Juniperus oxycedus subsp. oxycedrus and J. oxycedrus subsp. macrocarapa based on morphological characters

M. Klimko[1], K. BoratyŒska[2], J. M. Montserrat[3], Y. Didukh[4], A. Romo[3], D. Gomez[5], M. Kluza-Wieloch[1], A. BoratyŒski[2];
[1]August Cieszkowski Agricultural University, Department of Botany, Poznan, Poland, [2]Polish Academy of Sciences, Institute of Dendrology, Kórnik, Poland, [3]Consejo Superior de Investigaciones Cientificas, Institute of Botany, Barcelona, Spain, [4]M. G. Kholodny Institute of Botany of National Academy of Sciences of Ukraine, Kyiv, Ukraine, [5]Consejo Superior de Investigaciones Cientificas, Instituto Pirenaico de Ecologia, Jaca (Huesca), Spain.

The aim of the present study was a biometrical comparison of *Juniperus oxycedrus* subsp. *oxycedrus and J. oxycedrus* subsp. *macrocarapa* on the basis of morphological features of cones, seeds and needles.
17 populations of *J. oxycedrus* subsp*. oxycedrus* and 3 of *J. oxycedrus subsp. macrocarapa* populations were examinated on the basis of features of 30 cones and 30 needles of mostly 20-30 specimen each. Results of the discriminating analysis and the cluster analysis showed significant differences between the two taxa examined. The most important morphological characters discriminating between them were the diameter of the cones and width of needles. *J. oxycedrus* subsp. *macrocarpa* has low level of morphological variation, while typical red juniper was more variable and showed significant morphological differences between the west- and east-Mediterranean populations. The results confirm rather specific than subspecific systematic position of compared taxa and probable origin of west- and east-Mediterranean populations of *J. oxycedrus* subsp. *oxycedrus* from two different Pleistocene refugia.

P0741. Endemic species and vegetation with endemic character in the National Park “Sharr Mountain” - Kosovo

F. Rexhepi[1], F. Millaku[1], E. Krasniqi[2];
[1]University of Prishtina, Department of Biology, Prishtina, Albania, [2]Ministry of Environment and Spatial Planning, Institute for Nature Protection of Kosova, Prishtina, Albania.

Abstract

Flora of Kosovo has considered number of endemic and rare species. From this aspect in territory of the National Park Sharr Mountain there are species: *Achillea alexandri - regis, Alyssum scardicum, Bornmulleria diecki, Crocus scardicus, Dianthus scardicus, Draba corabensis, Lilium albanicum, Melanpyrum scardicum, Micromeria albanica, Narthecium scardicum, Pinus peuce, Potentilla doerfleri, Saxifraga scardica, Sedum flexuosum, Sesleria corabensis, Thymus doerfleri, Verbascum scardicum* ect. Phytocenosis with endemic character in territory of the National Park Sharr Mountain are: *Quercetum trojanae dukagjini, Betulo - Verrucosae coritniensis, Abieti albae koritniensis, Piceetum subalpinum, Rhododendro ferruginei - Pinetum peucis, Achilleo - Pinetum mugo, Pinetum mugo serpentinicum, Achilleo - Aubrietum gracilis, Potentillo doerfleri - Juncetum trifidii, Coccineo - Deschampsietum scardici, Trifolieto - norici caricetum, Achilleo alexandri - regis - Onobrychietum scardici, Ranunculetum crenati scardicum, Cynancho - Saponarietum intermadiae, Sedo - Bornmullerietum dieckii, Carici - Nartecietum scardici* ect.

P0742. Classification of iris populations inferred by fruit and seed morphology points at interesting diversification pattern

M. Biljakoviĺ [1], T. Safner[2], B. Mitiĺ [3];
[1]RuĽer Bo koviĺ Institute, Zagreb, Croatia, [2]Faculty of Agriculture, Zagreb, Croatia, [3]Faculty of Science, Zagreb, Croatia.

The aim of this work was to classify the iris populations into groups based on fruit and seed characters in order to examine their geographical structuring and speciation processes indicated by previous research.

The material was collected on 16 sites along the Croatian coast, of which 11 associated to *I. illyrica* Tomm. and 5 to *I. pseudopallida* Trinajstic. Eight seed and 4 fruit characters were chosen for their diagnostic value.

MANOVA showed that examined characters could differentiate the species as currently described. Classification (clustering and discriminant analysis) placed populations into 2 distinct zones: the northern part of *I. illyrica* areal (north coast) and the southern part of *I. pseudopallida* areal (south coast), while the central transient zone is represented by populations from neighbouring regions of both areals. Correlation between two types of distances showed that the distance between plants based on morphological characters is to the most extent function of their geographical distance, regardless of the species affiliation.

The results show the need for further study of evolutionary processes and relationships of irises in Croatia.

P0743. Taxonomic relations between Juniperus thurifera, J. excelsa and J. foetidissima based on morphological characters

A. Boratynski[1,2], K. Marcysiak[2], A. Romo[3], J. M. Montserrat[3], Y. Didukh[4], K. Boratynska[1], M. Mazur[2], P. Kosinski[1];
[1]Polish Academy of Sciences, Kornik, Poland, [2]Pedagogic University, Department of Botany, Bydgoszcz, Poland, [3]Botanical Institute of Barcelona, Barcelona, Spain, [4]National Academy of Ukraine, Institute of Botany, Kyiv, Ukraine.

The aim of the present study was a biometrical comparison of *Juniperus excelsa*, *J. thurifera* and *J. foetidissima* on the basis of morphological features of cones, seeds and shoots. *Juniperus excelsa* and *J. thurifera* are considered to originate from the same ancestor, their divergence could take place at the end of the Tertiary, with the climate cooling, as a result of occurring in geographically isolated refuges: *J. excelsa* in SE Europe and SW Asia and *J. thurifera* in SW Europe and NW Africa. Their present ranges are separated, but the species are morphologically similar and additionally *J. foetidissima*, growing in SE Europe and SW Asia, joints them.

5 populations of *J. excelsa*, 4 of *J. thurifera* populations and 2 of *J. foetidissima* were examinated on the basis of features of 10 cones and 10 shoots of 18-36 specimen each. Results of analysis of discriminating and the cluster analysis showed great similarity of *J. excelsa* and *J. thurifera*, while *J. foetidissima* was more distant. The results can confirm the thesis of a common ancestor of *J. excelsa* and *J. thurifera*.

P0744. Northern limits of the area of the genus *Onosma* in Slovakia and in the Czech Republic.

P. Mártonfi[1], V. Kolarcik[1], L. Mártonfiová[2];
[1]Institute of Biology and Ecology, PJ Safarik University, Kosice, Slovakia, [2]Botanical Garden, PJ Safarik University, Kosice, Slovakia.

The area of the genus *Onosma* in the Central Europe reaches 49° of northern latitude. *Onosma tornense* Jáv. (2n=14S, S - short chromosomes) from the sect. *Stelligera* Schur is a primitive taxon occurring in Slovakia. It is a microendemic with unclear relation to balcan species. Another species are the following: *Onosma visianii* G. C. Clementi (2n=18L, L - long chromosomes), which is the most common species in the territory, *Onosma arenaria* W. et K. (2n=12L+8S) and *Onosma pseudoarenaria* Schur (subsp. *tuberculata* (Kit.)Rauschert, 2n=12L+14S). In the Czech Republic the only species occurs *Onosma arenaria*, which has, however, been missing since 1992. In Slovakia all of the four species occur, the occurrence is bound to southernmost pannonian regions of Slovakia, however both number of localities and number of individuals in populations decreases. All af the species are critically endangered in Slovakia and require consistent protection. Support for this research was provided by the Grant Agency VEGA, Slovakia (no. 2/3041/23 and 1/2354/05).

P0745. Biosystematics in *Crocus vernus* agg.

G. Dietrich;
private, Wien, Austria.

Caryology, macroscopic morphologic characters and colour patterns in *C. vernus* agg. result in four groups:

1) Western clade: Tepal segments with dark blotches at the outer bases, often with darker veining; corms have shoots only at the tips: diploid: *C. albiflorus, C. purpureus, C. siculus* (species status unclear), tetraploid: *C. vernus*

2) Eastern clade: Tepal segments with dark blotches at the outer bases and mostly at the tips; large corms have also young shoots from the base or center of the corm: diploid: *C. heuffelianus*, aneuploid: *C. "Cakor Pass",* tetraploid-aneuploid: *C. discolor,* amphidiploid: *C. exiguus*

3) Southern clade: Tepal segments with dark blotches at the outer bases, inner segments usually with darker veining, outer segments sometimes with blotches at the tips: *C. "sarplaninae"*

4) Southeastern clade: Tepal segments usually without any dark blotches, rarely with white or dark blotches at the tips: *C. tommasinianus*

P0746. Seed micromorphology in European Orchidinae: taxonomixal aspects

R. Gamarra, E. Ortúñez, E. Dorda, P. Galán;
Universidad Autonoma de Madrid, Madrid, Spain.

A survey of the literature on european Orchidaceae subtribe Orchidinae, reveals that taxonomic interpretations have been primarily made on the basis of morphological characters. Recent phylogenetic analysis of this subtribe (R.M. Bateman & al. in Lindleyana 12: 113-141, 1997, R.M. Bateman & al. in Bot. J. Linn. Soc. 142: 1-40, 2003) suggested a rearrangement in the systematic of the european Orchidinae, with remarkable changes in comparison with the ancient taxonomical proposals. These analyses provide a suitable frame for the study we present here on the seed testa and its taxonomic implications.

Morphological and biometric analyses have been undertaken, and SEM images obtained from several european species of the genera Anacamptis, Serapias, Ophrys, Himantoglossum (incl. Barlia), Neotinea, Orchis (incl. Aceras), Gymnadenia (incl. Nigritella), Dactylorhiza (incl. Coeloglossum), Pseudorchis and Platanthera.

General shape of the seed and sculpturing of the periclinal walls are the principal taxonomic characters between the studied genera. Our results show a strong concordance with the phylogenetic analysis cited above.

P0747. Analysis of Essential Oil Composition Revealed Inter-Specific and Inter-Population Differentiation in Two Salvia Species

M. Maksimovic[1], D. Vidic[1], M. Milos[2], M. Solic[3], S. Abadzic[4], S. Siljak-Yakovlev[5];
[1]University of Sarajevo, Faculty of Science, Department of Chemistry, Sarajevo, Bosnia and Herzegovina, [2]University of Split, Faculty of Chemical Technology, Split, Croatia, [3]Institute “Mountain and Sea", Makarska, Croatia, [4]Zemaljski Muzej, Sarajevo, Bosnia and Herzegovina, [5]Ecologie, Evolution et Systématique, Université Paris-Sud, Paris, France.

Two Salvia species (S. officinalis L. and S. brachyodon Vandas) belonging to the same section (Salvia) were investigated. Material of both species was collected at Mt Sv. Ilija (Peljesac Peninsula, Croatia), where they grow together in the same population. Hydrodistilled volatile oils from the aerial parts of the plants were analysed by GC-MS. Genome size and bases composition were determined by flow cytometry.

Despite the same genome size for S. brachyodon and S. officinalis (0.95 and 0.97pg) and GC% (38.52 and 38.55 %) respectively, and the same chromosome number (2n=14), these two species showed marked differences both in qualitative and quantitative composition of their essential oils. The main components of S. officinalis oil were oxygenated monoterpenes, with alpha- and beta-thujone as the major constituents (57.01% and 14.97%, respectively). In contrast, the chemical composition of essential oil of S. brachyodon was characterised by high content of sesquiterpenes with humulene epoxide II, as the major compound (22.94%). No intermediary patterns, which display existence of reproductive isolation between two investigated species, were observed.

P0748. The possible ways of speciation in Papaveraceae family

I. I. Bara, C. I. Bara;
University Alexandru Ioan Cuza, Iasi, Romania.

The species of *Papaveraceae* family have X = 6, 7, 9, 10 and 11. Till now, does not exist unanimous accepted explanations about the speciation ways in this family.
The *Papaver* genus is the biggest one in the *Papaveraceae* family. It is the genus with species strong differentiated as kariologycal, morphologycal, physiologycal, biochemical and serological traits. In *Papaver* genus there are only 3 fundamental chromosomal numbers (X = 6, 7 and 11).
To explain the appearance of X = 7 and X = 11 (n = 11, 2n = 22, characteristc for the *Papaver somniferum* species), we are proposing the following hypothesis.
Individuals of species with X = 6, n = 6, 2n = 12, by aneuploidy, have produced n = 5, n= 6 and n = 7 gametes. By random fusion of gametes have appeared the individuals with 2n = 10, 11, 12, 13 or 14 chromosomes.
From 2n=11 individuals, by poliploidy, it was possible to appear 2n=22 (n=11) individuals. On the other side, the 2n=14 (n=7) individuals, being tetrasomics, could easy survuve.
By investigations on different populations we pointed out similitudes between *Chelidonium majus* and *Papaver somniferum* species and between *Chelidonium majus* and *Papaver bracteatum* species karyotype.

P0749. Phylogeny and classification of Rutaceae based on two noncoding regions of cpDNA.

M. Groppo[1,2], J. R. Pirani[2], M. L. F. Salatino[2];
[1]Instituto de Botânica, São Paulo, Brazil, [2]Universidade de São Paulo, São Paulo, Brazil.

A phylogenetic analysis of Rutaceae, based on two noncoding regions of cpDNA (the *rps16* intron and the *trnL-trnF* region) was conducted. This study included representatives of all subfamilies and tribes and of most subtribes (65 species in 59 genera, more than 1/3 of the genera in the family). Consensus trees from both separate and combined analyses are largely congruent and consistent with results found in previous *rbcL* and *atpB* studies. The results confirmed that *Cneorum, Ptaeroxylon, Spathelia* and *Dictyoloma* form a clade sister to the remaining Rutaceae. None of the Englerian subfamilies with more than one genus (except Aurantioideae) emerged as monophyletic. The traditional subfamilial classification of the family is revised, and only two subfamilies need to be recognized: Rutoideae and Spathelioideae. Aurantioideae, even though monophyletic, was reduced to tribal rank (Aurantieae) and included in Rutoideae, in the light of the position of *Ruta*. The circumscription of tribes and some subtribes within Rutoideae will also need to be reevaluated. Characters of the gynoecium, fruits and seeds are not reliable for the circumscription of subfamilies.(FAPESP)

P0750. New insights into the evolution and speciation pattern of Mediterranean Carlina L. (Asteraceae - Cardueae)

U. Wahrmund, E. Welk, B. von Hagen;
Institut für Geobotanik und Botanischer Garten, Halle/Saale, Germany.

The genus *Carlina* L. (Asteraceae - Cardueae) is mainly distributed in the Mediterranean region, few species expanding into Northern Europe and Siberia. It contains 28 species with a variety of growth forms ranging from woody shrubs to annuals. We examined a nearly complete phylogeny of *Carlina* using nuclear ETS sequence and chloroplast markers. Our results show for instance, that the shrubby habit of species from Macaronesia and Crete is a derived and independently acquired adaptation to the insular habitat as has been shown for several other woody island endemics. Traditionally, it was presumed to be a primitive character of species growing in relict areas. In addition, we defined and compared the ecological niches of all species using GIS data (global information system) of the actual geographical distribution. By combining this with our phylogeny we were able to test whether the speciation events in *Carlina* were caused by ecological or geographical separation.

P0751. Assessing the Atlantic-Mediterranean disjunction of Armeria pungens with AFLP

R. Piñeiro Portela, J. Fuertes Aguilar, G. Nieto Feliner;
Real Jardín Botánico, CSIC, Madrid, Spain.

AFLP were used to investigate the disjunct distribution (Iberian-Corso-Sardinian) of a diploid coastal shrub species from sand dunes, *Armeria pungens*. We examined variation in 240 individuals from 23 populations that span its geographical range using two different restriction enzyme combinations (*Eco*RI/*Mse*I and *Kpn*I/*Mse*I) and three primer pairs. Three genetically divergent groups that correspond to geographic regions were detected: (i) Mediterranean populations (Corsica and Sardinia), (ii) Atlantic Iberian populations north of S. Vicente Cape (including offshore Cíes islands NW Spain), (iii) Atlantic Iberian populations east of S. Vicente Cape. In concordance with previously assessed variation for ITS, cpDNA and morphology, populations from Corsica and Sardinia were genetically closer to Portuguese than to southern Iberian. This pattern suggests that Portuguese populations are the immediate source of plants that colonised Corsica and Sardinia. A highly divergent population from the Gibraltar Strait is likely due to introgressive hybridisation with congeners; an interpretation that is also supported by sequence data.

P0752. Iberian endemisms in the Beira-Duriense mountains (Portugal)

J. D. Almeida;
University of Coimbra, Coimbra, Portugal.

I have been studying the flora and vegetation of a group of mountains situated S of the river Douro and N of the Mondego. This area can be divided in 4 major groups of mountains: Caramulo; Arada/Freita; Montemuro/Lapa; Penedono/Trancoso; and other minor sierras. The height of this area (2000 km^2), ranges from 700 to 1382 m. Granites and schists are the dominant rocks.
There are 5 Portuguese endemic taxa: *Anarrhinum longipedicellatum*, *Centaurea herminii* ssp. *lusitana*, *Ceratocapnos claviculata* ssp. *picta*, *Murbeckiella sousae* and *Teucrium salviastrum*.The Iberian endemisms are more than 90 (more than 10 % of the total number of taxa: ca. 900), including *Ranunculus bupleuroides*, *R. nigrescens*, *R. olissiponensis*, *Ortegia hispanica*, *Silene acutifolia*, *S. marizii*, *Ulex micranthus*, *Omphalodes nitida*, *Linaria triornithophora*, *Digitalis thapsi*, *Odontites tenuifolia*, *Galium broteroanum*, *Knautia nevadensis*, *Pterocephalidium diandrum*, *Hieracium castellanum*, *Hispidella hispanica*, *Narcissus cyclamineus*, *Gagea lusitanica*, *Paradisea lusitanica*, *Crocus carpetanus*, *Festuca summilusitana*, *Koeleria crassipes*, *Periballia involucrata*, *Trisetaria ovata*, etc.

P0753. Phylo-climatic modelling: Phylogenies, Palaeo-climate and Environmental Preferences

C. Yesson, A. Culham;
University of Reading, Reading, United Kingdom.

A new technique is demonstrated for the interpretation of the role played by climate in plant diversity through the optimisation of climate variables on phylogenetic trees. This is achieved by calculating climate preferences for individual species based on established bioclimatic modelling techniques using point distribution data from distributed sources. We demonstrate a new technique for optimising the component parameters on phylogenetic trees. These parameters can be re-combined into bioclimatic models for ancestral nodes throughout the phylogenetic tree. The combination of DNA-sequence data and the fossil record is used to establish time-calibrated phylogenies. Using these chronograms, bioclimatic models can in turn can be projected into the relevant palaeo-climate scenario to establish possible areas of palaeo-distribution. This technique is demonstrated using exemplar plant groups from Mediterranean-type winter-wet climate zones.

P0754. Characterisation of olive germplasm from Molise region by microsatellite markers

G. Godino[1], N. Lombardo[1], **I. Muzzalupo**[1], M. Pellegrino[1], E. Perri[1], A. Sajjad[2];
[1]C.R.A. - Istituto Sperimentale per l'Olivicoltura, Rende - Cosenza, Italy, [2]Università degli Studi della Calabria, Rende - Cosenza, Italy.

In the whole Mediterranean basin a large number of varieties of *Olea europaea* are present. This produce a series of problems concerning the germplasm characterization, management and preservation. In addition there is the problem arising from the existence of homonyms and synonyms. This make difficult the cultivar identification. The single sequence repeats (SSR) are co-dominant markers, showing a large number of polymorphisms per primer set and often multiple alleles in a variety, which can be highly informative. In the present work 21 olive accessions were used, corresponding to the major part of the autochthon germplasm of Molise region.

The identification of 19 genotypes and characterization of 17 olive cultivars with unique genotype allow us to affirm that SSR technology is an efficient tool for genotyping the olive germplasm collection of Molise region and could be valid to distinguish other accessions which can be introduced into the collection.

P0755. Comparision of glandular and aglandular hairs in some endemic species of *Phlomis* L.

C. Özdemir, E. Alçitepe, Y. Altan;
Science-Art Facult Biolgy Department, Manisa, Turkey.

In this study the glandular and aglandular hairs were examined and classified in the various vegetative and reproductive organs of *Phlomis lycia* D. Don, *Phlomis armeniaca* Wild, *Phlomis capitata* Boiis, *Phlomis sieheana* Rech., *Phlomis nissolii* L. The investigated species are endemic to small areas of Turkey. The plant samples were collected from natural population between 2002-2004. It observed that the investigated species have aglandular and glandular hairs of various shapes, sizes and modes of secretion. Certain types of hairs predominant on different organs of the species. The glandular and aglandular hairs differ in variety and density according to the kinds of species and organs related. These characters about hairs will help to distinguish the species from each other. In addition these features of anatomy that the differences in hair morphology are ancillory obsorvations that serve to increase generally the anatomical knowledge of the genus.

P0756. Morphological, anatomical, palynological and ecological studies on *Gynandriris sisyrinchium* (L.) Par l.

E. Alçitepe, C. Özdemir, Y. Altan;
Science-Art Faculty Biolgy Department, Manisa, Turkey.

The study is based on morphological, anatomical, palynological and ecological investigations of *Gynandriris sisyrinchium* (L.) Parl. of which flowers each lasting only a Few hours. The genara Gynandriris is represented one taxon, only by *Gynandriris sisyrinchium* in Turkey. In anatomical studies vhich used paraffin methods cross-section the plants parts were examined and demonsrated.

In palynological studies, the pollen grains morphology, the types of the pollens and the measurements in polar and ecvatoral using the Wodehause methods were determined. This study used it has been determined that the plant prefers clayey-loamy textured soil, poor in calcium carbonate, acitic soil and containing varying amounts of organic matter being very rich in nitrogen. The plant grows on nonsaline soils. The analysis of some elements (N,P,K) was carried out in both above and underground parts of this taxon. In addition the chemical analysis of the soil sample belong to the plant was carried out.

P0757. Systematics of Cistaceae

J. M. Arrington;
Duke University and *Randolph-Macon Woman's College, Lynchburg, VA, United States.

The Cistaceae, rock roses, is a flowering plant family of malvalean affinity that comprises approximately 180 species. They are showy or small flowered herbs and shrubs that are particularly abundant in sunny areas of the western Mediterranean region, followed by the southeast coastal plain of the United States. The first phylogenetic hypothesis of the relationships within the family, based on nuclear ITS and chloroplast matK-trnK and trnL-F nucleotide data, is presented. The Old World *Helianthemum* are sister to a clade that comprises two subclades. One contains *Cistus*, *Halimium*, and *Tuberaria,* and the other contains New World *Helianthemum* and *Hudsonia*. *Fumana* represents the first branch of the phylogeny, followed by *Lechea*, which is sister to the remaining Cistaceae. Ovule- and pollen-type, staminodes, stigma ultrastructure, funiculus and embryo morphology, mode of sepal development (calyx initiation), leaf arrangement, a host-parasite association, geographical distribution, chromosome number, and a newly described characteristic of the style were found to be among the most valuable nonmolecular characters to the systematics of the family.

P0758. Phylogeny of *Withania* (Solanaceae)

A. Kool, B. Oxelman, M. Thulin;
Department of Systematic Botany, Evolutionary Biology Centre,
Uppsala University, Uppsala, Sweden.

Withania consists of about 11 species, six endemic in the Horn of Africa region, three in the Canary Islands, North Africa and Spain, one in southern Asia, and one widespread in the Old World tropics and subtropics. A phylogeny was inferred from a data matrix of cpDNA sequences of 2300 aligned positions, as well as from nuclear ITS-data.

We found evidence for the monophyly of *Withania.* The enigmatic *Mellissia begonifolia,* endemic to St Helena, is probably *Withania's* sistergroup and we found evidence for a clade consisting of *Athenaea* and *Aureliana* as sister of *Withania* and *Mellissia*. All species of *Withania* except for the Macaronesian and West Mediterranean *W. aristata* and *W. frutescens* form a clade that have *W. aristata* and/or *W. frutescens* as sister group. *W. coagulans* from southern Asia groups together with *W. riebeckii* from Socotra in the chloroplast phylogeny. This appears to be contradicted by the ITS data, and may indicate an allopolyploid origin of *W. coagulans*. The sister of the widespread and important medicinal plant *W. somnifera* is *W. sphaerocarpa* from the Horn of Africa. Very little variation was found in the chloroplast sequences of the Horn of Africa taxa.

P0759. Preliminary phylogenetic analyses of Sempervivum (Crassulaceae) inferred from DNA sequence data

K. Topalov[1], M. E. Mort[1], P. Neeff[2];
[1]University of Kansas, Lawrence, KS, United States, [2]Universitat Dusseldorf/Essen, Essen, Germany.

Sempervivum (Crassulaceae) is a medium size genus comprising 50 species of hardy alpine leaf-succulents. The genus is distributed mainly in mountainous regions of central and southern Europe and the Mediterranean. Phylogenetic studies of Crassulaceae confirm that Sempervivum is monophyletic and place the small genus Jovibarba (five taxa) as sister to the genus; however, other studies have suggested that Jovibarba is actually derived within Sempervivum. Jovibarba was separated from Sempervivum based on the differences in flower morphology; Jovibarba species have 6-parted, bell-shaped flowers, whereas species of Sempervivum have polymerous flowers. There has not yet been a focused phylogenetic study of Sempervivum. We used parsimony analyses of DNA sequence data derived from the nuclear (nrDNA ITS) and chloroplast (trnL-trnF) genomes to reconstruct phylogeny for Sempervivum. Our analyses indicate that these data will provide a robust estimate of phylogeny for Sempervivum. Furthermore, our data suggest that several widespread species of Sempervivum are not monophyletic, suggesting a need for a taxonomic revision of the genus.

P0760. Pollen morphology of various Croatian Endemic Plants

B. Mitiĺ [1], H. Halbritter[2], S. Bogdanoviĺ [1], I. Dobroviĺ [1], I. Re etnik[1], P. Cigiĺ [1];
[1]Department of Botany, Faculty of Science, Zagreb, Croatia, [2]Institute of Botany, University of Vienna, Vienna, Austria.

Recently we began a complex study on pollen morphology of Croatian endemic plants. From about 400 Croatian endemic taxa we chose various species narrow endemic to Croatia and/or surrounding areas: 20 taxa from the Genus *Anthyllis*, *Asperula*, *Corydalis*, *Iris*, *Lilium*, *Limonium* and from famillies Asteraceae, Brassicaceae, Campanulaceae and Orchidaceae. Some of them are very rare and stenondemic for Croatia, such as: *Asperula staliana* Vis. ssp. *arenaria* Korica, *Asperula staliana* Vis. ssp. *issaea* Korica, *Asperula staliana* Vis. ssp. *staliana*, *Corydalis acaulis* (Wulfen) Pers., *Iris rotschildii* Degen, *Limonium vestitum* (C.E.Salmon) C.E.Salmon subsp. *brusnicense* Trinajstic and *Sibiraea altaiensis* (Laxm.) C. K. Schneid. subsp. *croatica* Degen. The pollen samples of all taxa were obtained from field collections and examined by Scanning Electron Microscope in dry and hydrated state. Descriptions of pollen grains will be presented and commented on. Results will contribute to better knowledge about Croatian endemic plants.

P0761. The biodiversity and geography of Eurasian Crassulaceae

V. V. Byalt;
Komarov Botanical Institute RAS, St. Petersburg, Russian Federation.

The Crassulaceae (1) is biggest succulent family of Eurasia. It includes 716 species of 25 genera (or 42% of family). Moreover 450 spp. _ cultivated at Europe. In sum it is more than ½ of family diversity (ca. 1700 spp. of 50 genera). The biggest genera of 1 are Sedum _ 250 spp., Rhodiola_90, Sempervivum 50, Hylotelephium_30 &c. There are several endemic genera for Eurasia_Meterostachys, Orostachys, Sinocrassula, Prometheum &c. Species of 1 are distributed practically around of all Eurasia, but nevertheless they are spread very partial. The most amount of species are concentrated in mountain region (not less then 75 %). Exist several centers of diversity of 1. The most of species 1 concentrated at China (13 gen. & 230 spp. _ 130 endemics) and in Tibet-Himalaya area (300 spp. or 40% of all Eurasian 1). 2 center _ in S. & C. Europe_60 spp. of Sedum, all Jovibarba, many of Sempervivum and Umbilicus spp. 3 _ in Asia Minor and Caucasus with endemic genera Chiastophyllum, Prometheum and many endemic spp. of Sedum, Phedimus, Sempervivum &c. Some of regions of Eurasia are represented by a small amount of 1. It can be connected with historic, climate and geographical features of these areas.

P0762. Diversity and conservation of genus Sonchus sect. Pustulati

J. A. Mejías[1], J. González-Batanero[1], I. Mendoza[2];
[1]Universidad de Sevilla, Sevilla, Spain, [2]Universidad de Granada, Granada, Spain.

Biodiversity evaluation and conservation programs are directly dependent on the quality of taxonomic data. This value is increased when we are dealing with endemic plants. Based on biological and typological species concepts, we review the taxonomy of the endemic group *Sonchus* sect. *Pustulati* in order to obtain the basic information for the conservation of species. It is found that it comprises three taxa (instead of the four taxa distinguished until now), and we propose a taxonomic status change.

The section distribution is limited to about ten coastal or low altitude rocky walls enclaves from western Mediterranean area. Populations show reduced extensions and mean densities ranging from 21 to 55 individuals/100m^2. We study the population of *Sonchus pustulatus* Willk. from El Barranco del Caballar (Almería) as an example of population viability. It is compound of about 200 individuals and demographic structure indicates that, in spite of high fruit set, viability mainly relies on the survival of adults. Seed dispersal seems to be the factor limiting colonisation of similar enclaves. The role of small reserves is discussed as main way of preservation for the group.

P0763. *Campanula* Waldsteiniana and Pyramidalis lineages: Not more than Neighbours - or Truly Relatives?

Z. Liber[1], S. Kovacic[1], M. Tkalec[1], T. Nikolic[1], G. Schneeweiss[2];
[1]Department of Botany and Botanical Garden, Faculty of Science, University of Zagreb, Zagreb, Croatia, [2]2Institute of Botany and Botanical Garden, University of Vienna, Vienna, Austria.

European amphi-Adriatic and Western Balkan region is floristically exceptionally rich, among other, comprising at least 85 species and subspecies of *Campanula* genus, without many poorly known lower (incipient) taxa and hybrids. Among the most interesting in the region are endemic indigenous lineages, such as “isophylloid” aggregates *Campanula* Waldsteiniana (*C. waldsteinana - C. tommasiniana*) and Pyramidalis (*C. pyramidalis - C. versicolor - C. secundiflora*). Being neither isophyllous nor heterophyllous, but a little bit of both, the Waldsteiniana and Pyramidalis relationships to other campanuloids in the region puzzle botanists for a long time. Comparative morphological and ecological data, isoenzymes, restriction-site variation of PCR-amplified cpDNA fragments and ITS1-5.8S-ITS2- sequences of the nuclear ribosomal DNA were used to provide better insights into these fine relationships. The data were analysed using multivariate statistical and cladistical methods: here are presented the preliminary results, showing that two morphologically distant lineages might be truly relatives after all.

P0764. An SEM study of peristomes and spores morphology of *Philonotis* (Bartramiaceae, Musci) from the Iberian Peninsula

A. Ordoñez, M. T. Gallego, M. J. Cano, J. Guerra;
Facultad de Biología, Murcia, Spain.

The genus *Philonotis* Brid. is the largest genus of the family Bartramiaceae, having 189 accepted species (Crosby M.R., Magill R.E., Allen B. & He S. 1999. A checklist of the mosses. Missouri Botanical Garden). In the Iberian Peninsula only eight of them appear [*P. caespitosa* Jur., *P. calacarea* (Bruch & Schimp.) Schimp., *P. capillaris* Lindb. ex Hartm., *P. fontana* (Hedw.) Brid., *P. marchica* (Hedw.) Brid., *P. rigida* Brid., *P. seriata* Mitt. and *P. tomentella* Molendo].

There are very few works where the peristomes and spores of the Iberian fructified species of *Philonotis* are described and only drawings and light micrographs have been published (Raeymaekers 1983. Lindbergia 9: 29-33; Smith 2004. The moss flora of Britain and Ireland). For this reason a complete description of these structures for the species of *Philonotis* from this area, accompanied with SEM photographs, is provided.

P0765. Molecular phylogeny of Ceroxyleae and Phytelephantoideae (Palmae) based on plastid DNA and two low-copy nuclear genes

P. Trénel[1], F. Borchsenius[1], M. Gustafsson[1], W. J. Baker[2], J. Dransfield[2];
[1]Aarhus University, Dep. of Sys. Botany, Aarhus, Denmark, [2]Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Recent data based on molecular, genus-level phylogenies for the palm family (Arecaceae) point to a sister group relationship between tribe Ceroxyleae, with its four genera *Oraniopsis*, *Ravenea*, *Juania* and *Ceroxylon* disjunctly distributed on the Southern hemisphere, and the morphologically highly distinct, trans-Andean subfamily Phytelephantoideae with its three genera *Phytelephas*, *Ammandra*, and *Aphandra*. The disjunct biogeographic pattern of Ceroxyleae, as well as the apparently rapid morphological evolution leading to the Phytelephantoideae, are two issues of palm natural history that are still unsolved. Here, we present molecular phylogenies of Ceroxyleae and Phytelephantoideae, including a total of 29 ingroup species, based on plastid DNA and two low-copy nuclear genes. Although resolution and support is generally low to moderate inside major genera due to a lack of variation in the data, all taxonomic groups are well-supported as monophyletic. *Ammandra* and *Aphandra* form a clade that is sister to *Phytelephas*. *Ravenea* is a likely sister to the rest of the Ceroxyleae, in which *Oraniopsis* appears basally to *Juania* and *Ceroxylon*.

P0766. Migration history and polyploidization in bipolar plants: the genus *Empetrum* (Crowberries)

V. Mirré[1], R. Elven[1], B. Stedje[1], J. Suda[2,3], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway, [2]Department of Botany, Charles University, Prague, Czech Republic, [3]Institute of Botany, Academy of Sciences, PrŢhonice, Czech Republic.

The bipolar genus *Empetrum* is taxonomically complex with 1-18 described taxa. It consists of dioecious, hermaphroditic or polygamous plants at the diploid or tetraploid level. We analyzed samples from most of its range using AFLP, flow cytometric, and morphological data to address the origin of the bipolar disjunction and the evolution of polyploidy and breeding systems, and to contribute to delimitation of taxa. The molecular data suggest that the present bipolar distribution resulted from long-distance dispersal of diploids from western North America to the southern hemisphere. We recognized two distinct lineages based on the molecular and morphological data; the northern circumpolar di- to tetraploid *E. nigrum* s. lat. and the southern diploid *E. rubrum* s. lat. There was considerable molecular and morphological variation within these lineages. However, whether these lineages represent two species or two species groups, remains unresolved. Our data suggest that hermaphrodism and tetraploidy have originated repeatedly in the northern hemisphere.

P0767. Assessing the phylogeny of *Solanum* sect. Petota using cpDNA and AFLP

M. M. J. Jacobs[1], R. Hoekstra[2], R. van den Berg[3], B. Vosman[1];
[1]Plant Research International, Wageningen, The Netherlands, [2]Centre for Genetic Resources, Wageningen, The Netherlands,
[3]Biosystematics group, WUR, Wageningen, The Netherlands.

The potato (*Solanum tuberosum* L) is a crop with a large genepool consisting of more then 200 tuber-bearing species. The group has been studied extensively, mainly using morphological characters. Partly due to a complex evolutionary history phylogeny reconstruction proved difficult. Only recently, molecular data have been used but only for small parts of the potato genepool. A complete, comprehensive treatment of the systematic relationships between the species is urgently needed to solve taxonomic problems and to allow scientifically based selection of materials for breeding programs.

In this project we will solve the systematic problems of the *Solanum* sect Petota. Around one thousand gene-bank accessions, representing most tuber-bearing species, have been collected from all over the world. First, a backbone phylogeny of the group is constructed by sequencing chloroplast DNA regions *trn*LF and *psb*A/*trn*H of all (sub)species available. Next, AFLP is used to get a detailed phylogeny of the branches at the accession level. Results of the analysis will be presented at the meeting.

P0768. Assessing the speciation history of closely related wild tomatoes (*Lycopersicon peruvianum* and *L. chilense*)

U. Arunyawat, T. Staedler, K. Roselius, G. Feldmaier-Fuchs, W. Stephan;
University of Munich, Planegg, Germany.

Their recent divergence and the diversity of mating systems make wild tomatoes (clade *Lycopersicon*) an ideal plant speciation model system. We used a multilocus approach to assess the suitability of the Wakeley-Hey isolation model in two outcrossing species. This allopatric speciation model assumes divergence without gene flow. We analyzed DNA sequences of 14 unlinked nuclear loci and found that average levels of silent polymorphism are more than threefold higher in *L. peruvianum* than in *L. chilense*. Although the isolation model cannot be rejected by goodness-of-fit criteria, patterns of intragenic linkage disequilibrium are suggestive of historical gene flow at least in some regions of the genome. In combination with the geographic pattern of postzygotic reproductive isolation, our results indicate that speciation occurred under residual gene flow. Therefore, natural selection is implied as one of the evolutionary forces driving speciation processes in wild tomatoes.

P0769. Phytogeographical relationships of the Chilean vascular flora: tectonic vicariance v/s long distance dispersal

A. Moreira-Muñoz;
Institute of Geography, Erlangen, Germany.

South-western South America has been divided into several phytogeographic provinces mainly based on bioclimatic and vegetational data. On an attempt to identify real floristic units, I classified the 801 Chilean native genera into 13 classes, later regrouped into 7 floristic elements. The neotropical and pantropical genera reach 33% (together), and the temperate genera (boreal and austral) 27%. The austral-asiatic and endemic genera contribute each 9%. I further analyzed the data via track analysis and identified several basic patterns: South Pacific, North Pacific, Andean, Tropical and Cosmopolitan. The analysis suggests tectonic vicariance as the main factor generating the overall disjunct distribution pattern. But recent results arising from molecular dating of lineage divergences suggest that the importance of oceanic dispersal has been strongly underestimated against the predominance of vicariance. A closer analysis of some key genera (e.g. Nothofagus and its parasites) let us discuss the confronting dispersal v/s vicariance hypotheses, and the assumptions in cladistic systematics, vicariance biogeography and molecular dating.

P0770. Phylogenetic relationships of Palaua Cav. (Malvaceae) and the positioning of the enigmatic P. sandemanii (Sandwith) Fryxell

M. L. Huertas[1,2], J. V. Schneider[3], G. Zizka[1,2];
[1]Forschungsinstitut Senckenberg, D-60325 Frankfurt/Main, Germany, [2]J.W. Goethe-Universität, Frankfurt/M., Germany, [3]Universität Leipzig, D-04103 Leipzig, Germany.

Palaua comprises about 15 species of annual to perennial herbs or subshrubs, including some highly polymorphic taxa, particularly those with deeply dissected leaves (P. dissecta, P. mollendoensis, P. pusilla). The genus is endemic to the lomas formations, the so-called fog oases of the coastal deserts of Peru and N-Chile. The mericarps are arranged spirally or in several superimposed whorls in all species - a character not observed among its closest relatives - except in P. sandemanii, in which they are disposed in a circle. Nuclear (ITS1, 5.8S, and ITS2) and plastid (psbA-trnH spacer) sequence data were used to reconstruct phylogenies, to test the monophyly of the genus, and to determine the position of the enigmatic P. sandemanii. Phylogenies show poor resolution within Palaua. However both, the nuclear as well as the plastid data set, support monophyly of the genus, including also P. sandemanii.

P0771. Genetic affinities among populations of South-American conifers inferred by AFLP markers

M. L. F. Salatino[1], A. Salatino[1], G. T. Ceccantini[1], F. Pinheiro[1], M. Ledru[2];
[1]University of São Paulo, Institute of Biosciences, São Paulo, SP, Brazil, [2]University of Montpellier, Montpellier, France.

South American conifer populations are assumed as remnants of wide distributions prevailing before the Quaternary climatic changes. The present work aimed to establishing degrees of genetic affinity among populations of *Araucaria* and *Podocarpus*, by means of AFLP markers and UPGMA, using Jacquard coefficients. Plants from six *Araucaria* and 26 *Podocarpus* populations were analyzed, generally three plants per population, involving areas of Brazil (most populations), Argentina, Bolivia and Chile. Populations of *A. angustifolia* have close affinities among each other and are genetically distant from *A. araucana*. Populations of *Podocarpus* form two clusters, one grouping *P. brasiliensis*, *P. sellowii* (both in Brazil) and *P. montana* (Chile), and the other *P. lamberti* (Brazil) and *P. parlatorei* (Argentina and Bolivia). The results suggest a) the recognition of two species of *Araucaria* and also two of *Podocarpus*, the latter corresponding to the two mentioned clusters, and b) the most ancient populations of *Araucaria* and *Podocarpus* correspond to southeastern Brazil, wherefrom radiations probably occurred toward other regions of South America.

FAPESP, CNPq

P0772. How the pteridophytic diversity of the South Cone took form

E. R. de la Sota;
Facultad Ciencias Naturales & Museo, UNLP, La Plata, CONICET, Buenos Aires, La Plata, Argentina.

The South Cone (Chile, Argentina, Paraguay, Uruguay, Southern Bolivia and Brazil) shows high pteridophytic diversity in Frozen Yungas, Southern Brazil and Austral Andes. During their building took roles 3 Gondwanic provinces, Western, Eastern and Southern, with different shares, being Africa a weak player.

A “dry diagonal”, producing two opposite sections of rain shadows from the North to the South and the miocene marine transgression should have worked later.

The last floristic interchanges between the 3 areas would have been during the pleistocenic glaciations, by displacement of Atlantic costal line to East and through a “Residual Pleistocenic Seasonal Formation Arc”, which could have connected Southern Brazil and Yungas, nearby Santa Cruz de la Sierra, where in its latitude is found the frontier between Frozen and Peruvian-Bolivian Yungas. The hilly migrant routes through the Pampas, played another role in its interchanges.

P0773. Phylogeny and evolution on *Salvia* subgenus *Calosphace* (Lamiaceae): a Brazilian view.

E. P. Santos[1,2], A. J. Paton[3], V. Savolainen[4];
[1]Departamento de Botânica, Universidade Federal do Paraná, Curitiba, Brazil, [2]Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Brasília, Brazil, [3]The Herbarium, Royal Botanic Gardens, Kew, Richmond, United Kingdom, [4]Jodrell Laboratory, Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Salvia L. with 900 species is the largest genus in the Lamiaceae. Most of the South and Central American Species belong in the New World subgenus Calosphace. This subgenus is divided into over 100 sections, some of which group unrelated species, often from very disparate geographical regions. A DNA analysis using the plastid and nuclear DNA regions (*trnL- trnF, ITS* and *psbA-trnH*) was carried out in order to determine the phylogenetic and geographical relationships within *Salvia* subgenus *Calosphace,* and to identify the placement of the Brazilian species. At least four lineages with different distributions are evident: a pan-American clade (*Uliginosae* Group), a Central American clade, Central America/Andes clade and a largely Brazilian clade. The Brazilian clade is sister to Andean species. Issues relating to systematics and biogeography in the Brazilian lineage and relatives are discussed.

P0774. Biogeographic patterns in the flora of southern South America

J. V. Crisci;
Museo de La Plata, La Plata, Argentina.

According to recent historical biogeographic studies, South America is a continent of hybrid origin with its southern portion closely related to the southern temperate areas, such as Australia, New Zealand, New Guinea, New Caledonia, and Tasmania (reflecting the existence of an ancient austral biota), and the northern portion closely related to the Old World tropics. An approximation of a definition of southern South America may be obtained by looking at the distribution of many individual taxa of plants and animals. Based on these distributions, southern South America is defined here as the area south 30 degrees south latitude. For some authors, the Andean highlands north of 30 degrees south latitude (for instance Puna and North Andean Paramo) should be also included in this area. The objectives of this presentation are to present a biogeographical sketch of southern South America, and a summary of the knowledge of the phytogeography of this area.

P0775. Biogeography and phylogeny of the sandalwood genus Santalum (Santalaceae) based on sequence data and morphology

D. T. Harbaugh, B. G. Baldwin;
University of California, Berkeley, CA, United States.

Phylogenetic analyses using a combination of morphological and sequence data (ITS, ETS, *3'trn*K intron and *trn*G intron) from all currently recognized taxa in *Santalum* provide evidence for broad-scale, historical biogeographic patterns in the genus. A well-supported basal grade of taxa from Australia supports an origin of the genus on that continent. Multiple long-distance dispersal events must be postulated to account for the distribution of *Santalum* in India and the Pacific. As previously proposed, the Hawaiian species recently treated in sect. *Hawaiiensia* (*S. ellipticum* and *S. paniculatum*) are evidently more closely related to one another than to the other Hawaiian endemics, *S. freycinetianum* and *S. haleakalae*, recently treated in sect. *Santalum* and appear to have resulted from two independent colonization events to Hawaii. The lineage including *S. freycinetianum* and *S. haleakalae* also includes *S. boninense* from the Bonin Islands and *S. insulare* from French Polynesia, Cooks Islands, Henderson Island and the Marquesas Islands, which indicates that Hawaii may act as a source for dispersal to island groups in the South Pacific and the Western Pacific.

P0776. Comparative phylogeography of eastern North American trees

A. B. Morris, M. A. Gitzendanner, D. E. Soltis, P. S. Soltis;
University of Florida, Gainesville, FL, United States.

Single species phylogeographic studies, while providing an interesting story about the individual species, say very little about the biogeographic history of a region. Comparative studies of multiple, unrelated species with different life history strategies are the key to gaining a more complete record of regional history. The purpose of this research is to trace the biogeographic history of eastern North America, using long-lived tree species as study organisms. The choice to include only trees in this study was based on the fact that many trees in the eastern United States have well-preserved and well-documented fossil pollen records, whereas most herbaceous species do not. The fossil information provides some background data on which many hypotheses have been based. Here we present haplotype networks based on non-coding chloroplast sequence data for North American Fagus, Hamamelis, Illicium, and Liquidambar to test alternative hypotheses regarding the timing of the disjunction between the United States and Mexico and potential Pleistocene refugia.

P0777. Biogeography of arctic-subarctic plants during the glacial period: molecular phylogeny of Tofieldiaceae

H. Azuma, H. Tobe;
Dept Botany, Graduate School of Science, Kyoto University, Kyoto, Japan.

The climatic deterioration from the late Tertiary to the present made development glacier at middle to high latitude of the Northern Hemisphere. The effect on distribution and evolution of arctic-subarctic plants is one of interesting issues. Because glacier develops in valleys rather than on ridges of mountains, we can expect that arctic-subarctic plants which grow in ridge (rocky place) of mountain easily survive the glacial period than the plants in valley (wet place) in the same mountain area. We conducted molecular phylogenetic analysis of Tofieldiaceae [*Tofieldia* 18 samples from 9 spp. (7-20 spp. known in rocky place of mountains with circumboreal distribution), *Triantha* 8 from 4 (4 in wet place of northern part of NA and Japan), *Isidrogalvia* 3 from 3 (5 in SA), *Harperocallis* 1 from 1 (1 in southeastern NA) and *Pleea* 1 from 1 (1 in southeastern NA)] using plastid *matK*, *trnL* intron and *trnL-F* spacer regions. The molecular phylogenetic analyses indicated that the sequence divergences among *Tofieldia* spp. (max 0.03144, av. 0.02047) are higher than those of *Triantha* spp. (max 0.00566, av. 0.00353). These results are consistent with the scenario mentioned above.

P0778. Molecular phylogenetics and biogeography of subtribe Melittidinae (Lamiaceae)

A. Scheen, V. A. Albert;
Natural History Museum, Oslo, Norway.

The five genera *Physostegia*, *Brazoria, Macbridea*, *Warnockia*, and *Synandra* are all endemic to North America. Together with the monotypic Eurasian genus *Melittis* and the East Asian genus *Chelonopsis*, these taxa have been classified as subtribe Melittidinae. Previous morphological studies have failed to uncover synapomorphic characters for this group. Our molecular data show *Melittis*, the type genus of the subtribe, as sister to the greater *Stachys* clade. Thus, the monophyly of subtribe Melittidinae is supported neither by molecular nor morphological data. However, the North American endemics do form a monophyletic group based on molecular data. The molecular relationships among these genera are reflected by morphological and cytological data. The expected close relationship between *Warnockia* and *Brazoria* and their sister relationship to the genus *Physostegia* is confirmed. Most of the North American endemics are restricted to the southeast of the continent. Migrations westwards and northwards are correlated with an increase in chromosome numbers as well as several morphological characters.

P0779. Genetic centers of *Juglans regia* L. origin.

S. L. Zhygalova;
M.G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv, Ukraine.

Our researches deal with the centers of beginnings of *J. regia*. The majority of botanists tend to the idea that the primary center of origin for *J. regia* are Asia Minor, Iran, Afghanistan, Transcaucasia, Middle and Central Asia, and also a belt which stretches towards Tien Shan and the Himalayas. Assumptions of researchers about primary and secondary centers of occurrence of *J. regia* are still disputable in some cases.

M.I. Vavilov considered that the primary genetic center of origin of *J. regia* was the Central Asian center which includes Afghanistan, Northwest India, Tajikistan, Uzbekistan and Western Tien Shan, and also Asian center, which includes internal Asia Minor, Iran and mountainous Turkmenistan.

P.M. Zhukovsky and I.G. Komanich specify the secondary genetic center of origin for *J. regia*, which is Moldova. P.M. Zhukovsky also accepts Southwest Europe as the secondary genetic center of *J. regia*. M.K. Vekhov agrees with him, specifying to Romania, Southern Hungary, Bosnia and Thessaly, where this species is a part of wood plantings and forms pure small groves.

P0780. Systematics, phylogeny and biogeography of *Euphrasia* inferred from morphology and molecular markers.

G. L. Gussarova[1,2], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway, [2]Department of Botany, St. Petersburg State University, St. Petersburg, Russian Federation.

The genus *Euphrasia* L. (Scrophulariaceae s.l.) includes perennial and annual green parasitic (hemiparasitic) plants distributed in temperate regions of both hemispheres. It is a taxonomically complex group with frequent interspecific hybridisation, and mainly quantitative traits are used for delimitation of sections and species. In this ongoing study, we integrate morphological and molecular evidence to infer phylogenetic relationships between the Northern Hemisphere species and to produce a revised classification. A preliminary maximum parsimony analysis of 100 species based on morphological characters resulted in a partially resolved phylogeny, supporting so far only some of the traditional subdivisions of the genus at the section level. We are currently sequencing two non-coding cpDNA regions and one nuclear DNA region (ITS) for a large number of the Northern Hemisphere species as well as some Southern Hemisphere representatives, and the inferred molecular phylogeny will be compared to that based on morphological characters. We also present a recent revision of the taxa occurring in the geographical area of the former USSR.

P0781. Circumboreal-circumarctic phylogeography and taxonomy of bog bilberry (*Vaccinium uliginosum*) inferred from DNA, ploidal levels, and morphology

I. G. Alsos[1], J. Suda[2], P. B. Eidesen[1], S. Øyvind[1], T. Engelskjøn[3], L. Gielly[4], P. Taberlet[4], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museum, Oslo, Norway, [2]Department of Botany, Charles University, Prague, Czech Republic, [3]Tromsø Museum, University of Tromsø, Tromsø, Norway, [4]Laboratoire d'Ecologie Alpine, Université Joseph Fourier, Grenoble, France.

We address the effect of the ice ages on the phylogeography and taxonomy of the bird-dispersed *Vaccinium uliginosum* L. complex. Populations from throughout its circumboreal-circumarctic range are analyzed for chloroplast and nuclear DNA, morphology, and ploidal levels. Three main cpDNA lineages are identified, which probably diverged before all major glaciations. These lineages can also be distinguished based on morphology. Polyploidizations have probably occurred at least five times at different times and geographic locations. The impact of the ice ages apparently differed conspicuously between geographic regions: northern survival and extensive postglacial migration in the Arctic, isolation of southern European alpine populations, bottlenecking in previously glaciated boreal amphi-Atlantic areas, and diversification in Beringia. Beringia was apparently important for the initial divergence and expansion as well as for continuous survival during all ice ages, but played a minor role as a source for later interglacial expansions. We are now examining AFLP and ITS diversity in the species.

P0782. Phylogeography of *Quercus robur* L. in Portugal

T. Azevedo[1], M. Ricca[1], A. Séneca[1,2];
[1]CIBIO/ICETA - University of Porto, Porto, Portugal, [2]Department of Botany of FCUP - University of Porto, Porto, Portugal.

Present genetic structure of many tree species was shaped to a large extent by the last glacial period of the Quaternary and postglacial recolonisation processes, and by human impacts.

During the last glacial period, temperate forest species were restricted to small areas (termed refugia) with a milder climate. Fossil pollen data from sites across Europe have been used to reconstruct the location of the refugia of deciduous oak species, and the spread from these into their current ranges. Three areas of southern Europe have been identified as major refugia: Iberian Peninsula, Italian Peninsula and the Balkan Peninsula.

The present work aims to identify likely micro-refugia in Portugal. The particular ecogeographical conditions in the Iberian Peninsula, with several east-west range of mountains, have possibly played a major role in the distribution of refugia and in the dynamics of postglacial recolonisation.

A common strategy for molecular screening, based on restriction analysis of three PCR - amplified cpDNA fragments, is being used to study the distribution of diversity within and among *Quercus robur* populations.

P0783. A chloroplast phylogeny for 100 of the 122 genera of Cucurbitaceae reveals the family's spatiotemporal evolution

A. Kocyan[1], L. Zhang[2], S. S. Renner[1];
[1]Ludwig Maximilians University, Munich, Germany, [2]Department of Biology, Colorado State University, Fort Collins, CO, United States.

Cucurbitaceae (760 spp.) present a challenge for phylogenetic work because of many poorly collected and understood taxa. We present a tree based on four chloroplast loci (5000 bases) that includes 140 spp. from 100 gen., all 11 tribes, and all but one subtribe (following the classification of Jeffrey 2004). The tree confirms the traditional division of Cucurbitaceae into Nhandiroboideae (=Zanonioideae; 19 gen.) and Cucurbitoideae (103 gen.). Basal groups occur in Africa, Madagascar, SE Asia, and China, with six New World (NW) groups nested within them. Within Nhandiroboideae sits one NW clade (15 spp.), and within Cucurbitoideae sit four or five NW clades, namely a subclade of Luffeae (3 spp.), the highly distinct Cucurbiteae (97 spp.; spiny pantoporate pollen) and Sicyeae (126 spp.; polycolporate pollen), and previously unrecognized N American (21 spp.) and S American (52 spp.) subclades of Coniandreae. Eocene to Miocene Laurasian fossils of Cucurbitaceae plus the nesting of NW in OW clades suggest entry of Cucurbitaceae into S America from N America. Most of Jeffrey's tribes are supported by our data, pointing to conserved sets of morphological characters.

P0784. A geographical analysis of the *Caryophyllaceae* family within the flora of Ukraine

M. M. Fedoronchuk;
M.G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv, Ukraine.

According to the geographical spectrum, the family *Caryophyllaceae* within the flora of Ukraine is represented mostly by Ancient-Mediterranean, Steppe-Eurasiatic and Holarctic elements. Within the *Caryophyllaceae*, 81 species (37.8%) belong to the Holarctic type of area, and most of them (43 species or 22.0%) belong to the European class. The Steppe-Eurasiatic type of area is presented by 67 species (31.3%), within which the Pontic group of areas includes 42 species (19.6%), and most of these taxa are comparatively young Steppe ones. The presence of a large number of endemic and subendemic species of the both Steppe-Eurasiatic (Pontic group) and Ancient-Mediterranean (Crimean group) types testifies to the autochtonous origin of the core of the Pontic and Crimean groups. However, there was a considerable influence of the allochtonous elements on the development of the *Caryophyllaceae* within the flora of Ukraine because of a lot of their species having widely areas.

P0785. A geographical analysis of the genus *Linum* L. in Ukraine

O. M. Moroz;
M.G.Kholodny Institute of Botany, National Academy of Sciences of Ukrane, Kiev, Ukraine.

A geographical analysis of the genus *Linum* L. (*Linaceae*) in the Ukrainian natural flora (21 species) is presented. According to the classification of geographical floristic elements (Kleopov, 1990), Ukrainian *Linum* species are represented by 5 types of geographical elements: Submediterranean (10 sp.), Mediterranean (3), European (2), Nomadic (2), Eurasian (1), and 1 transitional type (3 sp.); and 11 geographical elements: East-Submediterranean (4 sp.), Crimean-Caucasian (3), Crimean (2), East-Mediterranean (2), Pontic (2), European-Mediterranean (2), Central European (2), Carpathian-Balkan-Asia Minor (1), Middle European-Submediterranean (1), Mediterranean (1), and European-Asian (1).

There are two centers of species diversity of the genus in Ukraine: Crimea (15 sp., incl. 2 endemic), and southeastern Ukraine (10, incl. 2 endemic). The diversity of the species composition of *Linum* in Ukraine is determined by ecological, geographical and historical factors of their formation.

P0786. Phylogeny and biogeography of *Cardamine* (Brassicaceae), with emphasis on section *Cardaminella*

T. Carlsen, R. Elven, C. Brochmann;
National Centre for Biosystematics, Natual History Museum, University of Oslo, Oslo, Norway.

The genus *Cardamine* (Brassicaceae) is cosmopolitan, but most taxa inhabit boreal, alpine or arctic habitats in the northern hemisphere. The 200-250 species, representing diploids to high polyploids, are divided into 12-15 sections. One section (*Dentaria* L.) has previously been inferred to be polyphyletic based on molecular data, but no whole genus phylogeny is available. Section *Cardaminella* Prantl. is predominantly arctic-alpine and contains about ten species, and has a centre of diversity in Eastern Asia and Western North America. We use nuclear and chloroplast DNA sequences from 80 species of *Cardamine* representing different continents and sections to reconstruct the phylogenetic and biogeographic history of the genus. Of particular interest is to test the monophyly of section *Cardaminella*, and to identify the source area(s) for colonisation of the Arctic for this section.

P0787. A geographical analysis of the *Caryophyllaceae* family within the flora of Ukraine

M. M. Fedoronchuk;
M.G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv, Ukraine.

According to the geographical spectrum, the family *Caryophyllaceae* within the flora of Ukraine is represented mostly by Ancient-Mediterranean, Steppe-Eurasiatic and Holarctic elements. Within the *Caryophyllaceae*, 81 species (37.8%) belong to the Holarctic type of area, and most of them (43 species or 22.0%) belong to the European class. The Steppe-Eurasiatic type of area is presented by 67 species (31.3%), within which the Pontic group of areas includes 42 species (19.6%), and most of these taxa are comparatively young Steppe ones. The presence of a large number of endemic and subendemic species of the both Steppe-Eurasiatic (Pontic group) and Ancient-Mediterranean (Crimean group) types testifies to the autochtonous origin of the core of the Pontic and Crimean groups. However, there was a considerable influence of the allochtonous elements on the development of the *Caryophyllaceae* within the flora of Ukraine because of a lot of their species having widely areas.

P0788. Correlations and differences between local and general ranges of vascular plants and mosses

M. Zajac, A. Zajac;
Intitute of Botany Jagiellonian University, Krakow, Poland.

Local ranges of chosen vascular plants were accepted after Distribution Atlas of vascular plants in Poland (A. Zajac & M. Zajac eds. 2001), the general ranges after existing atlases of Meusel and Hultén schools and collaborators, but for mosses local and general ranges of Atlas of the Geographical Distribution of Mosses in Poland (R. Ochyra & P. Szmeja eds. 1983-1994) were used.

During comparison analyses the universal rules were noticed. The general ranges of mosses are in principle extent and comprise eg. the Holarctic as a whole. Ranges of vascular plants in the most cases are considerably tightened. However local ranges of mosses and vascular plants in the territory of Poland can be classified to the same distributional types. Such a fenomenon is probably connected with the joint history of taxa expansion from the two different groups in period of the late glaciation and the Holocene.

P0789. Phylogeny and biogeography of Balsaminaceae based on chloroplast trnL-F sequences

Y. Song, Y. Yuan, P. Küpfer;
Laboratoire de botanique Evolutive, Institute de Botanique, Neuchatel, Switzerland.

Balsaminaceae are a morphologically diverse family with two genera, Hydrocera (one species) and Impatiens (~ 1000 species), distributing primarily in the highlands and mountains of the Old World tropics and subtropics area. In order to understand further the phylogeny of this family and clarify the biogeographic relationships among the main diversification centres, we obtained chloroplast trnL-F sequences for 138 samples of Balsaminaceae worldwide and one species of its closest relative Marcgraviaceae. Phylogenetic analyses applying Kimura 2-Parameter distance estimates and Neighbor-Joining method confirmed the monophyly of the genus Impatiens. The topology of the trnL-F tree is in principle congruent to that of our earlier ITS tree, both implying that extant Impatiens species are of Southeast Asian origin, from where dispersals to Southeast Asian islands and North America, to central Asia and Eastern Europe via the Himalayas, and to India and Africa have occurred. The Madagascan Impatiens shows an African origin.

P0790. Taxonomic diversity and diversification of Araliaceae in India

A. K. Pandey[1], J. Wen[2];
[1]TM Bhagalpur University, Bhagalpur, India, [2]The Field Museum, Chicago, IL, United States.

In India Araliaceae are represented by 16 genera mostly in N and NE region and a few in South India. They are: *Aralia* (11 spp.), *Arthrophyllum* (1 sp.), *Brassaiopsis* (ca. 10 spp.), *Dendropanax* (1 sp.), *Eleutherococcus* (2 spp.), *Gamblea* (1 sp.), *Hedera* (1 sp.), *Heteropanax* (1 sp.), *Macropanax* (3 spp.), *Merriliopanax* (3 spp.), *Panax* (3 spp.), *Polyscias* (2 spp.), *Schefflera* (ca. 30 spp.), *Tetrapanax* (1 sp.), *Trevesia* (1 sp.), and *Tupidanthus* (1 sp.). The 11 species of *Aralia* belong to three sections. In India, sect. *Aralia* has two species: *A. cachemirica* in Kashmir and *A. tibetana* in Sikkim. Indian sect. *Dimorphanthus* has four species with *A. malabarica* endemic to South India. *Aralia* sect. *Pentapanax* has five species with *A., leschenaultii* disjunct between NE and South India. *Panax assamicus* is similar to *P. wangianus* from West Central China, in their narrow leaflets, elongated rhizomes with short internodes, and fruit color. The ITS data suggest that *P. assamicus* is clearly distinct. Two clades can be recognized within Indian *Brassaiopsis*: (1) *B. aculeata, B. glomerulata, B. hainla, B. mitis, B. shweliensis*, and (2) *B. hispida, B. griffithii,* and *B. simplicifolia*.

P0791. Molecular phylogeny and biogeography of two genera of Northern Hemisphere lamioid mints; *Lamium* L. and *Galeopsis* L. (Lamiaceae)

M. Bendiksby, V. A. Albert;
Botanical Garden, Natural History Museum, Oslo, Norway.

We have examined the phylogeny and biogeography of two Northern hemisphere lamioid genera, *Galeopsis* and *Lamium*, by comparing non-coding chloroplast and nuclear DNA sequences to morphological, cytological and distributional data. The distribution of *Galeopsis* and *Lamium* is temperate Eurasian with centers of diversity in Europe and the Irano-Turanean/Mediterranean region, respectively. An extensive taxon sampling of both genera, including some putative hybrid taxa, was included in this study. Our results indicate that *Galeopsis* is monophyletic, and previously suggested subgroups within *Galeopsis* are supported. *Lamium*, however, is not monophyletic. As currently circumscribed, *Lamium* is paraphyletic with the monotypic genus *Lamiastrum* and the SW-Asian genus *Wiedemannia* as subclades. Furthermore, few of the previously suggested taxonomic subdivisions within *Lamium* are supported. Both genera are prominent in the Fennoscandian flora and appear to have invaded Fennoscandia several times based on our phylogenetic results.

P0792. Species Level Phylogeny and Biogeography of the Dogwood Genus *Cornus* (Cornaceae) Inferred from *matK* and ITS Sequences and AFLP Data

Q. Y. J. Xiang, D. T. Thomas, W. H. Zhang;
North Carolina State University, USA, Raleigh, NC, United States.

Cornus is a horticulturally important genus with approximately 55 species divided among 10 subgenera in four major morphological groups. We employed ITS and *matK* sequences and AFLP data to reconstruct a species level phylogeny of the genus with the goal of clarifying relationships among species. Results from phylogenetic analyses support the monophyly of most subgenera with the exception for Subgen. *Cornus* and Subgen. *Kraniopsis*. Subgenus *Afrocrania* and Subgen. *Sinocornus* are nested within Subgen. *Cornus*. Subgen. *Kraniopsis* is monophyletic if *C. peruviana* is excluded. Within Subgen. *Kraniopsis*, species from North American form a clade separated from species from Eurasia. Relationships within each of these clades are not well resolved by the sequence data but better resolved by AFLP data. A new classification scheme better reflecting the phylogeny will be proposed. Phylogenetic dating employing penalized likelihood and Bayesian methods and dispersal-vicariance analysis including fossil species suggested five intercontinental dispersals between Eurasia and North Aermica via the North Atlantic land bridge from the earliest Tertiary to the Miocene.

P0793. Biogeographic diversification of Altingiaceae in the Northern Hemisphere.

S. M. Ickert-Bond, J. Wen;
The Field Museum, Botany Department, Chicago, IL, United States.

The Altingiaceae are a well-defined group of ca. 15 species that show a classic Asian/ North American disjunct intercontinental biogeographic distribution. To resolve species-level relationships and biogeographic diversification we have generated nuclear sequence data from the *GBSSI* gene, chloroplast data from the *trn*L-*trn*F intergenic spacer, the *rps*16 intron, the *trn*S-G intergenic spacer, and the mitochondrial *nad1*-bc intron. Parsimony and Bayesian analyses resulted in congruent relationships among several lineages. Most notably, (1) *Liquidambar* is paraphyletic; (2) *L. acalycina* and *Altingia gracilipes* constitute a separate Asian tropical to subtropical lineage; (3) *Semiliquidambar* nests within the *L. formosana* lineage; and (4) the eastern North American *L. styraciflua* groups with the western Asian *L. orientalis*, but is highly distinct from other lineages. Our morphological cladistic analysis supports the monophyly of *Liquidambar* with *Altingia* as its sister. The discordance between the morphological and the molecular data sets may be due to different rates of morphological evolution as well as convergence in these taxa.

P0794. Floristic changes on the Kem-Ludy islands (Russian White Sea, 1962-2004)

L. A. Abramova[1], A. B. Shipunov[2];
[1]Moscow State University, Moscow, Russian Federation, [2]Institute of Information Technologies, Moscow, Russian Federation.

The lists of flora of Kem-Ludy archipelago (Russian White Sea, near Arctic Circle) produced in years 1962 and 2001-2004 were investigated by different methods of data analysis. The full species list contains 284 species. 27 islands were studied, four new islands were appeared due to the tectonic events. Main dynamic features of islands and island group's floras and of species areas were clarified. Most important factors are island square and openness (accessibility for winds). The close vicinity with species-rich island does not prevent the species disappearance. The presence of forest, ecotops formed by crowberry (*Empetrum* spp.) and *Sphagnum*-bogs are most stabilizing factors whereas riches of rocks play negative role in the floristic stability. Marine birds are most important biological factor for island flora maintenance. Many of effects depend on shoaling of channels between islands and probably on improvement of local climate.

P0795. Origin of the genus *Allium*: place and time.

N. Friesen;
Botanical Garden, Osnabrueck, Germany.

The genus *Allium* is currently regarded as a member of the Alliaceae, subfamily *Allioideae*. *Allium* is distributed almost exclusively in the northern hemisphere and 88 % of the 780 species are distributed in Eurasia.

Genus *Allium* is subdivided into 13 subgenera. Most of the subgenera show one center of diversity respectively while subgenus *Amerallium* is distributed in all three continents i.e., North America, Europe and Asia. Current molecular studies (ITS and cpDNA) support the monophyletic origin of the genus *Allium* and it is subdivided into two major clades i.e., subgenera Nectaroscordum (x=9), *Amerallium* (x=7) along with monotypic section *Microscordum* (x=8) versus remaining subgenera of genus *Allium* (all x=8). The phylogenetic position of subgenus *Amerallium* as sister to Mediterranean subgenus *Nectaroscordum* and east Asian section *Microscordum* provides evidence for an Old Word (x=7,8,9,10) origin of the genus *Allium*.

One conspicuous feature of the ITS data is the unusually large intrageneric genetic distances within *Allium.* These molecular differences together with the distribution area of *Allium* indicate an origin of the genus early in the Tertiary.

P0796. Spatial structure of a willow hybrid complex in European rivers

K. Van Puyvelde, T. Le, L. Triest;
Vrije Universiteit Brussel, Brussel, Belgium.

The tree forming willow species, *Salix alba* L (white willow), *Salix fragilis* L. (crack willow) and their hybrid *Salix x rubens* are widely distributed tetraploids across Europe in riparian zones and wetlands. 2000 individual willow trees distributed along major rivers or their tributaries across Europe were analysed with codominant introns of consensus gene families and with dominant ISSRs. The co-dominant markers were ideal markers to identify these *Salix* species, their hybrid and the introgressed hybrids. Much of the ISSR variation is kept within populations of *Salix alba*. Significant relationships between the individual *S. alba* phenotypes based on ISSR markers and their position along a N-S and a W-E gradient in the Western plains and Central Highlands ecoregions were found. For *S. fragilis* a significant relationship was found along a W-E gradient in the Western and Central Highlands ecoregions. Introns and ISSRs could give useful information at different geographical levels.

P0797. The pteridophytic diversity in Yunnan, China

S. G. Lu;
Institute of Ecology and Geobotany, Yunnan University, Kunming, China.

This paper deals with the diversity of the pteridophytes of Yunnan, China. Yunnan ranks first among China in its number of pteridophytic taxa. There are 60 families, 198 genera and 1500 species of pteridophytes making up 95.2 percent, 85.7 percent and 57.7 percent of the Chinese totals respectively according to Ching's system. There are also many taxa unique to Yunnan/China, *Phlegmariurus yunnanensis*, *Archangiopteris bipinnata* Ching, *Angiopteris esculenta* Ching, *Angiopteris sparsisora* Ching and *Gymnosphaera austro-yunnanensis* (S. G. Lu) S. G. Lu et C. X. Li are examples. While *Christensenia assamica* (Griff.) Ching and *Platycerium wallichii* Hook. belong to families are only occurrence in Yunnan around China. Yunnan has the richest taxa of pteridophytes in China and this area is one of the richest taxa of pteridophytes in the world. The richest taxa of pteridophytes in Yunnan is a combination of long geological history, complicated geographical environment and sustained biotic evolution. Yunnan's pteridoflora vary from tropical to temperate, in the area exist multiple climate types, it is actually an epitome of Eurasia continent's pteridoflora.

P0798. The chloroplast PCR primer database: tools for comprehensive phylogeographic analysis of a whole genome.

B. Heinze;
Federal Research and Training Centre for Forests, Natural Hazards and Landscape, Vienna, Austria.

A data base is presented which collects published PCR primer information for chloroplast DNA (http://bfw.ac.at/200/1859.html). Chloroplast genes evolve slowly, and many PCR primers have been designed to work across species ('universal primers', Taberlet et al. 1991). Amplicons are either the genes themselves, typically in studies of sequence variation in higher-order phylogeny, or spacers, introns, and intergenic regions in studies of phylogeographic patterns within and among species. The current list of 'generic' primers consists of more than 350 sequences. Our experience shows that many of these primers can be combined into pairs quite freely if 'generic' PCR conditions ('two-step PCR') are applied. With this set of primers it becomes possible to study the whole chloroplast genome for variation in a comprehensive way for many taxa. Efficient methods for analysing polymorphisms are necessary - traditional sequencing may not be an option in large-scale studies. Alternatives are simple PCR-RFLP in gels, or denaturing high-performance liquid chromatography for simultaneous detection and analysis of polymorphisms. Examples will be given.

P0799. Molecular defined migration pathways of rare species of the genera *Lathyrus* and *Oxytropis* (Fabaceae)

M. Schlee[1], G. W. Grimm[1], W. Sauer[2], V. Hemleben[1];
[1]Center of Plant Molecular Biology (ZMBP), Tübingen, Germany,
[2]Special Botany & Mycology, Tübingen, Germany.

Studies of a large nrDNA data set of the cloned and sequenced ITS region and 5' ETS revealed a detailed insight into intraspecific and intraindividual genetic variability of the morphologically and genetically conserved *Oxytropis pilosa* in contrast to *Lathyrus pannonicus* originally sharing the same Eurasian steppe habitat. The evaluation of the molecular data allowed a defined reconstruction of inter- and postglacial migration patterns. During the westward migration of populations of *L. pannonicus* obviously an ecological shift from xerothermic to wet habitats occurred - inferred by phytosociologic classifications. Numerous mutations characteristic for populations within the disjunct relict habitats could be detected; they are linked to habitat preference and support the assumption that the ecological shift is the driving force for biodiversity. The presently unclear classification of some *L. pannonicus* subspecies due to diffuse morphologic characters and ecologically undefined or intermediate habitat use can now be explained by interpreting such populations as relicts of a transition zone and as a result of repeatedly endured (re-) colonisation.

P0800. Phylogeny and phylogeography of myrmecophytic Macaranga species from the Malesian region

G. Bänfer[1], B. Fiala[2], F. R. Blattner[3], D. Guicking[1], K. Weising[1];
[1]Institute of Biology, University of Kassel, Germany, [2]Biozentrum, Zoologie III, University of Würzburg, Germany, [3]IPK, Gatersleben, Germany.

Twenty-nine of the about 300 species of the palaeotropic tree genus Macaranga (Euphorbiaceae) are obligate ant-plants, or myrmecophytes. We used ITS sequencing and AFLP profiling to reconstruct a phylogeny of 37 species from sections Pachystemon, Pruinosae, and Winklerianae, the only sections containing myrmecophytes. Whereas the resolution achieved by the ITS data set is limited, the AFLP trees support the monophyly of sect. Pruinosae and sect. Pachystemon, and also suggest a subdivision of sect. Pachystemon into four well-defined groups. The same set of taxa was screened for polymorphisms within non-coding chloroplast DNA. More than 50 haplotypes were obtained, and subjected to a phylogeographic analysis. Among closely related species, the distribution of haplotypes correlates with geographically circumscribed regions rather than with taxonomic boundaries, suggesting either chloroplast introgression or ancient lineage sorting. Nuclear microsatellites are currently being developed to complement the phylogenetic and phylogeographic data sets by classical population genetic studies on a local scale.

P0801. Phylogenetic relationships and population structure of species of *Hypochaeris* sect. *Seriola* (Asteraceae, Cichorieae) in the western Mediterranean Basin based on AFLP analysis

M. Á. Ortiz[1], K. Tremetsberger[2], S. Talavera[1], T. F. Stuessy[2];
[1]Departamento de Biología Vegetal y Ecología, Facultad de Biología, Sevilla, Spain, [2]Department of Systematic and Evolutionary Botany, Institute of Botany, Vienna, Austria.

The genus *Hypochaeris* L. includes c. 15 species in the Mediterranean Basin. Two of its four sections, sect. *Seriola* and sect. *Hypochaeris*, form a monophyletic group. Sect. *Seriola* ($2n = 12$) is the sister group of sect. *Hypochaeris* ($2n = 8, 10$). Sect. *Seriola* is composed of four species: *Hypochaeris leontodontoides* (endemic to the Middle Atlas, Morocco), *H. rutea* (endemic to the Betic Cordillera, Spain), *H. achyrophorus* (Circummediterranean) and *H. laevigata* = *H. alliatae* (Central and East of the Mediterranean Basin and North West of Africa). Except for *H. achyrophorus*, which is annual, all the other species are perennials. From ITS sequences we know that *H. leontodontoides* is sister to *H. achyrophorus*, *H. rutea* and *H. laevigata*; and *H. achyrophorus* is sister to *H. rutea* and *H. laevigata*. Amplified fragment length polymorphism (AFLP) has been used to resolve relationships among species and populations. These relationships, plus other factors such as geographical distribution, ecology, breeding system, karyotype, and geological history of regions, are used to formulate hypotheses about factors leading to speciation in this group.

P0802. Phylogeography of multiple polyploid lineages in the rare slim-leaf onion (*Allium amplectens*).

E. J. Wheeler;
Department of Biology, University of Victoria, Victoria, BC, Canada.

Polyploidy is an important evolutionary mechanism in flowering plants. Within species, ploidy differences occur both within and among populations, and can occur in closely related lineages, suggesting that polyploid evolution is an ongoing process rather than a rare, macroevolutionary event. The western North American slim-leaf onion (*Allium amplectens*) is found from southwestern British Columbia to southern California. In this species, diploid, triploid and tetraploid plants ($2n = 14, 21, 28$) occur in both mixed and homogeneous populations. DNA sequences in the TrnT-L chloroplast region differ among populations in at least 24 indels and 4 base substitutions. These differences imply two phylogenetically distinct lineages each containing diploids and polyploids, suggesting that polyploids have arisen independently at least twice in this species. Chloroplast haplotype diversity is highest in the Sacramento Valley of California while a small subset of haplotypes occurs in British Columbia, Washington and northern Oregon, where populations are largely triploid and asexual.

P0803. Predicting plant species distributions using altitude and climatic parameters: the case study of African *Ancistrocladus* Wall. (Ancistrocladaceae)

C. E. N. Ewango, **R. E. Gereau**, G. M. Walters;
Missouri Botanical Garden, St. Louis, MO, United States.

We test the methods proposed by Skov and Borchsenius (1997) for African species of *Ancistrocladus* Wall. (Ancistrocladaceae), using elevation, mean annual temperature, and annual precipitation variables combined with the existing locality records for each species. We predict the potential and probable distributions of taxa and generate species richness maps of both potential and probable distributions for all taxa. Using these distributions, we assess the collection effort of the genus at a mesoscale pattern of ecosystem properties: i.e., how well do the existing collections coincide with the species distribution and richness models?

In general, species with a large number of records produced good models. The Gulf of Guinea arc and Gabon, and Sierra Leone to Liberia in Upper Guinea, along with very isolated points in the Congo basin of the Democratic Republic of Congo, are the areas with a high ratio of potential to probable species richness, indicating the areas that are potentially poorly collected, i.e., not well explored. Supplemental fieldwork is needed to find additional areas for the collection and conservation of poorly represented taxa.

P0804. Chloroplast and nuclear phylogeography of two peat mosses in Europe

P. Szövényi, Z. Hock, E. Urmi, J. Schneller;
Institute of Systematic Botany, Zürich, Switzerland.

Phylogeographic structure of *S. palustre* and *S. fimbriatum* has been investigated in Europe using chloroplast (*trnL-L-F*, *rpl16*) and newly developed nuclear (GapC gene) markers. Resolution power of the *rpl16* gene was higher than that of the *trnL-L-F* region. The single copy GapC gene resolved twice as much haplotypes as the chloroplast genes and it seems to be applicable in population level studies.

Both chloroplast and nuclear genes supported the existence of three main strongly differenciated nested clades in Europe: Central-European, North-Europen and a South-European clade. Surprisingly the European clades were more divergent than the North-American and European ones, indicating recent intercontinental dispersal. High divergence among the European clades implicates long lasting past isolation and recolonization at least from three different refugia following the LGM. In the case of *Sphagnum palustre*, chloroplast markers separated a mountain and a lowland clade, which might be also in relation to recolonization or specialization processes. To obtain higher resolution, development of SNP markers as well as AFLP and ISSR analyses are in progress.

P0805. Phylogeographical observations on species complex Ophrys fuciflora inferred from nuclear ribosomal ITS sequences

G. Sramkó[1], G. Gulyás[1], A. V. Molnár[1], S. Rudnóy[2], Z. Illyés[2], Z. Bratek[2];
[1]Department of Botany, Faculty of Sciences, University of Debrecen, Debrecen, Hungary, [2]Department of Plant Physiology, Faculty of Sciences, Eötvös Loránd University, Budapest, Hungary.

In order to clarify the phylogenetic relationship among species from Ophrys fuciflora complex nr ITS region of 19 taxa, representing 44 populations from 13 European and North-African countries, was sequenced. We found that the nrITS types were strongly correlated to geographical regions, while they were totally shared by the species in a discrete area. The geographical pattern of the nrITS types is assumed to relate to the primary glacial refugies in Southern-Europe where the different nrITS types had been separated during last glaciation. Surprisingly overlapping sequences were detected north of the Mediterranean peninsulas in the Carpathian-basin, South-Germany and Eastern-France, which could be separated as different paralogue sequences after cloning the PCR products. The paralogues imply recent hybridization in the abovementioned geographical regions, where the expanding postglacial lineages may have met forming hybrid zones. Since paralogue sequences thought to have rapid merging into the domineering ITS type, the hybrid zones seem to be recent ones on postglacial time-scale.

P0806. Maternal and paternal DNA lineages reveal geographic genetic structuring among the populations of *Rumex acetosa* (Polygonaceae)

H. Korpelainen, K. Kostamo;
University of Helsinki, Helsinki, Finland.

The weed *Rumex acetosa* is one of the few angiosperm species which have sex chromosomes (XX in females and XY_1Y_2 in males). The two Y chromosomes are assumed to be of a common origin, and they are believed to recombine during meiosis. Such a homology brings about individual male plants that may be either homozygous or heterozygous in regard to those areas. The presence of Y chromosomes allows investigations of paternal DNA lineages, while analyses of chloroplast DNA allows examinations of maternal DNA. In this study, DNA sequence polymorphisms present in a 850 bp Y-chromosomal section, representing heterochromatin, and in a 409 bp chloroplast section (trnL-trnF spacer) of *R. acetosa* originating from several European locations were investigated. In the chloroplast area only one substitution and two deletions resulting in four haplotypes were detected while in the Y-chromosomal DNA 179 substitution sites and four deletions/insertions were discovered. Concerning 73% of the substitution sites, heterozygous individuals were found among the sampled males. The pattern of sequence variation detected *R. acetosa* revealed considerable geographic structuring.

P0807. Phylogeography of pantropical sea-drift seed dispersal plants III -- Speciation through sea-drift species: *Canavalia rosea*

Y. Tateishi[1], T. Kajita[2], M. Sousa S.[3];
[1]Department of Science Education, Faculty of Education, University of the Ryukyus, Okinawa, Japan, [2]Dapartment of Biology, Faculty of Science, Chiba University, Chiba, Japan, [3]Instituto de Biologia, Universidad Nacional Autonoma de Mexico, Mexico, Mexico.

The genus *Canavalia* Adans consists of ca. 50 species mostly distributed in tropics and sub-tropics of the world. Four subgenera are known in the genus: subgen. *Cantodonia* and *Wenderothia* are distributed in the New World, *Maunaloa* is endemic to Hawaii, and *Canavalia* has pantropical distribution because of the presence of the pantropical sea-drift seed dispersal plants, *C. rosea*, in the subgenus. To clarify if the present distribution pattern of the genus was caused by the seed dispersal of *C. rosea*, we performed molecular phylogenetic analysis using extensive samples. Phylogenetic tree constructed by ITS sequences of nrDNA showed a clear clade consisting of members of subgen. *Canavalia* and *Maunaloa*. All the Hawaiian endemic species, as well as, some species that have sea-drift seeds were in the same clade together with numbers of samples of *C. rosea* obtained from vast range of its distribution. This result suggests that the Hawaiian endemic subgen. *Maunaloa* was derived from *C. rosea* that migrated to Hawaii by sea-drift dispersal, and loss of sea-drift ability occurred in the speciation process.

P0808. Phylogeography of pantropical sea-drift seed dispersal plants IV --Classification and phylogenetic relationships of *Entada phaseoloides* (Leguminosae; Mimosoideae) and its allies.

N. Wakita[1], T. Kajita[2], T. Ohi-Toma[3], J. Murata[3], Y. Tateishi[4];
[1]Graduate School of Science and Technology, Chiba University, Chiba, Japan, [2]Department of Biology, Faculty of Science, Chiba University, Chiba, Japan, [3]Botanical Gardens, Graduate School of Science, The University of Tokyo, Tokyo, Japan, [4]Department of Science Education, Faculty of Education, University of the Ryukyus, Okinawa, Japan.

Entada phaseoloides is famous for its gigantic sea-drift seeds, which are sometimes washed ashore in coastal regions distantly apart from its original habitat. *E. koshunensis* is an endemic species to Taiwan and very similar to *E. phaseoloides*, and the systematic treatments of these species have been confused. In order to reveal their relationships in detail, we performed molecular and morphological analyses using extensive samples obtained from the Ryukyus, Taiwan, Vietnam, Samoa, Vanuatu, and Australia including samples obtained from the type locality of *E. koshunensis* in Taiwan. Molecular phylogenetic tree using about 3,700bp sequences of cpDNA was clearly separated into two clades. One is composed of samples from Taiwan, the Ryukyus and south Pacific, for which small convex seeds are common characters. The other clade is composed of samples from Vietnam, Taiwan, and two islands of southern Japan, for which large compressed seeds are common. The difference of the two is conspicuous, and the former will be corresponding to *E. phaseoloides*.

P0809. Vascular plants of Ukraine as perfect models for phylogeography

A. S. Mosyakin;
National University Kyiv-Mohyla Academy, Kyiv (Kiev), Ukraine.

The rich and diverse vascular flora of Ukraine contains many relict, endemic and otherwise interesting taxa, which are often subjects of taxonomic, phytogeographical, and paleobotanical controversies. Many of these controversies can be efficiently solved by phylogeographical methods. Phylogeography is currently a booming field, especially in Europe, but Ukrainian plants were barely touched by such studies. The author attempted to identify the most interesting and promising groups of Ukrainian plants suitable for phylogeographical studies in cooperation with European botanists: endemic and relict species, taxa with disjunctive ranges, some trees (e.g., taxonomically complicated *Betula* spp., model taxa of *Quercus*), and other plants crucial for understanding the historical patterns of Ukraine's flora (and the European flora in general) in the Pleistocene and Holocene. Geographically such taxa are concentrated in the Carpathians, Crimea, the Volhynian and Podolian area, and some parts of the steppe and forest zones. Phylogeographical data should be correlated with extensive data of paleopalynological studies accumulated in Ukraine.

P0810. Phylogeography of pantropical sea-drift seed dispersal plants I -- Scope in General and a case of *Ipomoea pes-caprae* (L.) R. Br. (Convolvulaceae)

T. Kajita[1], Y. Tateishi[2];
[1]Department of Biology, Faculty of Science, Chiba University, Chiba, Japan, [2]Department of Science Education, Faculty of Education, University of the Ryukyus, Okinawa, Japan.

"Pantropical Sea-drift Seed Dispersal Plants" have extremely wide distribution area that spread over the littoral areas of tropics of the five continents. This intriguing distribution pattern is thought to be the results of long distance seed dispersal of their sea-drift seeds. To clarify how this unique distribution pattern has achieved, to estimate the levels of migration among populations to maintain the unity of the species over the world, and to reveal the speciation process through these species, extensive field and molecular works have been done for four representative plants: *Ipomoea pes-caprae*, *Hibiscus tiliaceus*, *Entada phaseoloides*, and *Canavalia rosea*. In this presentation, we introduce a general scope of the study of pantropical sea-drift seed dispersal plants, and a case study on *Ipomoea pes-caprae*. CpDNA analysis showed no nucleotide substitutions over 4kb length among samples of I. pes-caprae. On the other hand, considerable amount of genetic variation in an intron of nuclear DFR-B gene. A phylogenetic tree of DFR-B gene of nrDNA suggested clear geographic differentiations.

P0811. Molecular phytogeography of Castanopsis forests in Japan, based on mtDNA variation of weevil insects

K. Aoki[1], M. Kato[2], N. Murakami[3];
[1]Kyoto University, Graduate School of Human and Environmental Studies, Kyoto, Japan, [2]Graduate School of Human and Environmental Studies, Kyoto University, Kyoto, Japan, [3]Department of Botany, Graduate School of Science, Kyoto University, Kyoto, Japan.

In order to elucidate the past distribution and colonization routes of broad-leaved evergreen forests in Japan, we have compared the intraspecific phylogeographical patterns of chloroplast DNA (cpDNA) among 6 plant species growing in *Castanopsis*-dominant forests. However, the molecular evolutionary rate of plant cpDNA is relatively slow at the nucleotide sequence level. In this study, we tried to use intraspecific variation in mitochondrial DNA (mtDNA) of phytophagous insects for the phylogeographic study of host plants. The mtDNA of weevil *Curculio* proved to have a greater amount of intraspecific variation than that of the cpDNA of the plants distributed in the same geographical region. The geographical boundary between the two groups of mtDNA haplotypes found in *C. hilgendorfi* lies in the Chugoku-Shikoku region. This pattern could be consistent with the result based on the intraspecific phylogeographical patterns of cpDNA variation among 6 plant species growing in *Castanopsis*-dominant forests, which suggested the existence of additional impotant refugia from Muroto to the Kii Peninsula along the Pacific coast of Japan during the glacial ages.

P0812. Postglacial chloroplastic phylogeography of the autotetraploid *Biscutella laevigata* L. (Brassicaceae) in the Western Alps

C. Parisod, G. Besnard, N. Galland;
Department of Ecology & Evolution, Lausanne, Switzerland.

Biscutella laevigata is a perennial herbaceous species supposed to have colonized the Alps before the Würm as a diploid (2x) and have thereafter recolonized this area as an autotetraploid (4x). This study points out the putative 2x parent populations of the Western Alps 4x by counting chromosomes and analysing new polymorphic markers on chloroplastic DNA in 60 populations.

Thirty haplotypes were analysed by Median-Joining network to get insights into the evolutionary history of this young polyploid complex.

Most of the 2x populations show well differentiated, rare but fixed, haplotypes and are interpreted as interglacial depauperate relicts. Tetraploids display haplotypes belonging to different lineages located in the northern and the southern parts of the western Alps. The southern 4x are linked to different Italian 2x haplotypes. The northern 4x populations share their haplotypes with a relictual 2x population located in a peripheral refugia and interpreted as the origin of this lineage.

Post-glacial recolonisation of *B. laevigata* is characterised by polytopic autopolyploidy out of refugia and admixture of expending lineages in the central Alps.

P0813. Population history of the *Euphrasia transmorrisonensis* (Orobanchaceae) complex in Taiwan based on isozyme data

M. J. Wu[1], T. C. Huang[2];
[1]National Hualien Teachers College, Hualien, Taiwan Republic of China, [2]National Taiwan University, Taipei, Taiwan Republic of China.

Genetic distribution pattern of populations of *Euphrasia transmorrisonensis* complex in Taiwan has been recently studied. Nested clade analysis based on internal transcribed spacer region of nuclear ribosomal DNA and chloroplast DNA sequences has shown a strong association between genetic data and geographical location. In this study, isozyme data, which served as a non-neutral genetic data, were used for further investigation. Three well resolving polymorphic loci, AAT-1, MDH-5, and SkDH-1, including nine alleles were detected and combined to 14 haplotypes. These haplotypes were reconstructed to a nested cladogram using a majority consensus tree of the 82 most parsimonious ones. The associations of haplotypes and geographical location were then analyzed using GeoDis 2.0 with homozygote individuals (192/ 676 individuals) in 23 populations. The contingency test indicates that haplotypes and geographical location are associated. The restricted gene flow with isolation-by-distance can also be inferred for the population history at the lower clade level.

P0814. Phylogeography of pantropical sea-drift seed dispersal plants II -- Massive introgression in *Hibiscus tiliaceus* and *H. pernambucensis* (Malvaceae)

K. Takayama[1], T. Kajita[2], J. Murata[1], Y. Tateishi[3];
[1]Botanical Gardens, Graduate School of Science, The University of Tokyo, Tokyo, Japan, [2]Department of Biology, Faculty of Science, Chiba University, Chiba, Japan, [3]Department of Science Education, Faculty of Education, University of the Ryukyus, Okinawa, Japan.

To understand how genetic differentiation leading to speciation proceeds in pan-tropic sea-drift seed dispersal plants, we focus on *Hibiscus tiliaceus* and its allied species. *Hibiscus tiliaceus* is one of sea-drift seed dispersal plants widely distributed in the tropics of the Old World. One of its allied species, *H. pernambucensis*, is only in the New World, and the total distribution ranges of the two spread over the earth in tropics. Three other related species, *H. elatus*, *H. glaber*, and *H. hamabo* are distributed in restricted areas. We performed sequencing analyses, PCR-SSCP and PCR-SSP analyses using cpDNA in more than 1000 individuals around the earth. The molecular data demonstrated that *H. tiliaceus* could be the source of speciation for all the allied species, and they had frequent migration by sea-drift seeds among the populations. Furthermore there is obvious genetic subdivision between populations of *H. tiliaceus* and *H. pernambucensis* over the east Pacific Ocean, but in the Atlantic, there is some semblance of genetic homogeneity contrary to their distribution boundary. This might suggested cytoplasmic introgression occurred between the two species.

P0815. Phylogeography of *Hymenaea stigonocarpa* (Leguminosae-Caesalpinioideae): a tropical tree from the Brazilian Cerrado.

A. C. S. Ramos, J. P. Lemos Filho, F. R. Santos, **M. B. Lovato**;
Universidade Federal de Minas Gerais, Belo Horizonte, Brazil.

The polymorphism level and spatial distribution of chloroplast genome variation were investigated in populations of *Hymenaea stigonocarpa* (Leguminosae). *H. stigonocarpa* is a neotropical tree that occurs mainly in the Cerrado (a savanna vegetation), a Brazilian biome classified as hotspot for conservation priorities. Twenty-six different haplotypes of the chloroplast noncoding region between the genes psbC and trnS were identified in seven populations (13º - 21ºS and 41º - 48ºW). Mean haplotypic diversity within populations, total haplotypic diversity and differentiation among populations (d_{ST}) were 0.70, 0.91 and 0.46, respectively. Phylogeographic analyses showed a clear association between the haplotype phylogeny and geographic distribution of populations, revealing distinct groups probably related with vicariance events. A hierarchical analysis of molecular variance corroborated this hypothesis, indicating that most of the variation can be attributed to differences among these groups (57%) and only 5% to differences among populations within groups.

P0816. Discriminant analysis of isozymic data on classification of Brazilian species of *Cryptocarya* (Lauraceae)

P. L. Rodrigues de Moraes;
Institute of Biology, Campinas, Brazil.

This study evaluated isozymic data in combination with morphological criteria for classifying Brazilian species of *Cryptocarya*. Through the analysis of 41 polymorphic isozyme loci, 124 alleles were recorded from 739 adult trees of 35 natural populations of ten species of *Cryptocarya* native to the Atlantic rain forest. Isozyme loci that best discriminated among pre-defined populations of different species were selected by stepwise discriminant analysis. Using a *k*-nearest-neighbour algorithm, the classification of individuals into their respective populations resulted in 92.8% correct classification. Similarly, the quadratic discriminant function generated from the selected loci that best discriminated among pre-defined species, using 2-nearest-neighbours, resulted in a resubstitution of individuals accounting for 94.15% correct classification. Results demonstrated that discriminant analysis of isozymic data can be used for efficient marker-based allocation of individual trees into pre-defined groups of populations and species of *Cryptocarya*, complementing and/or confirming information obtained from classical taxonomic studies.

P0817. Band pattern or allele frequencies in phylogeographic analysis of AFLP data: How much does it matter?

D. Ehrich[1], I. G. Alsos[1], C. Brochmann[1], P. Taberlet[2];
[1]Natural History Museum, Oslo, Norway, [2]Laboratoire d'écologie alpine, UJF, Grenoble, France.

Amplified Fragment Length Polymorphism (AFLP) is a universal and increasingly used method to investigate population structure and phylogeography, especially in genetically little known organisms like many plant species. A drawback of AFLP's is the dominant nature of the data, which prevents a straightforward estimation of allele frequencies. Two approaches are common: statistical analysis is either based on similarities among individual band patterns, or allele frequencies are estimated assuming Hardy-Weinberg equilibrium. The first avoids assumptions which are difficult to check for many plant populations, but the second allows a more powerful and sophisticated data analysis. Here I compare these two approaches in inferring the phylogeography of two arctic-alpine amphi-atlantic flowering plants, whose main distribution area is in Europe: *Arabis alpina* and *Saxifraga stellaris*. The recolonization history of the formerly glaciated regions in northern Europe is inferred and migration rates within and among regions are addressed.

P0818. Mountain flora of Sila (S Italy). Statistics, ecological characteristics and phytogeography

C. Gangale, D. Uzunov;
Museo di Storia Naturale della Calabria ed Orto Botanico, Rende (CS), Italy.

Mountain ecosystems in Mediterranean region, representing “islands” of wild Nature, are object of different scientific studies aiming to describe the patterns of floristic diversity and suggest causes of this pattern; to develop methods for predicting how biodiversity may change; and to discuss the consequences on the ecosystem. Sila Mt., localized in S Italy, represents the northernmost part of Calabrian arc, a siliceous Ercinic complex including S Calabrian and NE Sicilian mountains. Data about mountain floristic complex of Sila, situated is presented. Like Mountain flora is considered the species occurring in beech (*Fagus sylvatica*) and Calabrian pine (*Pinus nigra ssp. calabrica*) vegetation belt reaching altitudinal range (800) 1000 - 2000 (1927) m. For every species are identified: attitude to basic rock, attitude to water regime, life form (after Raunkiaer), vertical distribution (valuated using altitudinal steps of 500 m) and horizontal distribution (geoelement). For the analysis the concept of “concrete” flora is applied and some hypothesis for flora relations and consolidation are evaluated.

P0819. The spatial patterns of the flora in large European cities

B. Jackowiak;
Adam Mickiewicz University, Poznań, Poland.

For more than 25 years, in many European cities, researchers conduct intensive mapping of spontaneously occurring species of vascular plants. Such research was conducted in several capital cities: Berlin, Brussels, London, Rome, Warsaw, Vienna and Zurich, and also in other German (e.g. Bielefeld, Bochum, Duisburg, Münster) and Polish cities (Poznan, Krakow, Lodz). The research has enormous significance from the documentary and practical, as well as cognitive, point of view. On the basis of the analysis of several thousands of range maps, it may be concluded that in the impact zones of large urban centers, specific ranges of plant species and the unique spatial structure of the flora are formed. They present an essential relationship with the forms and intensity of the land use, and in particular, with the structure of built-up areas. Those factors have a considerable impact, among others, on the spatial layout of the species abundance of the flora and the layout of species of a varied geographical-historical origin and various ecologic requirements. Those relationships comprise the special patterns of the flora, presented on the poster.

P0820. The Caryophyllaceae Family in Argentina: an Atlas.

C. R. Volponi;
Facultad de Ciencias Naturales y Museo, La Plata, Argentina.

Caryophyllaceae is present in Argentina with 23 genera and 119 species. The indigenous genera are: *Cardionema* DC. (with 4 species), *Colobanthus* Bartl. (3), *Drymaria* Willd. ex Roem. et Schult. (5), *Philippiella* Speg. (1), *Polycarpaea* Lam. (1), *Pycnophyllopsis* Skottsb. (1) and *Pycnophyllum* Remy (7). Genera introduced present only with 1 species are: *Agrostemma* L., *Dianthus* L., *Holosteum* L., *Petrorhagia* (Ser.) Link, *Saponaria* L., *Scleranthus* L. and *Vaccaria* Medik. Genera present with indigenous and introduced species are: *Arenaria* L. (8), *Cerastium* L. (14), *Herniaria* L. (3), *Paronychia* Mill. (7), *Polycarpon* L. (4), *Sagina* L. (4), *Silene* L. (25), *Spergula* L. (12) and *Stellaria* L. (14). The first part of the Atlas contains a description of each genera, a key of differentiation, a short description of each species and a map with its distribution in Argentina. The second part is bound to illustrations of each species including habit, flower parts (sepals, petals, stamens, gynæceum and fruit), and photographs from seeds and pollen grains obtained with scanning electron microscope.

Acknowledgments: to the C.I.C., Buenos Aires, Argentina, for financial support.

P0821. Geographic patterns of tree taxa in the Brazilian Atlantic Rain Forest

F. R. Martins[1], V. V. Scudeller[1], M. F. Siqueira[2], J. Y. Tamashiro[1];
[1]Campinas State University, Campinas, SP, Brazil, [2]Environment Information Reference Center, Campinas, SP, Brazil.

To investigate how arboreal taxa are distributed in the Brazilian Atlantic Ombrophilous Dense Forest domain we selected 63 surveys and analyzed their occurrence on neighboring phytogeographic formations (“cerrado”, seasonal semideciduous forest, and montane forest). After checking synonyms, we came to 1,498 valid binomials in 465 genera and 104 families. We defined seven possible geographical patterns, and analyzed the presence of each taxon in each survey at the levels of species, genus, and family. No species occurred in more than 33 surveys, and species, genera and families showed a quite similar geographic distribution. No taxon showed disjoint distribution, and most species and genera showed a Southeastern-restricted geographical pattern, thus indicating that the Southeastern coast could act as a diversity center for the whole Atlantic Ombrophilous Dense Forest. Analysing the occurrence of taxa in neighboring formations, we corroborate the concept that the Atlantic Forest (Mata Atlântica) is a very large phytogeographic province south of the Amazon and east of the Andes, which includes forest and non-forest formations.

P0822. Floristic Relationships of Seasonal Forests in Northeastern Brazil

M. R. V. Barbosa[1], M. J. N. Rodal[2];
[1]Federal University of Paraíba, João Pessoa, Brazil, [2]Federal Rural University of Pernambuco, Recife, Brazil.

Northeastern Brazilian seasonal forests were examined to determine if they contain one or more floristic groups and possible correlations between the spatial distribution of abiotic factors and the forest communities were investigated. A TWINSPAN analysis comparing the distribution of genera present in different sites located between the regional climatic extremes - the semi-arid *caatinga* and the moist Atlantic Coastal Forest separated the areas in two groups: Group 1 with up to 8 dry months per year and/or a total annual rainfall >1000 mm, with floristic links with the Atlantic Forests, and Group 2 with more than 8 dry months per year and/or a total annual rainfall <1000 mm. Group 2 is further divided into two clades, one corresponding to the semi-arid core, within the *caatinga* domain, and the other occupying the eroded peaks as well as the western slopes of the Borborema Plateau, where the driest seasonal forests are found. Ours results suggest that the Borborema Plateau functions as a geographic barrier separating the humid and dry floras, and that 1000 mm/year is the upper limit for the present distribution of dry plant formations in northeast Brazil.

P0823. Irano-Turanian endemic plant species of SE Iran

M. Mirtadzadini;
Shahid-Bahonar university, Kerman, Islamic Republic of Iran.

South-east Iran with high plateau and solitary mountains was considered as a part of Irano-Turanian region .The area has an important situation in case of phytobiodiversity.The vegetation of the area is mostly consist of steppic plants and somewhere with scattered shrubs.Although some Irano-Turanian species in this area are common to west Pakistan,Afghanistan and central Iran flora,some of them are endemic.Almost 1/4 of endemic plant species are spesific of SE Iran.Among these plants ,only 6 species belong to *Liliopsida*.*Asteraceae* with 2.9 percent and *Fabaceae* with 1.8 percent have the most species.Some of other families which have endemic species are *Plumbaginaceae,Lamiaceae,Apiaceae,Rosaceae* and *Caryophyllaceae*.Most of endemic species which are spesific of the area belong to genera *Astragalus,Cousinia,Acantholimon,Nepeta,Silene* and *Ferula*.It is noteworthy that most of species of genera *Cousinia*(9 species) and *Acantholimon*(7 species) are spesific of this area.

P0824. Relicts of former cultivations in Central Europe

Z. Celka;
Adam Mickiewicz University, Poznań, Poland.

The flora of each area contains species that are relicts of cultures conducted ages ago. Nowadays, many of them are not used any more, and they are not even connected with arable plants. The group of such species is commonly called the relicts of cultivations. Both foreign (the so-called ergasiolypophytes) and native (the so-called eciolipophytes) arable species for a given flora may be included in this group. Some relicts of cultivations occur only on the sites of former cultures, others - have widely spread in favorable conditions.

The relicts of cultivations may be classified on the basis of the historic periods when they were cultivated, e.g. the relicts of pre-historical or medieval cultivations. Moreover, the names of some groups of relict plants derive from the name of tribes that had brought and cultivated them, e.g. plants from the Slavic times, or from the name of structures, next to them they survived, e.g. “earthworks” plants.

Relicts include former healing plants (among others, Malva alcea), former dyeing plants (Isatis tinctoria), decorative species (e.g. Viola odorata), spices (among others, Allium scorodoprasum).

P0825. Characterization and efficiency of the floristic inventory methods employed in the Madidi National Park, Bolivia

P. M. Jørgensen[1], M. J. Macía[2], A. Araujo-Murakami[1,3], A. Fuentes[1,3], L. Cayola[1,3], R. Seidel[1,3], N. Paniagua[1,4], C. Maldonado[1,4];
[1]Missouri Botanical Garden, P.O.Box 299, St. Louis, MO, United States, [2]Real Jardín Botánico de Madrid, Plaza de Murillo 2, 28014 Madrid, Spain, [3]Herbario Nacional de Bolivia, Correo Central Cajón

Postal 10077, La Paz, Bolivia, [4]Herbarium Jutlandicum, Department of Systematic Botany, University of Aarhus, Building 137, Universitetsparken, Aarhus, Denmark.

We compare effort [number of persons/day × number of days] and efficiency [number of species/effort] in an inventory of the woody plant species in a quantitative floristic inventory of 152 plots of 0.1 ha (all stems >2.5 cm dbh) in 14 sites and 8 plots of 1 ha (all stems ≥ 10 cm dbh) in seven sites in the Madidi National Park, Bolivia. We inventoried mainly tropical rainforests below 1000 m, but also dry and montane forests. As expected, with the plots of 0.1 ha we observed a lower effort (5±1.4) and a higher floristic efficiency (18±3.3) than for the 1 ha plots (25±9.1; 5±1.8). In general, the plots both of 0.1 and 1 ha located below 1000 m elevation have a lower number of stems and a higher number of species than plots above 1000 m. Within the 0.1 ha plots we observed a slightly higher effort (5.4±1.6) and a lower efficiency (13.6±7.0) for plots below 1000 m than above (4.6±1.2; 20.5±4.9). We did not observe significant differences in species richness along the latitudinal gradient.

P0826. A survey about plant association of Miankale peninsula in north of Iran

T. Gholami Terojeni;
Islamic Azad University North Tehran Branch, Tehran, Islamic Republic of Iran.

Abstract: In this research plant associations of Miankale peninsula are presented.Miankale peninsula is situated in beside of Caspian sea(North of Iran).This Area is about 68800 hectares.The altitudeis about 21-26 meters below sea level.
The vegetation of Miankale Reserve was studied ,using thr Braun-Blanquet method. 123 releve in different habitats were recorded.
Phytosociological data were analysed by Correspondence Factorial
Analysis (CFA) and Hierarchical Ascendent Classification (HAC)
Methods.Using the Anaphyto software ,26 associations and 1 subassociation were distinguished.The distribution of associations and subasoociation in this area mainly affected by chemical characters of thr soil,namely Ec,Cl,CO3H Na, Mg, Ca, SO4,in fact the vegetation patterns are affected by this factors .And so a total of 263 species and subspecies taxa were identified based on samples collected in several years in this area.
Keywords:plant associatioc,Anaphyto software,Miankale peninsula.

P0827. A surveyof species diversity in Koshk (South of Iran)

D. Mirzabagheri;
Islamic Azad university,Bam Branch, Bam, Islamic Republic of Iran.

Abstract: The area is located in southwest of Kerman,it has an area about 40000 Hectars. The region is located between 54°,32´-56°,45´ longitude and 28°,38´-28°,50 LatitudeT he lowest part of this region is about 1800 meters and the highest is about 3273 meters above the sea level.The averge rainfall is about 295.5 mm, and the average annual temperature is 15.6 centigrades..In this survey the plant specimens were collected in two years (1382&1383). In Koshk region 200 species belonging to 47 families and 145 genera are recognized. The largest genus is *Astragalus* with 13 species . 28 families have medical values(59% total of families).65 percent of species belong to 8 families of *Asteraceac,Fabaceae,Poacea,Apiaceae,Boraginaceaa,Lamiaceae* and *Liliacea.e* Therophytes with 35.5 percent is the largest life form.And so,12 vegetation types are recognized.The *Artemisia sieberi, Pistacia atlantica* and *Amygdalus scoparia* is the dominant species 2/3 of the area.

P0828. Contributions of Takenoshin Nakai on the Korean and Eastern Asiatic Botany

Y. Chung[1], B. Sun[2], C. Park[3];
[1]Sunchon National University, Sunchon, Republic of Korea, [2]Chonbuk National University, Jeonju, Republic of Korea, [3]Seoul National University, Seoul, Republic of Korea.

Takenoshin Nakai (1882-1952) was one of the most distinguished plant taxonomists in the first half of the 20th century, particularly as the authority on the Korean Flora. His Flora Koreana vol. 1 and 2 were published in 1909 and 1911 respectively. His monographic study of Korean woody plants, Flora Sylvatica Koreana in 22 volumes (1915-1939), included detailed descriptions of 1839 pages and 569 accurate plates, and can be regarded as one of the most important early contributions to the Korean and eastern Asiatic flora. Life-long work of 37 years on vascular plants indigenous to Korea was summarized in his last paper, Synoptical Sketch of Korean Flora, in which 3176 species, 841 varieties and 174 formas, (4191 kinds) of vascular plants comprising 110 orders, 226 families and 968 genera were enumerated. During the period from 1907 to 1953 he had written over 600 botanical papers, and more than 300 were on the Korean flora; he also proposed more than 4000 new names. He also compiled Notulae ad plantas Japoniae et Koreae (1911-1935), Notulae ad plantas Asiae Orientalis (1937-1950), Iconographia plantarum Asiae orientalis (1935-1952) and Nova flora Japonica (1938-1951)

P0828a. Biogeography of the Afrotemperate Regions

B. Gehrke, H. Linder;
Institut for Systematic Botany, Zurich, Switzerland.

The temperate - upper montane to alpine - floras of tropical and southern Africa contain several floral elements. Recent research has shown that those elements (e.g. *Pentaschistis, Disa, Protea*) derived from the southern Cape flora most likely migrated northwards at an as yet undetermined time, and in several instances have radiated in the Eastern Highlands. Many elements are derived from the northern temperate areas, Europe and Asia. These include, for example, *Ranunculus, Alchemilla, Carex* and *Carduus*. These groups all include several African species, although the greatest diversity is found in Eurasia. Many other northern genera are represented in Africa by solitary species, such as *Rosa abyssinica* or *Primula sinensis*. We will address questions of origen and diversification of the more speciose Eurasian Afrotemperate floral elements by a phylogenetic and biogeographical analysis of selected taxa, and will attempt to establish how often they reached Africa, and approximately when.

P0829. Phylogeography of *Pulsatilla vernalis* in Europe based on chloroplast DNA analysis

M. Ronikier[1], J. Fuertes Aguilar[2], A. Costa[2], P. Küpfer[3], G. Nieto Feliner[2];
[1]Institute of Botany, Polish Academy of Sciences, Kraków, Poland, [2]Real Jardín Botánico, CSIC, Madrid, Spain, [3]Laboratoire de botanique évolutive, Université de Neuchâtel, Neuchâtel, Switzerland.

Pulsatilla vernalis is an European endemic with a particular geographic distribution pattern referred to as «*Pulsatilla vernalis* type» and encompassing two ecologically distinct parts: isolated areas of European mountains' alpine and subnival zones (Alps, Pyrenees, Carpathians, Balkans and mountains of southern Norway) on the one hand and the lowlands of central Europe and southern Scandinavia on the other hand (but without expanding farther north into the boreal zone). In the phylogeographic analysis covering the whole distribution area of *P. vernalis*, direct sequencing and PCR-RFLP approaches were used to study 3 and 7 cpDNA regions respectively. 27 polymorphic sites (both length polymorphisms and nucleotide substitutions) were detected and analysed in 55 populations across Europe to assess the distribution of cpDNA haplotypes. Two main genetic lineages emerge, dominating the geographical structure of the variability and unravelling the history of post-glacial colonisation in Central and Northern Europe. A comparison of sequencing and RFLP approaches in studying phylogeographical patterns is also discussed.

P0830. Phylogeography of Japanese alpine plants

N. Fujii, K. Senni, T. Sugawara, M. Wakabayashi;
Makino Herbarium, Graduate School of Science, Tokyo Metropolitan University, Hachiouji, Tokyo, Japan.

In the high mountains of the Japanese Islands in easternmost Asia, a relatively rich alpine flora is found (ca. 500 species). The populations of each species show a disjunct distribution in these areas. In order to clarify the evolutionary history of the alpine flora of Japan, we conducted phylogeographic studies using the molecular maker of chloroplast DNA (cpDNA). Through analyses using 25 species of Japanese alpine plants, intraspecific cpDNA variations were detected in most species. Additionally, phylogenetic analyses among the populations of each species indicate an endemic clade of eleven species (Anemone narcissiflora, Arnica unalaschcensis, Cardamine nipponica, Carex hakkodensis, C. stenantha, Diapensia lapponica, Loiseleuria procumbens, Pedicularis yezoensis, Pedicularis chamissonis, Primula cuneifolia, Tilingia ajanensis, etc.) in the central part of

Honshu Island, Japan. From the point of view of vicariance biogeography, such similar genetic structures are explained by certain common factors. Our results suggest that the alpine region of central Honshu has served as a refugia for Japanese alpine plants during the Pleistocene period.

P0831. Differentiation and migration in the arctic-alpine diploid *Dryas octopetala* L. (Rosaceae)

I. Skrede[1], P. Bronken Eidesen[1], R. Piñeiro Portela[2], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway, [2]Real Jardín Botánico de Madrid, Madrid, Spain.

Dryas octopetala s. lat. comprises long-lived, wind-dispersed, diploid shrubs that are ecologically important in arctic and alpine areas. Here we address differentiation and migration history of the species with emphasis on the Eurasian part of its distribution area, also including some Beringian and Greenlandic populations (partly referred to as the closely related *D. integrifolia* M. Vahl). We analyzed 459 plants from 52 populations for 155 AFLP markers. Three major groups were identified. The Eurasian plants were separated into two groups, both quite distinct from the third Beringian/Greenlandic group. The Eurasian groups probably reflect isolation and expansion from two major glacial refugia. Northwestern Europe including Scotland, Iceland, and Scandinavia appear to have been colonized by a central/southern European lineage, whereas the arctic archipelago of Svalbard appears to have been colonized from the east by a northern Russian lineage occurring in the Ural Mountains and eastwards to the Taymyr area. The single populations analyzed from the Caucasus and Altai Mountains were divergent from the remaining Eurasian populations.

P0832. Do life-history characteristics determine phylogeographic patterns?

C. Thiel-Egenter[1], R. Holderegger[1], P. Linder[2], F. Gugerli[1];
[1]WSL, Birmensdorf, Switzerland, [2]Institute for Systematic Botany, Zürich, Switzerland.

The alpine plants Geum reptans and G. montanum differ considerably in range size, altitudinal range, habitat, successional status and mode of reproduction. Therefore, one would expect that the two species reacted differently to Quaternary climate oscillations. Owing to its high-alpine distribution on rocks and virgin soils, G. reptans is considered capable of in situ glacial survival, having resulted in genetic patterns related to nunatak areas. As G. montanum grows in late successional grasslands of lower altitude, it assumably lacked suitable habitats inside the glaciated area or at the upper level of the former ice-sheet. Therefore this species is supposed to have survived in peripheral refugia and have re-immigrated during postglacial times. Within the scope of the EU project INTRABIODIV, we compare the distributions of genetic diversity (AFLPs) of G. reptans and G. montanum sampled in 141 and 60 populations. Due to the regular sampling over the entire Alpine and Carpathian ranges of the two species, we expect to find patterns of genetic diversity that are either clumped (nunatak-related) or gradual (induced by re-immigration from peripheral refugia).

P0833. Phylogenetic analysis of species radiations using split decomposition

D. C. Havell[1,2], K. McBreen[3], R. C. Winkworth[4], D. Bryant[5], M. Piripi[6], R. Carter[6], P. J. Lockhart[7], V. Moulton[8];
[1]UCOL, Palmerston North, New Zealand, [2]Alan Wilson Centre For Molecular Ecology and Evolution, Palmerston North, New Zealand, [3]Alan Wilson Centre for Molecular Ecology and Evolution,Massey University, Palmerston North, New Zealand, [4]Dept of Ecology and Evolutionary Biology, Yale University, New Haven, CT, United States, [5]Dept of Mathematics,Mc Gill University, Montreal, PQ, Canada, [6]Alan Wilson Centre for Molecular Ecology and Evolution, Massey University, Palmerston North, New Zealand, [7]Alan Wilson Centre for Molecular Ecology and Evolution. Massey University, Palmerston North, New Zealand, [8]The Linnaeus Centre for Bioinformatics, University of Uppsala, Uppsala, Sweden.

Where plant species radiations are characterized by hybridization or

polyploidy, complex patterns of phylogenetic relationship are expected, and bifurcating tree methods are often inadequate.

In this situation, network methods may have some potential for describing patterns of diversification.

One network method useful for investigating phylogenetic incongruence is split decomposition. However, in its standard implementation this approach is limited by a conservative criterion for branch length estimation. For this reason, we have introduced a least squares optimization technique for correcting branch lengths that may otherwise be underestimated in the standard implementation of split decomposition.

We report improved divergence time estimates for splits graphs, and demonstrate the application of split decomposition analyses in the phylogeography of New Zealand alpine Ranunculus.

P0834. Evolutionary lineages and species delimitation in the *Saxifraga rivularis* complex

M. H. Jørgensen, R. Elven, B. Stedje, C. Brochmann;
National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway.

In many arctic-alpine plant groups, reticulate histories combined with extensive range shifts have resulted in problems with species delimitation and phylogeny reconstruction. In the *Saxifraga rivularis* complex, the number of species recognized ranges from a single polymorphic one (*S. rivularis* s.l.) to several (e.g., the circumpolar *S. hyperborea*, the amphi-Atlantic *S. rivularis* and the three amphi-Pacific taxa *S. bracteata*, *S. flexuosa* and *S. arctolitoralis*). Two main chromosome numbers (2n = 26, 52) are known. We used molecular (AFLPs), flow cytometric and morphological data from most of the range to delimit taxonomic species and to assess their relationships. Three distinct lineages were identified based on the AFLP data (*S. bracteata*, *S. flexuosa*/*hyperborea*, *S. arctolitoralis*/*rivularis*); these lineages also differed in DNA ratios and in a combination of morphological characters. The DNA ratio data as well as the intermediate position of the *S. arctolitoralis/rivularis* lineage in analyses of the morphometric and molecular data suggest that it originated as an allopolyploid from the other two lineages, most likely in Beringia.

P0835. The geographical distribution of genetic variation in the toxic pasture weed *Veratrum album* in relation to its colonisation history

U. A. Treier, H. Müller-Schärer;
University of Fribourg, Department of Biology, Ecology & Evolution, 1700 Fribourg, Switzerland.

We quantified the genetic structure of *Veratrum album* populations along a transect from the Ural and Caucasus mountains to the specie's western distribution border in Portugal, using AFLP markers.

We found a highly significant correlation between the genetic and geographic distances among populations (R^2 = 0.55). Phylogenetic clustering and principal coordinate analysis reveal an east-west orientation in the genetic pattern and thus, provide little evidence for the importance of expected glacial refugial areas in Europe, such as the Balkan-Carpathians and the South-Western Alps.

Population differentiation is significant but moderate (F_{ST} = 0.13). The pattern of genetic diversity seems mostly to be shaped by local habitat conditions, such as population density (positive correlation) and soil phosphorous (negative correlation).

Although pollen records document the presence of *V. album* in Europe already in the late-glacial period, our results show that the genetic structure of today's populations in Europe are mostly shaped by post-glacial re-colonisation from East-European refugia or Asia.

P0836. *Saxifraga callosa* Sm.: a complex taxon resolved by a combination of morphological and molecular approaches

F. Grassi[1], M. Labra[2], L. Minuto[3], G. Casazza[3], F. Sala[1];
[1]Botanical Garden of Milan, Department of Biology, Milano, Italy, [2]Department of Environmental Sciences, University of Milano-Bicocca, Milano, Italy, [3]DIP.TE.RIS, University of Genova, Milano, Italy.

Saxifraga callosa Sm. is an evergreen perennial species distributed from Eastern Spain, through the Western Alps and the Apennines, to Southern Italy. Morphological variation among its subspecific entities and other related species (subsp. *callosa*, subsp *catalunica* (Boiss.) D.A.Webb, var. *australis* (Moric.) D.A.Webb and *S. lantoscana* Boiss.) suggests that phenotypic characteristics are not sufficient to produce a reasonable taxonomy. Preliminary study, using ITS, AFLP and cpDNA markers, allowed a reconstruction of the genomic relationships within *S. callosa* subtaxa and related species. However, ITS analysis gave no conclusive results to assess the phylogenetic position of them, possibly due to the recent evolution of this Alpine taxon. The application of the NewHybrids software to AFLP data-sets suggested that *S. lantoscana* derived from hybridization events between *S. callosa* subsp. *callosa* and *S. cochlearis* Reichenb., living toghether in Maritime Alps. Introgression of genetic traits was confirmed by cpDNA markers, a simple and quick method based on length variation in cpDNA sequences.

P0837. Tracking the origin and evolution of high polyploids in *Cerastium* (Caryophyllaceae) from non-coding regions of the RNA polymerase genes

A. K. Brysting[1,2], B. Oxelman[3], A. Scheen[1], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museum, Oslo, Norway, [2]Department of Biology, University of Oslo, Oslo, Norway, [3]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden.

The Arctic is one of the most polyploid-rich areas, in particular of high-level and recently evolved polyploids. The *Cerastium alpinum* group is a mature polyploid complex, with high ploidal levels dominating and no diploid progenitors known. Previous studies on morphology, isozymes, and DNA fingerprints have identified several evolutionary lineages, and the low level of cpDNA variation observed suggests recent origins and recurrent episodes of range expansions and contractions during the Quaternary glaciations. Non-coding regions of the RNA polymerase genes are now being used to identify progenitor lineages. Results from RPB2 suggest that only one functional paralogue exists in tetraploid *Cerastium* taxa. Arctic high-polyploid taxa appear to have European origins, with the tetraploid *C. semidecandrum* representing the maternal lineage and tetraploid taxa from the central and south-eastern European mountains representing different paternal lineages. However, the patterns of reticulate evolution are complicated and other putatively independent nuclear regions are needed to conclude on the origin of several individual taxa.

P0838. AFROALP - Phylogeography, glacial refugia, and conservation of the unique afroalpine ecosystem: a new project

M. Kebede[1,2], A. Assefa[1,2], P. Taberlet[3], C. Brochmann[2], S. Nemomissa[1];
[1]Department of Biology, Addis Ababa University, PO Box 3434, Addis Ababa, Ethiopia, [2]National Centre for Biosystematics, Natural History Museum, University of Oslo, PO Box 1172 Blindern, NO-0318, Oslo, Norway, [3]Laboratoire d'Ecologie Alpine, CNRS UMR 5553, Universite Joseph Fourier, BP 53, F-38041 Grenoble Cedex 09, France.

The unique afroalpine environment occurs in the scattered high mountains of tropical Africa like islands in a sea of lowlands. The afroalpine plants have their closest relatives not in the surrounding lowlands but in remote areas, even in the northern hemisphere. Where did their ancestors come from, how, and when? In the main part of this new project, we investigate the phylogeographic history and population genetics of 6-8 afroalpine ecological key species without obvious mechanisms for long-distance dispersal. Three populations per species have been collected in the 12 highest mountain systems of East Africa and Ethiopia, as well as from other areas. Using AFLP fingerprinting, sequencing of chloroplast DNA, phylogeographic analyses, and assignment statistics, we will determine migration rates among mountain systems, the number and location of glacial refugia, possible secondary contacts between differentiated glacial gene pools, and infraspecific diversity hotspots. In other subprojects, we address the deeper history of some afroalpine plant groups including speciation, phylogeny, and biogeography.

P0839. Phylogeography of Arabis alpina: What do populations from the distribution edges tell us about its evolutionary history?

M. Koch[1], **C. Kiefer**[1], J. Vogel[2];
[1]Heidelberg Insitute of Plant Sciences, Heidelberg, Germany, [2]National History Museum, London, United Kingdom.

Arabis alpina is widely distributed in northern hemispheric alpine habitats and the arctic regions. Its distribution range spans an area from Central Asia to E Africa, from the Canary Islands and N Africa to Iceland and Scandinavia. We analysed 200 accessions from the whole distribution range using DNA sequence data of the nuclear ITS and the plastidic trnL-trnF region. Both data sets are mostly in congruence with each other and favour the recognition of two major lineages:

1) Central Asia, Arabian Peninsula, East African hight mountains
2) All remaining areas.

DNA sequence commparisons of some selected alleles of the chalcone synthase and Ks-derived distance analysis revealed that both lineages have been separated since approximately 500.000 my. Consequently, Arabis alpina is not a tertiary relict in the East African mountains or the Canary Islands as hypothesized in the past, but has been greatly influenced by pleistocenic glaciation and deglaciation cycles. However, continously distributed genetic diversity in its southern distribution area indicates fragmentation processes rather than migration.

P0840. Plant evolution on the small islands of the Russian White Sea

A. V. Serebryanaya[1], E. P. Altshuler[2], O. O. Kudina[1], M. S. Levina[1], A. B. Shipunov[3];
[1]Moscow South-West High School, Moscow, Russian Federation, [2]Moscow State University, Moscow, Russian Federation, [3]Institute of Information Technologies, Moscow, Russian Federation.

Small islands and islets in the Kandalaksha Bay of the Russian White Sea are now rising. Thus, new islands are continuously appearing, these islands are settling from scratch and it is relatively easy to estimate the age of an island. We tried to find plant species that are polymorphic enough to show the differences between the mainland and island populations and the populations from the different islands. These differences could be the result of population bottleneck or even the evolutionary process on the isolated islands. Species of *Carex* (*C. salina* and *C. aquatilis* groups), *Euphrasia*, *Achillea*, *Rhodiola*, *Atriplex* and *Parnassia* were chosen for preliminary morphological analysis (~ 2200 plants were measured). In addition, geometric morphometrics methods were used for *Rhodiola* and *Atriplex* leaf shapes. We found that at least three groups show significant differences between mainland and insular populations. Some of our results are useful for the adjustment of the taxonomic boundaries in several taxonomically ``critical" groups.

P0841. Biodiversity of alpine flora of Iran

J. Noroozi, H. Akhani;
University of Tehran, Tehran, Islamic Republic of Iran.

Except the interior deserts and lowlands along the Caspian Sea, Persian Gulf, c. half of Iran composed of high mountains. The Alborz along the Northern, Zagros along the Western parts of Iran and several other mountains in Khorassan and Baluchestan provide diverse mountainous ecosystems. The flora and vegetation of Iranian alpine zones are not well known. A first evaluation of vascular flora show that 675 species belonging to 205 genera and 40 families are known in alpine zones (mostly above 3000m) of Iran. Asteraceae with 119 species ranks first, followed by Fabaceae (74), Poaceae (57), Caryophylaceae (54), Labiatae (48), Apiaceae (38), Brassicaceae (34) and Rosaceae with 32 species, respectively. *Astragalus* with 41, *Cousinia* with 20, *Nepeta* with 19, *Silene* with 18, *Oxytropis* and *Potentilla* each with 16 species are the largest alpine genera in Iran. The hemicryptophytic life form dominates in alpine zone with 73 % in Iran. The thorny cushion species are mostly dominate in the subalpine-zone. In spite of their dominancy in the alpine zone their absolute number of species with 41 species is not very high. The alpine flora of Iran consisted of 53% endemics and subendemics.

P0842. Historical and contemporary processes of *Gentiana ligustica*: toward evolutionary conservation at a regional hotspot scale.

K. Diadema[1,2], F. Bretagnolle[3], L. Affre[1], F. Medail[1];
[1]IMEP, Aix en Provence cedex 04, France, [2]Conservatoire Botanique National Méditerranéen, Hyères cedex, France, [3]INRA, UMR 1210, Dijon, France.

Gentiana ligustica is a submountain neoendemic species located in the Maritime and Ligurian regional hotspot (France and Italy). A phylogeographic analysis was performed using AFLPs in 270 individuals and 28 populations. A spatial genetic structure appears in congruence with the location of the five presumed glacial microrefugia distributed along valleys. High mountains on either side of valleys correspond to contact areas between groups and constitute the major barriers to gene flows. Among the five groups of populations identified, the central group exhibit the highest Shannon diversity. The high levels of AFLP variation observed among populations and among groups, together with the lower level of variation within groups suggest (i) a long term population insularization and (ii) the recent gene flow events over short distance. Phylogenetic analyses in relation to history and habitat diversity suggest that several populations acted as refugia during Pleistocene glaciations but did not contribute to the recolonization. These results could help to define adequate phylogeographical units and evolutionary significant units (ESUs) within this hotspot.

P0843. Phylogenetic studies in *Codium* (Chlorophyta). A molecular approach to mexican species

F. F. Pedroche[1,2], P. C. Silva[2], M. Chacana[2];
[1]Depto. Hidrobiología, Apdo. Postal 55-535, UAM-Iztapalapa, Mexico, D.F., Mexico, [2]University Herbarium 1001 VLSB 2465, UC-Berkeley, Berkeley, CA, United States.

Molecular phylogenetic studies in the marine green alga *Codium,* have been done with specimens from Pacific, Atlantic and Caribbean Mexico. Using information from mithocondrial LSU rDNA, we recovered clades that could correspond to 12 of the 16 nomenclatural species previously recorded in Pacific Mexico. These species are: *Codium fragile*, *C. amplivesciculatum*, *C. hubbsii*, *C. schmiederi*, *C. picturatum*, *C. brandegeei*, *C. simulans*, *C. latum* ssp. *palmerii*, *C. isabelae*, *C. giraffa*, *C. dawsonii*, and *C. setchellii*. In the other hand, topologies from Atlantic and Caribbean specimens showed only 5 clades that we recognized as species: *Codium isthmocladum, C. taylorii, C. simplex, C. intertextum*, and *C. decorticatum*. We also combined all data in a single matrix trying to recover Pacific and Atlantic history in this genus; parsimony and likelihood analysis resulted in similar topologies showing a complex relatiosnhips where Pacific and Atlantic clades are not monophyletic.

P0844. Classical or molecular systematics in algal taxonomy? Molecular systematic and morphological investigation of the Lemaneaceae (Rhodophyta, Batrachospermales)

P. Kucera[1], P. Marvan[2], T. Kerstan[3], W. Gross[3], P. Bures[1];
[1]Department of Botany, Masaryk University Brno, KotláŚká 2, 61137 Brno, Czech Republic, Brno, Czech Republic, [2]Academy of Sciences of the Czech Republic, Institute of Botany, KvŊtná 8, 603 65 Brno, Czech Republic, Brno, Czech Republic, [3]Institut für Biologie, Freie Universität Berlin, Königin-Luise-Strasse 12-16a, 14195 Berlin, Germany, Berlin, Germany.

All freshwater representatives of red algae with uniaxial cartilagineous and pseudoparenchymatous thalli are included in the broad genus *Lemanea.* Two subgenera of this genus were distinguished, *Lemanea* and *Paralemanea*. The recently proposed elevation of these subgenera to the generic level seems to be fully justified. The 18S rDNA (SSU) sequences from 10 populations of *Lemanea* and *Paralemanea* species in the Czech Republic were used to construct phylogenetic hypotheses. Our molecular systematic features correspond with classical morphological features and validate the separation of the two genera.

However, the increasing data from natural populations show that not all the traditional diacritical features are reliable for distinguishing species. Of the four species *Lemanea fluviatilis* and *L. torulosa* appear to be well-defined, but there are no clear differences between *Paralemanea annulata* and *P. catenata*. Our investigation found no differences between *P. catenata* and *P. annulata*. On the other hand, *Lemanea fluviatilis* and *L. torulosa* appear to be morphologically well-defined species, but our results do not support this interpretation.

P0845. Green Algae From Crytogamic Crusts, Santa Fe, New Mexico

S. L. Wallace, A. Peterson, J. Santiago, M. Tourjee, P. Mosto, G. B. Hecht;
Rowan University, Glassboro, NJ, United States.

Cryptogamic crusts are common in desert and arid regions of the western United States. Green algae from 10 cryptogamic crusts from Santa Fe, New Mexico were isolated. The algae were grown in liquid media, and transferred to agar plates for isolation and identification. Monocultures were transferred back to liquid for DNA analysis. Genomic DNA preparation protocols have been developed by modifying Qiagen Dneasy Plant DNA Isolation Mini Kit protocols. Preparation of optimal DNA samples for sequencing and species comparison is underway. Morphological identifications will be corroborated with the DNA findings. To date, 12 isolates were found and identified to genus and 2 to species. Further isolation and identification will be carried out for the next two years. Furthermore, cryptogamic crusts collected from the New Jersey Pine Barrens will be isolated, identified, and compared with the Santa Fe crusts' algae. Green desert algae are phylogenetically diverse, and comparison between different arid sites will allow for determination of the relationship among these green algae and their linkage to vascular plants.

P0846. A Taxonomic Study of *Hafniomonas* (Chlorophyceae) Based on Comparative Examination of Cultured Material.

T. Nakada, H. Nozaki;
Department of Biological Sciences, Graduate School of Science, University of Tokyo, Tokyo, Japan.

Hafniomonas is a unicellular green algal genus inhabiting freshwater. This genus is characterized by its quadriflagellated cell without cell wall/scales. Some studies of its flagellar apparatus and chloroplast multigene phylogeny indicated that this genus is one of the basal lineages of Chlorophyceae. However, electron microscopy and molecular phylogeny of cultured material has been examined in only two of eleven species, *H. reticulata* and *H. montana*. No comparative studies of multiple strains of *Hafniomonas* has been carried out.

We isolated *Hafniomonas* from six localities in Japan and compared them with two available culture strains of *H. montana*. These strains were classified into four species, *H. montana*, *H. reticulata* var. *conica*, *H. radiata* and an undescribed species, based on differences in cell shape, surface appearance of chloroplast, number of contractile vacuoles, ultrastructure of pyrenoid, stigma and muciferous vacuoles. Molecular phylogenies of both nuclear-encoded 18S rDNA and chloroplast-encoded *psa*B supported the present species classification.

P0847. *Chlainomonas* and the chlorophyte radiation

P. M. Novis;
Manaaki Whenua - Landcare Research, Lincoln, New Zealand.

Chlorophyta and Streptophyta comprise most of the modern green plants. Chlorophytes are thought to contain three major lineages: the Ulvophyceae, Trebouxiophyceae, and Chlorophyceae. Their common ancestor was probably a quadriflagellate unicell, possibly with a scaly covering. This is inferred from the structure of prasinophyceans, the earliest divergent chlorophytes.

Recent molecular work supports a basal status for quadriflagellate taxa in the Chlorophyceae. However, few quadriflagellate taxa have yet been sampled. I add to this effort with a study of *Chlainomonas kolii*, an enigmatic quadriflagellate found in snow.

The four flagella of *Chlainomonas* and its highly unusual cytokinesis and cell covering suggest that it is a particularly early divergent chlorophycean.

Results show that *Chlainomonas* does not group with the quadriflagellates previously sequenced, but is basal in a clade including other snow taxa. Furthermore, use of *Nephroselmis* and *Chlorella* as outgroup taxa indicates that quadriflagellate relationships may be rather complex, but may be more congruent than previously thought with their variety of flagella apparatus structures.

P0848. Analysis of reproductive isolation mechanism in *Closterium*

Y. Tsuchikane[1], M. Ito[1], H. Sekimoto[2];
[1]Department of General Systems Studies, Graduate School of Art and Sciences, University of Tokyo, Tokyo, Japan, [2]Department of Life Sciences, Graduate School of Art and Sciences, University of Tokyo, Tokyo, Japan.

Closterium peracerosum-strigosum-littorale complex (*C. pslc*) is a unicellular charophycean alga. Progress of the sexual reproduction is strictly regulated by sex pheromones (PR-IP and PR-IP inducer). It was suggested that PR-IP inducer was a multi-functional pheromone, having at least three activities (stimulation of mucilage secretion, induction of sexual cell division, and induction of production of PR-IP). On the other hand, sexually isolated mating groups was known to be present in *C. pslc*, however, molecular phylogenetic relationship or variations of pheromone-encoding genes among groups had not been examined. We obtained sequences of putative orthologous genes encoding PR-IP inducer as well as the 1506 group I intron, which interruptted nuclear SSU rDNA, from each mating group. Based on the results, we will discuss phylogenetic relationships and mechanisms of reproductive isolation among these mating groups in *C. pslc*.

P0849. Additional diagnostic features of some cultured *Euastrum* species (Algae - Desmidiaceae) revealed by SEM

M. F. Santos, J. D. Santos Dias, A. M. Dinis;
Department of Botany (Laboratory of Electron Microscopy) and Institute for the Environment and Life, Coimbra, Portugal.

Identification of *Euastrum* species is based mainly on light microscopic (LM) observations of characters such as the contour and size of the cell and the cell wall sculpturing. However, these characters are often insufficient to solve some taxonomic problems, especially when the cell has a small size and the referred characters are similar in specimens belonging to different taxa. In these cases the cell wall sculpturing observed with the scanning electron microscope (SEM) has provided additional diagnostic characters for the distinction of LM hardly distinguishable and frequently confused taxa. In this report the characteristics of 4 species of *Euastrum* cultured at ACOI (http://www.uc.pt/botanica/ACOI.htm) were examined under the LM and SEM. The LM examination showed that the cell wall is smooth in all of the taxa studied and that, in a few taxa, both the form and size of the cell are quite similar. Under the SEM however, the cell wall showed the presence of various sculptural elements (scrobicles, creases, pores) whose number, form and distribution are quite variable among the different taxa studied but are constant in all of the strains belonging to the same taxon.

P0850. Symbiotic organisms are stored in the diaspores

O. V. Yakovleva;
Komarov Botanical Institute RAS, St.-Petersburg, Russian Federation.

Many species of higher plants develop symbiotic interactions with microorganisms (bacteria, algae, fungi). It is assumed that the inoculation takes place in the soil while germinating. With the help of TEM microorganisms are found in diaspores of 19 species belonging to 10 families. Microorganisms are found in such plants developing mycorthiza as Larix, Betula, Alnus, Festuca. In each single case microorganisms were in one of pericarp or testa tissues, or endosperm, but not in the embryo. Microorganisms are often attached to cell walls at the intercellular space side. For example in the species of Alcea genera microorganisms in inactive form are found in exotesta cells and in intercelular spaces of pigment layer in dry seeds. In four days old seedlings live microorganisms are found on the root surfaces. In two month old seedlings microorganisms are found on the surface and within epidermal cells of the roots, just under hypocotyls. The data obtained let us suppose that microorganisms penetrating into the seeds are stored there to play active role in germination and further plant development. The revealed phenomenon we consider to be progressive.

P0851. Diversity of arbuscular mycorrhizal fungi in the Brazilian semiarid.

L. C. Maia, A. M. Yano-Melo, B. T. Goto;
Universidade Federal de Pernambuco, Recife, Brazil.

The species of arbuscular mycorrhizal fungi (AMF) found in natural ecosystems, crop and impacted areas in the semiarid region of Northeast Brazil are presented. Fifty two from the 189 described species were identified (27.5% of the total). The most represented families were Glomeraceae, Acaulosporaceae, and Gigasporaceae (18, 17, 14 species, respectivelly). Considering that Glomeraceae has the highest number of species among the AMF, comparatively other families are better represented in the studied areas. From the total number of species, 44% of Acaulosporaceae, 57% of Gigasporaceae and only 18% of Glomeraceae were found in the Brazilian semiarid. This pattern of distribution is not similar to that mentioned for other semiarid areas, where species of Gigasporaceae were not registered. Most of the species of AMF in the Brazilian semiarid were from agrosystems (43%), followed by impacted (33%) and native areas (24%), as occurs in the other regions of the country. But this do not necessarily shows the real situation, once that most surveys were in agrosystems. Further studies are needed to increase the knowledge regarding diversity of AMF in semiarid areas.

P0852. Lichens of Oran Dosh protected area in the Lake Khubsugul National Park (Mongolia)

K. K. Palka;
Polish Academy of Sciences, Kraków, Poland.

The Lake Khubsugul National Park is located in north-central Mongolia in Khubsugul province. The park was established in 1992 and covers *ca* 9000 km^2. The park was nominated as a UNESCO World Cultural Heritage Landscape in 2002. Several scientists contributed to the knowledge of biodiversity of that region but the lichen flora of the area is still in need of detail investigations.

The results presented here are based on the material collected during the student expedition to Mongolia in August 2000. The lichens were collected in taiga forest and mountain tundra in Oran Dosh protected area. There were 145 taxa recorded in the studied area. Of these, 21 are new to Mongolia, e.g. *Caloplaca bohlinii*, *Lecanora zosterae*, *Lichenomphalia umbellifera*, *Trapeliopsis flexuosa*, *Xylographa vitiligo*, and further 40 are new to the lichen flora of the Khubsugul region, e.g. *Buellia geophila*, *Calicium abietinum*, *Diplotomma pharcidium*, *Fulgensia bracteata*, *Hypogymnia subobscura*, *Imshaugia aleurites*, *Japewia tornoensis*, *Parmeliella triptophylla* and *Xylographa parallela*. The Lake Khubsugul National Park is a lichen-rich site worthy of further lichenological examination.

P0853. Aphyllophoroid fungi of the North-West of Russia

V. M. Kotkova;
V.L. Komarov Botanical Institute of RAS, St. Petersburg, Russian Federation.

Aphyllophoroid fungi are important heterotrophic components in forests ecosystems. The first information about fungi of northwestern territories of Russia was published in the 18th and 19th centuries. More intensive investigations have been carried out for last 50 years. At present more than 660 species of Aphyllophorales are known in the North-West of Russia. However, degree of inventory of its different regions is very uneven: about 115 species were recorded for the Murmansk Region, 450 - for Republic of Karelia, 190 - for Arkhangelsk Region, 385 - for Komi Republic, 550 - for Leningrad Region, 90 - for Novgorod Region and 200 species - for Pskov Region. Aphyllophoroid fungi being mainly wood-destroying organisms are closely associated with species of trees. On investigated territory 259 aphyllophoroid fungi were collected on spruce, 229 - on pine, 209 - on aspen, 201 - on birch, 173 - on alder and 109 - on willow. Most interesting and rare species were found in primeval forests.

P0854. Growth forms of Lecanora argopholis in Kamenny Mogily reserve (Ukraine)

O. Nadeina;
M.G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv, Ukraine.

In spite of Kamenny Mogily`s lichens have been investigating since in 20-th in XX century (Oxner, 1927, 1961, 1962; Kovalenko, 1976, 1977), its lichenobiota is hitherto not completely inventoried. 79 lichen species, of which Arthonia varians is new for Reserve and Ukraine, are known for Reserve at present.

Lecanora argopholis (misapprehend as L. frustulosa) is analyzed, morphological variability of this species within territory of Reserve is illustrated.

Oxner (1961, 1962) describe variability of L. argopholis-frustulosa grope in Kamenny Mogily Reserve. After his data subfruticose growth is formed under influence of competitions, thallus development of another species. This growth form appeared to be often broken off at the basis of rocks. Vanska (1984) carries out detailed taxonomical investigation of L. argopholis-frustulosa grope and reported appearance of subfruticose forms together with typical in the same habitats.

Both (typical and subfruticose) thallus growth forms of L. argopholis are registered in Kamenny Mogily Reserve. They differs by apothecium size, namely typical form has apothecium about 3 mm diam, and subfruticose - about 0,3 mm diam.

P0855. Investigation of mycobiota in Armenia

S. G. Nanagulyan;
Yerevan State University, Department of Botany, Yerevan, Armenia.

Armenia, situated at the heart of the Caucasus region, is an important focus of biological diversity. An unusually high fraction of Armenia’s biota is endemic and the unique biological resources within Armenia are historically and economically significant. The main center for investigation of fungal diversity in Armenia is the Department of Botany, Yerevan State University. Research on Armenian fungi is currently very active with ongoing projects on the systematics, biodiversity, biotechnology, and ecology of the

Armenian mycobiota and edible mushrooms found within the country.
The Experimental Mycological Scientific Group within Department of Botany has conducted the investigations to reveal the specific composition of the Armenian fungi, inhabiting in natural and artificial ecosystems. There has been gathered more than 4000 species of micro- and macromycetes, studied their biological activity. In principal directions of mycological investigations are revealing the biodiversity, physiology and economic importance of the fungi, which are maintained in the scientific herbarium and culture collection.

P0856. Diversity and seasonal occurence of soil fungi from certain Indian soils

G. M. Rane[1], R. V. Gandhe[2];
[1]M.J.College, Jalgaon, India, [2]Modern College, Pune, India.

In the present investigation some cultivated soils, uncultivated soils, river soils and forest soils from India are explored for the fungal population. These fungi shows distinct diversity and seasonal variation. As far as the diversity is concernrd, Deuteromycotina species were dominant from all soil types. Maximum number of species were isolated from river soil , cultivated soil, forest soil and uncultivated soil respectively. Distinct and remarkable seasonal variation was observed in the soil mycoflora. Nearly, all the isolated fungi showed remarkable seasonal variation. However some of them also exhibited regular seasonal occurance in soil mycoflora. Minimum fungal species were isolated during summer and maximum species isolated during winter. Statistically there was a significant and remarkable correlation between pH, water holding capacity and occurance of species from all soil types. Little less significant correlation was observed between temperature and number of species. Four species of *Chaetomium* and one variety of *Circinella* are proposed as new.

P0857. Macromycetes of small spring fens in the area of the westernmost Carpathians

M. Vašutová[1,2], P. Hájková[3], M. Hájek[3];
[1]Department of Botany, Faculty of Science, Palacký University, Olomouc, Czech Republic, [2]Department of Biology, Faculty of Pedagogy, Palacký University, Olomouc, Czech Republic, [3]Department of Botany, Faculty of Science, Masaryk University, Brno, Czech Republic.

Macromycetes, vegetation and water chemistry of small spring fens (poor and rich *Sphagnum*-fens, calcareous fens and rich spring meadows) in the area of Moravian-Slovakian border were studied in 2001-2004. Our aims were to find out: a) fungi species richness; b) linkage between mycoflora composition and environmental factors; c) diagnostic fungi species for vegetation types of spring fens. Generally, species richness of spring fens was 5-21 species per locality, 95 species in total, and was equal along the pH/calcium gradient. Using CCA ordination, the variation in fungi species composition was explained best by the ordination score of vegetation. No other environmental factor significantly contributed to the CCA model. The most contrasting habitats were poor *Sphagnum*-fens (diagnostic species with the highest values of the Fischer´s exact test are *Hypholoma elongatum, Galerina tibiicystis, Entoloma conferendum* and *Tephrocybe palustris*) and rich spring meadows with the best diagnostic species *Coprinus* sect. *Alachnui.* The calcareous fens without meadow character of vegetation were characterised by e.g. *Galerina heterocystis* and *Mycena epipterygia.*

P0858. Lichens of parks of Poltava town (Ukraine)

L. V. Dimitrova, A. B. Gromakova;
V.N.Karazina Kharkiv National University, Kharkiv, Ukraine.

Poltava town with population a. 400000 inhabitants is situated in the Forest-Steppe zone of central part of Ukraine. Lichens of the Poltava town parks are for the first time inventoried.
64 lichen species of 30 genera and 12 families and Mitosporic Fungi are found.
Low species diversity of lichen-forming fungi in parks of the central part of Poltava town is connected with homogeneity of trees (phorophytes), dense cover with buildings and close position to numerous motorcar roads.
Much higher number of lichen species in parks situated closely to network of artificial water reservoirs and Vorskla River at the vicinities of Poltava town is connected with higher diversity of phorophyte species as well as higher humidity of air.
The highest species diversity of lichens (namely 37 species including rare in town taxa Bryoria capillaries, Xanthoria ucrainica, Strangospora pinicola, Evernia mesomorpha etc.) is found in town 'Dendropark' in the second group of parks.

P0859. Mycorrhizal mycobiota associated with European larch (Larix decidua Mill.) in Poland

T. Leski, M. Rudawska;
Institute of Dendrology Polish Academy of Sciences, Kornik, Poland.

European larch is native to Europe and wide distributed in Poland, obligatory ectomycorrhizal (ECM) forest tree. Until recently our knowledge about mycorrhizal fungi colonizing root system of this tree was limited to the above-ground sporocarp inventories. Molecular methods based on polymerase chain reaction (PCR) and investigation of restriction fragment length polymorphisms (RFLP) are among the most useful approaches for more detailed identification of the fungi from mycorrhizal roots and can be target at several taxonomic levels. Two different approaches were performed to examine ECM mycobiota of European larch: morphological analysis of ECM roots and molecular techniques (PCR-RFLP and sequencing of ITS rDNA region). Numbers of individual mycorrhizal morphotypes (richness) differed depending on the age of larch trees. Young trees (1-4 years old) were mostly colonized by ectendomycorrhizal fungus Wilcoxina mikolae and ECM fungus - Suillus grevillei. Important role at the below-ground ECM community structure in larch forests fulfills Cenococcum geophillum and Paxillus involutus.

P0860. Diversity of downy mildew fungus-like organisms (family Peronosporaceae) in Crimea (Ukraine)

I. A. Dudka;
M.G. Kholodny Institute of Botany, National Academy of Sciences of Ukaine, Kiev, Ukraine.

Field research and study of specimens in KW, LE and LEP herbaria revealed records of 79 species of downy mildew fungi in 5 natural zones of the Crimean peninsula. Downy mildew fungi were represented by species of *Peronospora* Corda (70), *Bremia* Regel (4), *Plasmopara* J. Schröt. (3), *Paraperonospora* Constant. (1) and *Pseudoperonospora* Rostovzev (1). They were obligatory associated with 107 species of vascular plants from 69 genera of 23 families. The highest diversity of downy mildew fungi was observed in the ecotopes of steppe Crimea (51species). In 4 other natural zones, including mountain Crimea with various types of forests and south coast zone with its parks and gardens, downy mildew fungi diversity was a half of that in steppe Crimea. The high diversity of those fungi in steppe zone is caused by especially rich composition of steppants and weeds belonging to host plants of downy mildews (Dudka, 2003).

P0861. Diversity and conservation of macrofungi in Sevan National Park of Armenia

A. Sirunyan, S. Nanagulyan;
Yerevan State University, Department of Botany, Yerevan, Armenia.

The specially protected areas of the Republic of Armenia amounting to the total of 3110 m^2 (about 10% of the common territory). They have very important role in conservation of biological diversity, in particular - fungal diversity. The goal of our investigation is to study biodiversity of macromycetes of Sevan National Park. The park covers an area of 1500 m^2, located at the altitudes ranging from 1897 m to 2100 m above the sea level and located in the recreation and urban zone of republic, where are great anthropogenic pressure on ecosystems. As a result of our investigation detected 322 species of macromycetes from 2 subdivisions: Ascomycotina and Basidiomycotina.
Ten species of these macromycetes are marked as the candidates for the Red Book of Armenia. The list of these species is cited below: Agaricus tabularis, A.xanthodermus, Clavariadelphus pistillaris, Hericium coralloides, Macrolepiota puellaris, Montagnea candollei, Mutinus caninus, Myriostoma coliforme, Rhodotus palmatus, Sarcosoma globosum. Finally, the mapping of rare species will be presented.

P0862. Comparative mycological investigations in undisturbed soils of the Northern and Southern European taiga

V. A. Terekhova[1], T. A. Semenova[1], O. V. Tropina[2];
[1]Institute of Ecology and Evolution , Moscow State University, Moscow, Russian Federation, [2]Moscow State University, Moscow, Russian Federation.

The soil fungal communities in the northern and southern taiga in Russia were characterised. All soils are rich in micromycetes; however, in the southern taiga the number of the colony formation units (58-143 thousands CFU/g) was higher than in northern (0,30-26 thousands CFU/g). Essential distinctions in fungal quantitative assessments between automorphic and hydromorphic soils have also been observed. More than 20 species have been identified in dominating complexes of micromycetes. The most frequent were species from *Penicillium, Trichoderma, Aureobasidium, Aspergillus, Acremonium, Chrysosporium, Cladosporium, Phialophora.* Mycelia sterilia was mainly isolated from northern soils. Cluster analysis of fungal species abundances, however, showed that automorphic soils of two taiga subzones have greater similarity than hydromorphic (peat) soils.

The research has been supported by RFBR grants (# 02-04-48870, # 03-04-06522).

P0863. Species of the genus Setulipes (Fungi, Basidiomycota, Agaricales) in tropical Africa

V. Antonín;
Moravian Museum, Brno, Czech Republic.

The genus *Setulipes* Antonín (= *Marasmius* sect. *Androsacei* Kühner) represents a rather small group belonging to gymnopoid fungi. Its basic characters are following: basidiocarps small, marasmioid; lamellae well-developed; stipe insititious; basidiospores smooth, thin-walled, hyaline; cheilocystidia in the form of broom-cells or coralloid cells, rarely absent; pileipellis nonhymeniform, of diverticulate hyphae, often mixed with single broom-cells, sometimes hymeniform in primordial stages only; hyphae dextrinoid at least in stipe apex.

A list of tropical African species with their known distribution: 1. *S. rhizomorphicola* Antonín (Cameroon, Malawi, Tanzania, probably also Burundi). 2. *S. afibulatus* Antonín (Burundi, Democratic Republic of Congo, Malawi, Nigeria, Tanzania). 3. *S. brevistipitatus* Antonín (Cameroon). 4. *S. curvistipitatus* Antonín (Burundi). 5. *S. congolensis* (Beeli) Antonín (Democratic Republic of Congo). 6. *S. kisangensis* (Singer) Antonín (Democratic Republic of Congo). 7. *S. hakgalensis* (Petch) Antonín (Democratic Republic of Congo, Malawi, Tanzania, also Sri Lanka, Lesser Antilles, South America).

P0864. Taxonomy and importance of *Hohenbuehelia*, *Resupinatus* and *Pleurotus* in *Meloidogyne javanica* control

M. T. L. Putzke, A. T. S. Matsumura[2], M. A. Cavalcanti[3], J. Putzke;
[1]Universidade de Santa Cruz do Sul, Santa Cruz do Sul, Brazil,
[2]Universidade Federal do Rio Grande do Sul, Porto alegre, Brazil,
[3]Universidade Federal de Pernambuco, Recife - pe, Brazil.

Were collected and identified species of *Hohenbuehelia*, *Pleurotus* e *Resupinatus* (fungi, Basidiomycota) in southern Brazil and their action as predators against *Meloidogyne javanica* assayed*.* The fungi were cultivated in PDA and the nematodes were inoculated from a tobacco isolate cultivated in roots of tomato plants (*Lycopersicum esculentum*) var. gaucho. Were identified 3 species of *Pleurotus*, 10 of *Hohenbuehelia* and 2 of *Resupinatus. Pleurotus cystidiosus*, *Resupinatus silvanus*, *Hohenbuehelia unguicularis* and *Hohenbuehelia singeri* are new refferences to Brazil and one species in new to science. In the tests against *Meloidogyne javanica*, the better predator was *Hohenbuehelia portegna* (85,64%), followed by *Pleurotus ostreatus* (76,44%). In greenhouse, *Hohenbuehelia paraguayensis, H. portegna, Pleurotus cystidiosus, P. ostreatus* and *P. ostreatoroseus,* isolated or in cocktail, were efficient in controlling *Meloidogyne javanica*. *Pleurotus ostreatus, P. ostreatoroseus* and the cocktail reducced 70% the gall numbers in roots and *Hohenbuehelia portegna* and *H. paraguayensis,* reduced 50% and 40%, respectivelly.

P0864a. Macromycetes of beech stands in Central Slovakia and their response to decrease on air polluting load over the last years

K. Bucinova;
Institute of Forest Ecology of Slovak Academy of Sciences, Zvolen, Slovakia.

The aim of this study was to evaluate how the species composition of macromycetes communities can contribute to the ecological stability of beech ecosystems. We examined quantitative data about macromycetes from three permanent research plots with various impacts of airborne pollutants generated by an aluminium plant in Central Slovakia. This topic was studied in the vegetation periods 2003 and 2004. We have found balanced values of abundance of fruiting bodies and species dominance on all the examined plots. We can conclude that the distribution of tree parasites decreased with decreasing imission load. We have also found relatively equal numbers of lignicolous saprophytes and terrestrial saprophytes on research plots. The negative influence of airborne pollutants on ectomycorrhizae forming species was observed at the beginning of the 1990s. The current assessment of their abundance and dominance allows us to conclude about an increase in ectotrophic forest stability.

P0865. Diversity in virulence of *Blumeria graminis f. sp. tritici* from five regions of Ukraine

A. Bogdanovych;
Institute of Plant Physiology and Genetics NAS of Ukraine, Kiev, Ukraine.

The virulence and race structure of the populations of powdery mildew fungus (*Blumeria graminis f. sp. tritici*) from five regions of Ukraine have been examining since 1998. This regions (Kyiv, Kherson, Ternopil, Zhitomir and Ivano-Frankivsk districts) have differences in soil-climatic conditions, levels of chemical pollution and cultivating varieties of wheat. It was found that populations of powdery mildew fungus from five regions were different elements of the same population. The maximum genetic distance between these elements was 0.06. The majority of 40 identified fungus races possessed low virulence. The most races diversity and high virulence of pathogen was determined in Ivano-Frankivsk district. It may be associate with chemical pollution of sown areas or with migration of fungus from western countries. Diversity in virulence (available virulence genes and their number) caused by efficiency of resistance genes.

P0866. Phylogenetic relationships between *Puccinia pachyderma, P. wolgensis* and *Aecidium gageae* (Uredinales) based on ITS sequence data

M. Abbasi[1], S. B. Goodwin[2], M. Scholler[3];
[1]Plant Pests and Diseases Research Institute, Tehran, Islamic Republic of Iran, [2]Crop Production and Pest Control Research Unit, USDA-Agricultural Research Service, West Lafayette, IN, United States, [3]Staatliches Museum für Naturkunde, Karlsruhe, Germany.

Puccinia pachyderma is a microcyclic rust species on *Gagea* spp. (Liliaceae) native of Europe and Asia. This species has erumpent telia with thick-walled teliospores. Another Eurasian rust species on *Gagea* is the anamorphic *Aecidium gageae.* Teliospores of *P. pachyderma* are morphologically almost identical with those of *Puccinia wolgensis* on *Stipa* spp. (Poaceae), which is, like nearly all grass rusts, supposed to be heteroecious. In order to find possible relationships between the three species (*Aecidium gageae* an aecial state of *P. wolgensis*? *P. pachyderma* a reduced microcyclic species evolving from *P. wolgensis* according to Tranzschel's law?), we sequenced rDNA (ITS1+5.8S+ITS2) extracted from herbarium specimens. Phylogenetic analysis indicates that there is no relation between *P. pachyderma* and *P. wolgensis* but strong similarity between *A. gageae* and *P. pachyderma* with only four bp difference. We assume *Puccinia pachyderma* to be an opsis form, i.e. with spore states 0, I (=*Aecidium gageae*), III, and IV.

P0867. Smut fungi from northwestern China

L. Guo;
Key Laboratory of Systematic Mycology & Lichenology, Institute of Microbiology, Beijing, China.

There are 110 known species belonging to eighteen genera of smut fungi known from Northwestern China until the end of the year 2004. These species were collected from the Shaanxi Province, the Gansu Province, the Qinghai Province, the Ningxia Hui Autonomous Region and the Xinjiang Uygur Autonomous Region by the author and her colleagues during several mycological expeditions. The study is also based on examinations of specimens deposited in the Mycological Herbarium of Chinese Academy of Sciences (HMAS). This number occurs in about half of the species of smut fungi existing in China. These 10 endemic species are considered to Northwestern China occurring in four genera, namely *Anthracoidea filifoliae*, *Anthracoidea kanasensis*, *Anthracoidea microspora*, *Anthracoidea pygmaea*, *Anthracoidea shaanxiensis*, *Anthracoidea striata*, *Sporisorium reticulatum*, *Thecaphora sphaerophysa*, *Urocystis helanensis* and *Urocystis qinghaiensis*.

P0868. The diversity of Ganodermataceae in Hainan province, south China

X. Q. Zhang;
Systematic Mycology & Lichenology Laboratory, Inst. of Microbiology, Chinese Academy of Sciences, Beijing, China.

Ganodermataceae species called “Lingzhi” in China, it has been used as Chinese traditional medicine and food from ancient China, China is a country in possession of most ganodermatoid fungi. Many people are very familiar with “Lingzhi” and there are many myths from ancient China. “Lingzhi” is an emblem of good fortune and prosperity in Chinese people. The diversity of Ganodermataceae has been investigated; Ninety-eight species have been reported from China belonging to four genera. (Zhao & Zhang, 2000)

Hainan Island is located in the tropics and is a southmost province in China. It is characterized by high temperature, humidity and so much rainfall throughout the year. Hainan has the highest diversity of pants, thus influence the richness of fungal resources. Particularly, there was a high diversity of Ganodermataceae, species of the Ganodermataceae were founded in Hainan province is over 79 % of the total in China. Seventy species of Ganodermataceae in Hainan were reported.

Six species of “Lingzhi” have been successfully cultivated and widely used as Chinese traditional medicine and health food in China and southeast Asia.

P0869. Analysis of genetic diversity in Colletotrichum acutatum using rDNA-ITS sequences

P. Talhinhas[1], S. Sreenivasaprasad[2], J. Neves-Martins[1], H. Oliveira[1];
[1]Instituto Superior de Agronomia, Lisboa, Portugal, [2]Warwick HRI, University of Warwick, Wellesbourne, United Kingdom.

The ascomycete fungus *Colletotrichum acutatum* is a cosmopolitan plant pathogen, responsible for diseases known as anthracnoses which cause important economic losses particularly in crops such as citrus, strawberry, olive, peach, almond, lupin and several ornamentals. This taxon was created by J.H. Simmonds in 1965 and since then several plant pathogens were assigned to it. Currently *C. acutatum* encompasses a high level of genetic diversity, leading some authors to define new species from within *C. acutatum* populations. In this work we have analysed the genetic variability of *C. acutatum* using rDNA-ITS sequences obtained by us and other authors around the globe and compare them with the host range and morphological characters of a selection of isolates. At least eight genetic groups can be defined within *C. acutatum*, some of which are geographically and/or host confined, while others can be found world wide in numerous hosts. Results suggest that *C. acutatum* is a single taxon but intra-specific differentiation could be useful to address the high degree of genetic diversity recorded within this pathogen populations.

P0870. The role of mycorrhizae in heavy metals tolerance of *Erica andevalensis*

B. Márquez-García, P. J. Hidalgo, M. A. Heras, F. Córdoba;
Biología Ambiental y Salud Pública, Huelva, Spain.

It is generally known that mycorrhizae plays an important role in heavy metal tolerance in Ericaceae. We have assessed the presence of mycorrhizal fungi infection in the species of Ericaceae (including Erica and Calluna genus) of the province of Huelva (Spain). In the piritic belt of Huelva, there is an endemic heather named *Erica andevalensis*, which is able to grow in highly polluted environments. This species grow in the bare spoil heaps resulting of the pyrite mining extraction activity that was frequent in the zone and in the river bank of the Odiel and Tinto rivers, which run through the area. High heavy metals concentration and low pH values (up to 2) have been detected in the area.

Our results show that *E. andevalensis* has a similar percentage of mycorrhizal fungi infection (lower than 10%) when compared with other analysed species from non-contaminated places. This result could indicate that the heavy metal pollution is not related to the abundance of mycorrhizal fungi infection in *E. andevalensis*. In this case, a non-mycorrhizal mechanism should be involved in heavy metal tolerance. This fact will be the subject of further research in this peculiar species.

P0871. Phylogenetic hypothesis of Microbotryum

M. Kemler, M. Göker, D. Begerow, F. Oberwinkler;
Spezielle Botanik & Mykologie, Tübingen, Germany.

Based on molecular studies, we discuss the phylogenetic relationships in the phytoparasitic family Microbotryaceae. The most prominent members of this family are the anther smuts of the genus Microbotryum, which form their sori in the anthers of Caryophyllaceae and are transmitted by pollinators. Besides the Caryophyllaceae, species of Microbotryum parasitise Asteraceae, Dipsacaceae, Gentianaceae, Lamiaceae, Lentibulariaceae, Onagraceae, Polygonaceae, and Portulacaceae. In addition to anther smuts, there are also species forming their sori in the gynoeceum/seeds, the whole inflorescence, leaves or the pedicels. Our analyses of the ITS show that parasitism of Microbotryum on Polygonaceae is the ancestral state for these parasites. We confirm the monophyly of the caryophyllaceous anther smuts and show that separation in European and North American anther smuts occured before their radiation. Sorus formation in anthers itself has evolved at least twice.

P0872. Does the phylogeny of the smut genus Entyloma relate to the evolution of host plants?

M. Lutz, M. Göker, D. Begerow, F. Oberwinkler;
Universität Tübingen, Spezielle Botanik & Mykologie, Tübingen, Germany.

The â€žwhite smutâ€œ Entyloma is easily recognized by the white dense leaf spots developed during teliospore formation. Although the 170 Entyloma species parasitize a phylogenetically wide range of dicots, about 85% of the species occur on Asterids or Ranunculales whereas single species show strict host specificity on the level of genera. Patterns where smut groups are restricted to certain host clades are common, but are not necessarily the result of cospeciation as the major speciation mode of the parasites. Admittedly, recent analyses comparing Entyloma and respective host phylogenies showed significant codivergence of parasites and hosts, but on the basis of a phylogenetic analysis of a relatively small dataset compiled from literature.

Here we reexamine the evolution of Entyloma with respect to the phylogeny of hosts on the basis of an enlarged molecular sampling and revised presence-absence data. The results are interpreted with respect to general parasitological rules including current theories of host-parasite evolution.

P0873. Arbuscular mycorrhiza in primary succession on coal mine spoil banks

D. Püschel, **M. Janoušková**, J. Rydlová, J. Fehrer, M. Vosátka;
Institute of Botany, Academy of Sciences of the Czech Republic, Pruhonice, Czech Republic.

Arbuscular mycorrhizal fungi (AMF) are an integral part of natural communities, but little attention has been paid so far to the establishment of arbuscular mycorrhiza in newly formed ecosystems.

Mycorrhizal associations of five pioneer plants with different mycotrophy are investigated in microcosm experiments simulating conditions of primary succession on a freshly levelled coal mine spoil bank. The aim of the study is to describe how mycorrhiza influences the coexistence of the pioneer plants and vice versa, how plants with different mycotrophy affect the colonisation of the spoil bank substrate with AMF.

Radiation of extraradical mycelium from intact root systems represented the most effective agent of AMF colonisation of the spoil banks in comparison with AMF proliferation from isolated propagules such as spores. The pioneer plant species differentially supported the development of AMF populations in the spoil bank substrate. The specific effects of plant species on individual AMF species in community were studied by PCR with specific primers.

The research is supported by grant No 526/04/0996 (Grant Agency of the Czech Republic).

P0874. Host preferences of arbuscular mycorrhizal fungi?

Z. Sykorova, A. Wiemken, D. Redecker;
Botanical Institute, Basel, Switzerland.

The aim of this study was to characterize the communities of arbuscular mycorrhizal fungi (AMF) in the roots of different plant species and to determine whether possible differences can be explained by host preference or spatial heterogeneity.

Two field sites in Switzerland were analyzed, a lowland and a subalpine species-rich grassland. In each site, four and nine plant species were sampled, respectively. The roots were analyzed by nested PCR of a region of the ribosomal RNA genes, RFLP analysis and sequencing. Sequences of AMF were analyzed phylogenetically and used to define monophyletic sequence types. The differences among AMF communities in different root samples were evaluated using canonical correspondence analysis.

Preliminary data show that the AMF communities in the lowland and the subalpine site were significantly different from each other. Spatial variability was not significant within any field site. Significant differences among AMF colonizing different plant species were observed in the subalpine field site. Two co-occurring gentian species (*G. acaulis, G. verna*) hosted very diverse but distinct AMF communities.

P0875. Studies on effect of fungal pigments on seed discolouration

A. M. Chavan;
Vasantrao Naik College, Aurangabad- 431 003 (MS), India.

ABSTRACT

Association of fungi with developing seeds in the field and with the matured seeds under ill storage has been found to cause biodeterioration of the seeds. This may cause various types of the abnormalitires in the seeds. These abnormalities include loss in food content, toxification of seed chemicals, loss in germinability, rottining and seed discolouration.

Among the above types of seed abnormalities, seed discolouration has been considered to be significantly important on the account of its distruction effects. Seed discolouration can be attributed mainly due to presence of coloured mycelia, conidia, conidiophore of the associated fungi, which produced coloured pigments, which can be retained in the staining of the seed coats. Discoloured seed mycoflora of few commonly growing cereals, Pulses & oilseeds were isolated to pin point the fungi responsible for seed discolouration.

Crude fungal pigments were tasted for its biological properties. Effect of fungal pigments on seed germination, fungal spore germination and on bacterial growth was studied. It was observed that the fungal pigments were antibacterial and antifungal in nature.

P0876. A new *Ophiostoma* species from oak in Europe.

D. N. Aghayeva[1], M. J. Wingfield[2], T. Kirisits[3], B. D. Wingfield[2];
[1]Institute of Botany, Baku, Azerbaijan, [2]Forestry and Agricultural Biotechnology Institute, Pretoria, South Africa, [3]Institute of Forest Entomology, Forest Pathology and Forest Protection, Vienna, Austria.

Ophiostoma stenoceras, a well-known sap staining fungus occurring on hardwoods and conifers in Europe and North America is characterized by a micronematous *Sporothrix* anamorph. Recent phylogenetic studies have shown that isolates of *Ophiostoma stenoceras sensu lato* include several closely related species. Isolates from oak in Poland and Hungary, which have previously been referred to as *O. stenoceras* as well as isolates of *S. inflata* were considered in this study. Sequence data for the ITS/5.8S gene regions of rDNA operon and partial ß-tubulin gene were used to characterize isolates. Phylogenetic analyses showed that the isolates reside in a well resolved clade, separate from those in the *O. stenoceras*-complex. In addition, distinct morphological differences in teleomorph and anamorph structures were found between isolates from Poland and Hungary and those in the *O. stenoceras*-complex. The fungus thus represents a new species, which is currently being described as *Ophiostoma dentifundum*. This species is phylogenetically related to isolates of *S. inflata,* which consist of four well-defined groups based on both morphology and DNA sequence phylogeny.

P0877. Dynamics of peroxidase complex activity in pathogen system *Claviceps purpurea - Secale cereale*

Z. Olteanu[1], S. Surdu[2], M. M. Zamfirache[1];
[1]University Al. I. Cuza, Faculty of Biology, Iasi, Romania, [2]Biological Research Institute, Iasi, Romania.

The strains of fungus have different biosynthetic alkaloid capabilities and predominantly produce a certain peptide alkaloid. In submerged cultures enzyme activity is lower at ergocristine strains and higher at cultures obtained from ergotamine and ergocryptine sclerotia. Peroxidase activity of sclerotia is strong at beginning of ontogenetic development, and decrease to the end of sclerotia development. The parasite influences peroxidase activity in host plants. The alkaloid accumulation in sclerotia and intensity of peroxidase activity there are in relation of inverse proportionality. The alkaloid complex influences the peroxidase activity in plant. Comparatively with control, enzyme activity level is lower in parasitized plants by ergotamine sclerotia and higher in parasitized plants by ergotoxine sclerotia. Peroxidase isoforms number in host plants varies depending on age and predominant alkaloid in sclerotia which growth on *Secale cereale.*

P0878. Genetic variation in the foliicolous *Porina epiphylla* group

E. Baloch, M. Grube;
Institute of Plant Sciences, Karl-Franzens-University Graz, Holteigasse 6, Graz, Austria.

More than one third of the species of the lichen family Porinaceae occur obligately on living leaves. Members of the species-rich genus *Porina* grow abundantly in tropical rainforests. Highly adapted to the ephemeral nature of their substrates, foliicolous lichens show significantly shorter lifecycles compared to lichens of other substrates. Therefore they are interesting objects to analyse evolutionary processes. In our studies we focused on selected species of the *Porina epiphylla* group collected in lowland rainforests in Costa Rica. All of the investigated species produce abundantly fruiting bodies, and in one of them, *Porina alba*, also vegetative diaspores are common. Sequences of the mitochondrial SSU rDNA were analysed using phylogenetic methods and haplotype networks. The genetic variation of various species is analysed with respect of geographical and ecological parameters, including symbiont selectivity patterns.

P0879. Terricolous Buellia species in Southern Africa

U. Grube[1], L. Zedda[2], J. Blaha[1], H. Mayrhofer[1];
[1]Institute for Plant Sciences, Graz, Austria, [2]Chair of Plant Systematics, Section Mycology, Bayreuth, Germany.

Buellia species growing on soil in xerophilic, rather alkaline situations which have more or less lobate growth-forms are currently merged in the Buellia epigaea group. Specimens of soil-growing Buellia were collected in semi-desert, lichenologically very poorly investigated, areas of Southern Africa. They were found to be morphologically very similar to species of the Buellia epigaea group and have been studied in greater detail for the first time.

Anatomical, chemical and molecular characters (mtSSU rDNA sequences) have been analysed to elucidate the relationship of these taxa. Four taxa could be distinguished from the already known species. These do not form a homogenous group. Preliminary molecular results show that two of the southern African taxa are nested within the Buellia epigaea group, comprising Australian taxa and species of the northern hemisphere, whereas the other two do not seem to be so closely related.

An outline of specimens collected from xerophilic sites from various parts of the world, with a special focus on the southern hemisphere, will be given. Thus, several other soil-growing species will be included in the study.

P0880. Contribution to the genus Cladonia in the Iberian Peninsula. III. Supergroup Perviae

A. R. Burgaz[1], T. Ahti[2], I. Martínez[3];
[1]Facultad de Ciencias Biológicas, Madrid, Spain, [2]Botanical Museum, Helsinki, Finland, [3]Escuela Superior Ciencias Experimentales y Tecnología, Móstoles (Madrid), Spain.

Phylogenetic studies of the genus *Cladonia* suggest a provisional supergroup *Perviae*, defined by axils usually dilated to gaping funnels, brownish apothecia and the presence of ß-orcinol depsides. It is constituted mostly by the old section *Perviae* and section *Strepsiles*. A complete morphological, chemical and biogeographical study of six species of this supergroup is presented to complete the knowledge of the genus in the Iberian Peninsula, as part of the project Spanish Lichenological Flore (BOS2001-0869-C04-04). In many cases the Iberian Peninsula (Portugal and Spain) represent the southern outpost in their European distributions: a) species distributed in the Eurosiberian Region which rarely reach the Mediterranean Region: *C. parasitica* and *C. crispata* var. *cetrariiformis*; b) species with the southern limit in the Sistema Central mountains: *C. cenotea* and *C. strepsilis*; c) species with the southern limit in Sierra Morena mountains: *C. glauca* and *C. squamosa*.

P0881. Calicioid lichens and fungi of Hungary

L. S. LŖkös[1], E. É. Farkas[2], L. Tibell[3], A. N. Titov[4];
[1]Botany Department, Hungarian Natural History Museum, Budapest, Hungary, [2]Institute of Ecology and Botany, Hungarian Academy of Sciences, Vácrátót, Hungary, [3]Department of Evolutionary Biology, EBC, Uppsala University, Uppsala, Sweden, [4]Komarov Botanical Institute, Russian Academy of Sciences, St. Petersburg, Russian Federation.

The recent revision of Hungarian calicioid lichens and fungi based on more than 200 literature records and 300 herbarium specimens kept in BP, EGR, hb. Seaward (Bradford), JPU, S, SZE, SZO, UPS, VBI and W confirmed the presence of the following 6 genera (with number of species in brackets): Calicium (7), Chaenotheca (10), Cyphelium (2), Microcalicium (1), Mycocalicium (1) and Sphinctrina (2). Compared to Verseghy's 1994 compilation Chaenothecopsis (6), Phaeocalicium (1), Sclerophora (1), Stenocybe (1) and Thelomma (1) are reported as new genera to the Hungarian lichen flora. Chaenothecopsis debilis, Chs. pusiola, Chs. rubescens, Sclerophora nivea, Sphinctrina tubaeformis, Stenocybe pullatula and Thelomma ocellatum are recently recognised species from Hungary. Characterisation of genera and species and distribution maps of the most frequent species are presented.

P0882. The high-alpine lichens of Dzherginsky natural reserve (Northern Pribaikalje)

T. M. Kharpukhaeva[1,2];
[1]Institute of General and Experimental Biology of SB RAS, Ulan-Ude, Russian Federation, [2]Dzheginsky natural reserve, Ulan-Ude, Russian Federation.

Dzherginsky reserve is situated in northern part of Baikal basin on slopes of South Muysky and Ikatsky ranges (54°56' - 55°27' S.L.,111°11´ - 111°58' E.L.) on altitude 800-2500 m. Peaks ("goltsy") are massive and gentle, windswept snow-free with talus and stone field. 108 lichens species are found in High zone. Arctic-Alpine species (57%) and widely spread lichens (99%) predominant. Dry lichens and dryas tundra dominate in plant cover of ridge. Community's with Alectoria ochroleuca, Thamnolia vermicularis, Cetraria laevigata, Bryocaulon divergens and Bryoria nitidula occur on scree soils. Caloplaca sibirica, C. jungermanniae, Ochrolechia upsaliensis, Mycobilimbia berengeriana grow on plant remnants. On excess moist substrate dwarf shrubby, sedges, mosses tundra develop. Mosses and plant remnant occupied by Lecanora epibryon, Rinodina roscida, Bryonora castanea, Pertusaria christae, P. trochiscea. Stones and rocks cover by different lichens: Asahinea chrysantha, Umbilicaria and Lasallia species, Ophioparma ventosum, Rhizocarpon and Porpidia species, Boreoplaca ultrafrigida, Clauzadeana macula, Fuscidea austera, Miriquidica griseoatra.

P0883. Species delimitation in the lichen subgenus Neuropogon

N. Wirtz[1,2], **C. Printzen**[1], T. Lumbsch[2];
[1]Forschungsinstitut Senckenberg, Frankfurt am Main, Germany, [2]Field Museum of Natural History, Chicago, IL, United States.

Species of the lichen genus *Usnea* subg. *Neuropogon* have their centre of distribution in polar regions of the Southern Hemisphere. Morphological and chemical variability is poorly understood and several asexual taxa with uncertain relationships to fertile taxa occur in the group.

Based on molecular data of three nuclear genes (IGS rDNA, ITS rDNA, RPB1) and one mitochondrial gene (COI) we study the species delimitations of three groups (288 ingroup specimens) within Neuropogon: 1) the *U. antarctica/ U. aurantiaco-atra*-group, 2) the *U. sphacelata/ U. trachycarpa/ U. subantarctica*-group and 3) the *U. perpusilla*-group. Each group consists of sexual and asexual individuals. In addition to the molecular analyses, thallus morphology and anatomy and secondary chemistry were analysed.

Phylogenetic, phenotypic and geographic species criteria were applied to test the species recognition in the groups. In addition, cohesion species recognition according to Templeton was employed and the results of the different approaches compared. Congruence in species recognition between the different methods was interpreted as indicating isolated evolutionary lineages.

P0884. Diversity of Georgia's Lichens

K. O. Batsatsashvili[1,2], N. Chelidze[2], T. Inashvili[1];
[1]Institute of Botany of the Georgian Academy of Sciences, Tbilisi, Georgia, [2]I. Javakhishvili Tbilisi State University, Tbilisi, Georgia.

Georgia's lichen flora has been studied since the beginning of the XIX century. During the 200 years separate regions of the country were studied by European, Russian and Georgian scientists: E. Acharius, F. Ruprecht, J. Steiner, A. Elenkin, E. Vainio, A. Jatta, V. Pakhunova, Ts. Inashvili, N. Chelidze, etc. By this time more than 730 species (987 taxa including subspecies, varieties, forms) are recorded in Georgia. These data do not reflect the actual lichenological richness of the country, as long as some regions are not yet investigated in this aspect. Therefore, the actual number of species must be much greater.

The paper includes an introduction on the history of lichenological research in Georgia, presents a complete checklist of Georgia's lichens with the distribution, ecology (habitats and distribution according to altitudes), frequency of occurrence, year of collection and the name(s) of the collector(s) indicated for each species. A discussion concerning the taxonomic, morphological, ecological and coenotic analyses of the presented checklist, appropriate diagrams and a vegetation map with indicated lichen vertical distribution is also provided.

P0885. 'Four' morphospecies within *Parmelina quercina*: geographic distribution

A. Argüello[1], P. Cubas[1], R. Del-Prado[1,2], **A. Crespo**[1];
[1]Universidad Complutense de Madrid, Madrid, Spain, [2]The Field Museum Natural History, Chicago, IL, United States.

Parmelina quercina is one of the oldest parmelioid names, and was proposed by Willdenow in 1787 to describe specimens from Germany. This lichen has a disjunct area, growing in zones with a Mediterranean climate in North America (California) and Europe, and has also been reported from similar climatic areas of South Africa and Australia. We studied specimens from Europe, America and Australia. Molecular analyses based on nrITS, nrLSU and mtSSU sequences show four monophyletic groups. The spores and epicortex features are correlated to the topology of the phylogenetic tree. The Australian specimen clearly separates from the other samples. The European samples split into two groups. The first one has wider spores and a maculated (fenestrated) epicortex, matching what was described as *P. carporhizans* by Taylor in 1847 based on Canary Islands specimens. The second group has narrower spores and lack maculated (fenestrated) upper surface. The latter is closest to the *P. quercina* description of Wildenow. The North American samples form another group and have fenestrated epicortex. Both the American and Australian specimens should be granted the status of new species.

P0886. Is Xanthoria parietina reliable model taxon?

N. M. Fedorenko, S. Y. Kondratyuk;
M.H. Kholodny Institute of Botany NASU, Kyiv, Ukraine.

Detail revision of material called as '*Xanthoria parietina'* with involving anatomical and biochemical characters shown it to be very heterogenous. A number of new taxa, namely *X. dissectulata* and *X. bonae-spei* from South Africa, as well as *X. elixii* and *X. streimannii* from Australia is recently described.

Detail comparative morphometric study of collections of *X. parietina* material from Europe and Asia is carried out during this study. Some specimens are similar with *X. steineri* by sporae size but they have different thallus morphology. Also, some specimens have similar morphological characters with *X. parietina* but they have different anatomical characters (including the spore length and width). Reinvestigation of the type of *X. parietina* with aim to check all characters used in modern taxonomy of xanthorioid lichens is in urgent need.

Determination of *X. parietina* material, especially from different continents including Europe and Asia, should be done with great care and with including anatomical characters. *X. parietina* is confirmed only by European material indeed. Asian Near East material of '*X. parietina*' shows characters of *X. steineri* aggr.

P0887. The New Records of Lichen from Iran

M. Haji Moniri Anbaran;
Biology Department, Faculty of Science, Islamic Azad University, Mashad Campus, Mashad, Islamic Republic of Iran.

The lichen taxonomy is a deep gap in the taxonomic studies for Iranian vegetations. In the course of a Ph.D thesis on the lichen flora, collection, number and identification of the available lichens in khorasan province were accomplished in the aim of preparing the references specimens for comparison. From phytogeographical point of view, Khorasan is in the Irano-Touranian vegetation region and located in the northeast of Iran. It's distinguished by the presence of mountain ranges that show much more symmetry and regularity. Geologically, the predominant series of the main Alborz- lower Jurassic and Cretaceous- continue uniterruptedly to form the main massifs of Khorasan.

Morphological and chemical studies were done with using microscopical standard techniques and spot tests with the current reagents.

10 species of lichens in the altiude ranging between 800-2200 m with

40 percents of the average daily humidity, were identified and are related as new species for Iran.

P0888. The lichen flora of Termessos National Park (Antalya) in southwestern Anatolia

O. Tufan[1], H. Sümbül[1], A. Özdemir Türk[2];
[1]Akdeniz University, Faculty of Arts and Sciences, Biology Department, Antalya, Turkey, [2]Anadolu University, Faculty of Sciences, Biology Department, Eskiκehir, Turkey.

This research aim to determine the lichen flora of the Termessos National Park. Termessos National Park is famous for its ancient city and biological diversity in Antalya, Southwest of Turkey. It was founded on a natural platform on top of Güllük Mountain, soaring to a height of 1665 meters from among the surrounding travertine mountains of Antalya, which average only 250 meters above sea level. Due to the area was protected, is far from the city center, has different topography and plant cover, the lichens live densely in this area. Until this research, there wasn't any lichen records from Termessos National Park.

Total 161 taxa (152 species, 4 subspecies, 5 varieties) were determined from 1114 pieces of lichen samples gathered in the area research done between the dates March 2002 and September 2003. All of 161 taxa for Termessos National Park, 93 of total taxa for Antalya Province, 43 of total taxa for Mediterranean Geographical Region, 30 of total taxa for Turkey's Mediterranean Phytogeographical Region, 11 of total taxa are new records for Turkey.

P0889. Phylogeny of *Dicranoloma* (Bryophyta, Dicranaceae), based on ITS and morphology

N. Klazenga;
Royal Botanic Gardens Melbourne, South Yarra, Australia.

Previous cladistic analyses into the delimitation of and higher level relationships within the Dicranaceae, based on chloroplast sequences, have resolved *Dicranoloma* and *Dicranum*, each with a few satellite genera, as separate monophyletic groups. The present study aims to reconstruct phylogenetic relationships within the *Dicranoloma* clade, using the more quickly evolving nuclear ITS region. Sequences of the entire ITS region have been obtained from specimens representing all Australian and New Zealand species and as many as possible non-Australasian species of *Dicranoloma*. Cladistic analysis of ITS sequences provides excellent resolution between the specific and generic levels and divides the *Dicranoloma* clade into two major subclades. ITS results are largely corroborated, if not independently obtained, by morphological data. Several species in both subclades show Southern Hemisphere disjunct distributions and make good candidates for future comparative phylogeographic studies.

P0890. Phylogeny of Lejeuneaceae (Jungermanniopsida) based on the cp rbcL, trnL-F and nrITS.

R. Wilson, R. Gradstein, J. Heinrichs, A. Iliku Borges, F. A. Hartmann;
Albrecht von Haller Institute of Plant Sciences, Göttingen, Germany.

Lejeuneaceae are the largest family of liverworts with about 1000 species in ca. 90 currently accepted genera in two subfamilies. Although morphological studies have gone a long way to help understand the phylogeny of Lejeuneaceae, they have been hampered by the lack of stable morphological characters. Ongoing molecular-phylogenetic studies based on the chloroplast markers *rbc*L, *trn*L-F and the nuclear marker ITS suggest that a reconsideration of the classification of Lejeuneaceae into 3-4 subfamilies is needed. *Metzgeriopsis* is resolved as a member of the *Cololejeuna* clade, *Taxilejeunea* and *Neopotamolejeunea* are nested within *Lejeunea*, and *Phaeolejeunea* is resolved as a member of the Ptychanthoideae. Molecular data indicate that the *Cheilolejeunea*-*Omphalanthus*-*Aureolejeunea* complex is in need of a thorough revision leading to a broader genus concept for this clade.

P0891. A taxonomic revision of Herbertus (Jungermanniopsida: Herbertaceae) in tropical America based on nuclear and chloroplast markers and morphology.

K. Feldberg, R. Wilson, J. Heinrichs;
Albrecht von Haller Institute of Plant Sciences, Göttingen, Germany.

Taxonomy of *Herbertu*s is notoriously difficult because of the lack of stable morphological characters. Currently, eleven species are accepted for tropical America. Phylogenetic analyses of the chloroplast marker *trn*L-F and the nuclear ITS1-5.8S-ITS2 region resolves the neotropical phenotype spectrum in two robust clades. Based on the molecular topology and morphology, a new concept is proposed for neotropical *Herbertus*, leading to the recognition of two species only. The neotropical *Herbertus juniperoideus* is subdivided into four subspecies (ssp. *acanthelius*, ssp. *divegens*, ssp. *pensilis*, ssp. *juniperoideus*). *Herbertus sendtneri* (*H. subdentatus* auct.) occurs in the Neotropics as well as in Europe and Asia. The species is nested in a clade with Holarctic, Asian and African taxa. Without much doubt, the morphologically similar *H. dicranus* is restricted to Asia and Africa.

P0892. The family Metzgeriaceae (Hepaticae) in the Tropical America.

D. P. Costa;
Rio de Janeiro Botanical Garden, Rio de Janeiro, Brazil.

The family Metzgeriaceae is represented in the Tropical America by one genus and 57 species. The species are characterized according to width of thallus, number of laminal cells from midrib to margin, of dorsal and ventral epidermal cells in the midrib, of medulla cells, size of laminal cells, verruculosity of the cuticle, types and disposition of hairs in the thallus, gemmae, and sexuality. They are mostly epiphytes in humid, submontane to upper montane tropical forests, between 500-4000 m. Most of the species are restricted to Tropical America and the highest species diversity is found in the Northern Andes, followed by the West Indies, Central Andes and Southeastern Brazil. In dry regions few species are found. About 13 % of the species are limited to undisturbed forest and 29,7 % are included in one of the IUCN categories: extinct (1,7 %), critically endangered (1,7 %), endangered (3,5 %), vulnerable (14 %), or data deficient (8,8 %). Fifteen new synonyms are proposed.

P0893. Systematics and distribution of Mexican Grimmias (Bryopsida)

C. Delgadillo-Moya, J. Villaseñor-Ríos;
Instituto de Biología, Mexico, D.F., Mexico.

Although broadly distributed in Mexico, the genus *Grimmia* is usually found between 1200 and 4600 m in elevation in three main areas: the northwestern states (Baja California to Chihuahua and Durango), along the Neovolcanic Belt, and in the dry areas of central Mexico. It is represented there by 18 species, sixteen of which are widely distributed in the world and two are endemic to the country. A preliminary cladistic analysis of the genus indicates that most Mexican species are grouped into three main clades that show no relationship to geography or to existing taxonomic schemes. Because of their broad range and uneven Mexican distribution, it is suggested that the species represent ancient lineages that spread at various times from northern areas, southward through the western Cordillera, and into the mountains of central Mexico.

The distribution of the Mexican endemics, *Grimmia involucrata* Card. and *G. pulla* Card., is under study to determine the relationship to other species and their ranges.

P0894. A taxonomic study of the genus *Syntrichia* Brid. (Pottiaceae, Musci) in Europe

M. T. Gallego, M. J. Cano, J. Guerra;
Facultad de Biología, Murcia, Spain.

The genus *Syntrichia* Brid. (Pottiaceae, Musci) is taxonomically revised in Europe based on the study of more than 3000 specimens from 62 herbaria, examination of type material and an extensive review of relevant literature. Nineteen species and five varieties are recognized: *Syntrichia calcicola*, *S. caninervis* var. *caninervis*, *S. caninervis* var. *abranchesii, S. caninervis* var. *astrakhanica*, *S. caninervis* var. *gypsophila, S. echinata, S. fragilis, S. glabra, S. handelii, S. laevipila, S. latifolia, S. minor, S. montana* var. *montana, S. montana* var. *calva, S. norvegica, S. papillosa, S. papillosissima, S. princeps, S. rigescens, S. subpapillosissima, S. ruralis* var. *ruralis, S. ruralis* var. *ruraliformis, S. sinensis* and *S. virescens.* A key for identification of species is provided, and for each one synonymy, description, illustration, distribution, diagnostic characters and new records are given. Five new synonyms are proposed. Lectotypes for 13 species are newly selected. Finally the name *Syntrichia aciphylla* var. *calva* is excluded from the *Syntrichia* genus.

P0895. Taxonomic studies on the genus *Cololejeunea* (Hepaticae, Lejeuneaceae) in Asia.--Revision of *Cololejeunea* in China

R. Zhu;
Department of Biology, East China Normal University, Shanghai, China.

Lejeuneaceae is a pantropical genus, containing over 90 genera currently accepted. It is the largest family in Hepaticae. *Cololejeunea* (Spruce) Schiffn., the second largest genus of Lejeuneaceae, is the most dominant genus of epiphyllous liverworts. Different from most other genera of leafy Hepaticae, the generic and subgeneric concept of *Cololejeunea* has been long disputed. In China, *Cololejeunea* is the largest genus of Hepaticae. However, the genus has not been revised. The present paper presents a taxonomic revision. Four traditional subgenera are accepted: subg. *Aphanolejeunea*, subg. *Chlorolejeunea*, subg. *Cololejeunea*, subg. *Leptocolea*. Subg *Pedinolejeunea* and *Chlorocolea* are proposed as synonyms of subg. *Chlorolejeunea*. *Cololejeunea calcarea*, *C. amoena, C. plagiophylla*, *.C. reinecheana*, and *C. yoshinagana* is excluded from China. *Cololejeunea shimizui* subsp. *shihuishanensis* were moved to *Chondriolejeunea*, and it is a synonym of *Chondriolejeunea chinii*. A total of 72 species are recognized in China. A key to subgenera and species in China is provided. Taxonomic notes, distribution, and habitats of each species are presented.

P0896. Tree fern phylogeny revealed by the simultaneous analysis of 8kbp of plastid DNA sequence data

P. Korall[1,2], K. M. Pryer[1], J. Metzgar[1], H. Schneider[3], D. S. Conant[4];
[1]Department of Biology, Duke University, Durham, NC, United States, [2]Swedish Museum of Natural History, Stockholm, Sweden, [3]Albrecht-von-Haller Institute of Plant Sciences, Georg-August University Göttingen, Goettingen, Germany, [4]Natural Science Department, Lyndon State College, Lyndonville, VT, United States.

Tree ferns are a large monophyletic group of mainly tropical leptosporangiate ferns, comprising approximately 600 species in seven families, the largest being Cyatheaceae (scaly tree ferns). Despite the name, not all tree ferns are arborescent: Metaxyaceae have long creeping rhizomes and Hymenophyllopsidaceae are diminutive. Although tree ferns hold a prominent position in fern phylogeny as sister group to the polypods (>80% of living fern species), relationships among major tree fern lineages have been elusive until now. Here, using a taxonomic sampling of 70 species, we reveal tree fern relationships based on 8 kbp of plastid DNA sequence data from coding and non-coding regions. In previous single-gene analyses, tree ferns were shown to have remarkably short branch lengths relative to most other ferns, and were labelled "molecular living fossils" in keeping with their relative morphological stasis for the past 200 million years. We ascertain that tree ferns have indeed undergone dramatic decelerations in their rates of molecular evolution. Possible explanations are considered in the context of tree fern ecology and life history patterns.

P0897. Higher spore-bearing plants collection in outdoors in the O.V. Fomin Botanical Garden

O. V. Vasheka;
O.V. Fomin Botanical Garden of the Taras Shevchenko Kyiv National University, Kyiv, Ukraine.

The collection of higher spore-bearing plants in outdoors was started in 1966 with a few common species. The exposition has been obtained by culture from spores and living plants from expeditions to the Far-East, Caucasus, Altai, Crimea, Carpathians, etc. The collection contains at present 120 taxa. There are 82 species, 6 subspecies, hybrids and varieties and 32 cultivars of ferns and horsetails. On the exposition plot grow the representatives of *Ophioglossaceae*, *Botrychiaceae*, *Osmundaceae* (sp. of genus *Osmunda, Osmundastrum*), *Onocleaceae* (sp. of genus *Onoclea, Matteuccia*)*, Athyriaceae* (sp. of genus *Athyrium, Cornopteris, Cystopteris, Diplazium, Gymnocarpium,* etc.), *Blechnaceae*, *Dryopteridaceae* (sp. of genus *Cyrtomium, Dryopteris, Polystichum*), *Hypolepidaceae*, *Thelypteridaceae* (sp. of genus *Phegopteris, Thelypteris,* etc.), *Adiantaceae*, *Aspleniaceae* (sp. of genus *Asplenium, Phyllitis*), *Woodsiaceae*, *Polypodiaceae*. There are two rare species of Ukraine in collection *Asplenium adiantum-nigrum, Woodsia ilvensis.*

P0898. Diversity of Pteridophytes in China

W. Bao[1], P. Pei-shanWang[2], C. Aur[3], X. Ji[1], J. Cao[4];
[1]Department of Biology, Harbin Normal University, China, Harbin, China, [2]academy of sciences, Guizhou Province, Guizhou, China, [3]College of Forest, Northeast Forestry University, China, Harbin, China, [4]Science and Environment College, Shanghai Normal University, China, Shanghai, China.

This video, introduces the diversity of pteridophyte in China, containing over 100 living species of ferns and fern allies. The first part demonstrates the sporophytes from NE to SW China. They are the representative of the Chinese pteridophytes, involving all the five subdivisions, i.e. Psilophytina, Lycophytina, Isoephytina, Sphenophytina and Filicophytina (Ching's system). The main body of this part deals with their form and structure. Geographically, there are not only the East Asia or Chinese endemic species, but also tropical and temperate members. Ecologically, various habitats are presented so as to understand why such a group of ancient plants is still flourishing in the world today. The second part records the diversity of the gametophytes of pteridophytes based on our own work. Like their sporophytes, they vary from each other in both adult prothallia and their whole course of developingment. Four typical patterns of gametophyte development, the Osmunda type, the Adiantum type, the Ceratopteris type and the Aspidium type, are pictured in detail. Spore morphology and apogamy, which also tell us the diversity of gametophytes, are given by tableaux.

P0899. The influence of soil evolution on pteridophyte diversification

M. Lehnert, M. Kessler, H. Schneider;
Albrecht-von-Haller-Institut für Pflanzenwissenschaften, Abt. Systematische Botanik, 37073 Göttingen, Germany.

We combined ecological data with phylogenetic analyses to evaluate the potential role of soil differences on the diversification of pteridophyte lineages. We hypothesize that three crucial changes took place during the evolution of modern angiosperm forests: the development of a dark understory, of canopy habitats sites suitable for epiphytes, and of nutrient-rich soils fertilized by angiosperm leaf litter and decaying wood. Basal pteridophyte taxa, which appear to be obligatory mycorrhizal, evolved on nutrient-deficient raw soils, acidic soils derived from gymnosperm litter, or peat soils on water-logged sites. The evolution of angiosperms resulted in improvement of soil nutrient conditions, triggering several radiations of pteridophytes, especially among the modern ferns (polypod) that are factultatively mycorrhizal, but also among some basal lineages that managed to adapt to nutrient-rich soils. In contrast, basal lineages restricted to "ancient" soil types are currently species-poor.

P0900. New data of early leaf development of Ophioglossum vulgatum L. (Ophioglossaceae).

M. S. Nuraliev, A. S. Beer;
Moscow State University, Moscow, Russian Federation.

The process of growing of the leaf and sheath from the apex of rhizome is the feature that can help in understanding of the phyllotaxy and even the taxonomy location of this species and its variations. We found out that the bud includes several (4-5) leaf primordium. Apex is situated lower then all the leaves. Every primordium is covered with its own sheath, and there is a cavity between them. Leaves are considered to grow, using cavities of the previous ones, but our data confutes this opinion. Cavities are not connected to each other, and all the leaves are embedded to the common tissue. Discover individual sheaths in this common tissue is quite difficult. New leaf doesn't grow to the cavity of the previous one and doesn't rupture the sheath of the previous leaf, but develops independently. Studying structure of three rhizomes on the transverse sections, we found no pores or holes between cavities there. Primordium-sheath complex develops, expanding and elongating, then growing of the sheath inhibits, and leaf perforates it. As a result, every petiole surrounded with a "collar".

P0901. Reticulate evolution of *Vandenboschia radicans* complex (Hymenophyllaceae) in Japan with special reference to its hybrid-dominant tendency

A. Ebihara[1], H. Ishikawa[2], S. Matsumoto[3], K. Iwatsuki[4], M. Ito[1];
[1]The Univeristy of Tokyo, Tokyo, Japan, [2]Chiba University, Chiba, Japan, [3]The National Science Museum, Tsukuba, Japan, [4]The Univeristy of the Air, Chiba, Japan.

Vandenboschia radicans complex is a filmy fern group distributed throughout the world, and was formerly considered as a cosmopolitan species. Plants of this complex are not rare in shady moist places of the Japanese Archipelago. Although four taxa are said to be present within quite a wide range of its morphological variation, boundaries between them are in fact ambiguous.
Our study combining ploidy, CpDNA (*rbcL*) and nrDNA (*GapCp*) analyses has clarified that it is a hybrid complex containing diploid, triploid and tetraploid originated from complicated hybridizations and polyploidizations involving at least three parental diploid species. Sterile triploids show much wider distribution than fertile diploids/tetraploids, and grow in localities where no fertile individuals are found. Nevertheless genetic variation of triploids suggests they are of recurrent origins (i.e. they are never asexually reproduced clones). We discuss the reproductive system of these hybrid triploids, including the possibility of the involvement of independent gametophytes in it.

P0902. The study of morphology, sporology and anatomy of different species of the genus: *Polystichum* along with introducing the new species: *Polystichum setiferum* in Iran

A. Mazooji, F. Fallahian, T. Nejad Sattari;
IAU-Roodehen branch, Roodehen, Islamic Republic of Iran.

The genus *Polystichum* is one of the species of *Dryopteridaceae*. Distribution of this genus in Iran is mainly in humid woodlands regions of Caspean Sea coasts in Hyrcanian phytogeographical region and sometimes within rock slots in timberline.
Wendelbo(1976) introduced three species of this genus named *Polystichum braunii* (Spenner) Fee., *Polysthicum aculeatum* (L.) Roth and *Polystichum* woronowii Fomin in Mon., which the last is classified a Hyrcanian plant.
In the current study on the ferns of Northern Iran, the species *Polystichum setiferum* (Forskal.) Woynar, is introducing in Iran for the first time.
However, the anatomy, sporology, morphology and sporange of various species of this genus in Iran are studied; distribution map and determination key are provided.

P0903. A new checklist of north Iran ferns

A. Mazooji[1], F. Fallahian[2];
[1]Azad university, roodehen branch, Tehran, Islamic Republic of Iran,
[2]Azad university, research and science branch, Tehran, Islamic Republic of Iran.

In a new study on the north Iran ferns, conducted in the hyrcanian phytogeographic region during the years 2001 to 2003, a total of 3 orders, 14 families, 22 genera and 40 species have been reported. In comparison to the reports of Wendelbo (1976), Denk (1998) and Jenkins (1980) which reported a total of 32 species for north Iran, this study has reported 8 new species, four subspecies and one variety in the Iranian flora for the first time.
The new species include:
1. Asplenium onopteris L.
2. Athyrium distentifolium Tausch ex Opiz.
3. Dryopteris caucasica (A. Braun) Frazer-Jenkins & Jermy
4. Dryopteris carthusiana (Vill.) H. P. Fuchs
5. Dryopteris dillatata (Hoffm.) A. Gray
6. Dryopteris expansa (C. Presl.) Frazer-Jenkins & Jermy
7. Dryopteris oreades Fomin
8. Polystichum setiferum (Forskal.) Woynar
The subspecies include:
1. Dryopteris affinis sub sp. Affinis
2. Dryopteris affinis sub sp. Borreri
3. Asplenium trichomanes sub sp. Trichomanes
4. Asplenium trichomanes sub sp. Pachyrachis
And the new variety is Thelypteris palustris var. thelypteriodes.

P0904. Introducing new species of genus: *Dryopteris* along with morphology, sporology and anatomical studies and proposition of its determination key and distribution map in Iran

M. Baghi, A. Mazooji, F. Fallahian;
IAU-Roodehen branch, Roodehen, Islamic Republic of Iran.

The genus *Dryopteris* belongs to *Dryopteridaceae* family. This genus have a great morphological diversity in Iran and its distribution is mainly in humid woodland regions from low altitude of Caspian Sea coasts to timberline in Hyrcanian phytogeographical region.
Wendelbo(1976) introduced three species: *D. filix-mas* (L.) SCHOTT, *D. borreri* NEWMAN and *D. pallida* (Bory) FOMIN for Iran flora.
Jenkins(1980) introduced *D. affinis* along with two subsp. named *D. affinis* subsp. *coriacea* and *D. afinis* subsp. *persica*.
In current study on ferns of Northern Iran, five new species of this genus named *D. caucasica* (A. Braun) Frazer-Jenkins & Jermy, *D. carthusiana* (Vill.) H. P., *D. expansa* (C. Presl.) Fraser Jenkins & Jermy, *D. dillatata* (Hoffm.) A. Gray and D. oreades Fomin. Have introduced for Iran flora.
Finally, along with anathomy, sporology and morphological studies, the determination key and distribution map of these species are provided.

P0905. Spore Morphology of the Caucasus Fern Species

M. R. Bokeria;
Georian State Museum, Tbilisi, Georgia.

Ferns are rather important component of the Caucasus flora, especially, in Colchic and Tallish refuge. Pteridophyta of the Caucasus presents 70 taxon , that belong to 31 genera. 25 species are common with the North American ferns. New data on spore morphology for 65 species (47monolete-trilete18) are given. The measurements of spores were made on the acetolyzed material, perisporium sculpture by SEM. Descriptions and microphotographs are presented. 7 main spore types are revealed. The data provides information for certain species, such as critical taxsons of genera (Asplenium, Cystopteris, Dryopteris, Polystichum, Woodsia). The structural peculiarities of the spores, gives us possibility to discuss available relationship between taxons and ploidy level.
The altitudinal distributions of each species and its habitat requirements, possible relationships are discussed.

P0906. Molecular phylogeny of *Danaea* Sm. (Marattiaceae).

M. J. M. Christenhusz[1], K. M. Pryer[2], J. Metzgar[2], H. Tuomisto[1];
[1]Department of Biology, University of Turku, Turku, Finland,
[2]Department of Biology, Duke University, Durham, NC, United States.

The taxonomy and ecology of the neotropical fern genus *Danaea* (Marattiaceae) have been mostly neglected. However, an ongoing revision of *Danaea* for the Flora of the Guianas, Flora of Bolivia, and Flora Neotropica has led to the description of several new species. In turn, recent field studies have yielded an extensive collection of herbarium and silica-gel specimens of all species of *Danaea*. Here, we present the first phylogenetic estimate of relationships within *Danaea* based on a broad sampling of 70 specimens from various ecological and geographical sites using DNA sequence data from three plastid regions (*atpB*, *rbcL* and *trnL-F*). Taxa from *Angiopteris*, *Archangiopteris*, *Christensenia,* and *Marattia* are used to root the tree. We identify three major clades within *Danaea* corresponding to rhizome symmetry: one clade, consisting of all species with erect rhizomes, is sister to the other two clades where all taxa have creeping rhizomes. This phylogeny provides us with an explicit framework for addressing questions related to the morphological, ecological, and biogeographical evolution of these ferns, all of which are crucial to a modern revision.

P0907. Molecular phylogeny of the Ophioglossaceae inferred from *rbcL* sequences with special emphasis on the genus *Mankyua*

B. Y. Sun[1], C. H. Kim[1], Y. Kim[2], C. W. Park[3], M. H. Kim[4], C. S. Kim[5];
[1]Chonbuk National University, Jeonju, Republic of Korea, [2]Hallym University, Chuncheon, Republic of Korea, [3]Seoul National University, Seoul, Republic of Korea, [4]Jeju National University, Jeju, Republic of Korea, [5]Instutute of Warm temperature forest research, Seogyupo, Republic of Korea.

Ophioglossaceae comprises four genera including *Botrychium* s.l., *Helminthostachys*, *Ophioglossum* s.l., and *Mankyua* which was recently described from Jeju Island, Korea. The *rbcL* sequences from 31 species of Ophioglossaceae were analyzed using maximum parsimony analysis. Parsimony analysis resulted in eight equally parsimonious trees, which differed mainly in terminal relationship within *Ophioglossum* group. The trees obtained have a length of 811 steps with consistency index of 0.5338 and retention index of 0.8225. In the consensus tree, the monophyly of the family Ophioglossaceae was well supported. In addition, the tree suggested the presences of two major clades within the family; they represent the Ophioglossoid and Botrychioid lineages. The former lineage corresponds to the genus *Ophiglossum* s.l., and the latter lineage includes the remaining three genera. Within the Botrychiod lineage, *Helminthostachys* and *Mankyua* appeared to be sister to the *Botrychium* s.l., but the relationship was not strongly supported.

P0908. Morphological and chromosomal variation of the *Dryopteris varia* complex (Drypoteridaceae) in Korea

S. Lee, **C. Park**;
Seoul National University, Seoul, Republic of Korea.

Dryopteris Adans. is a highly variable genus including more than 200 species worldwide. We have examined the variation in morphology, chromosome numbers and reproduction modes among Korean populations of the *D. varia* complex. Numerical analyses (landmark analysis and principal components analysis) revealed seven entities within the *D. varia* complex in Korea; these comprise *D. varia*, *D. pacifica*, *D. sacrosancta*, *D. bissetiana*, *D. saxifraga*, *D. saxifragi-varia*, and the Suak population which is considered to be a new taxon. Mitotic chromosome counts and examination of reproduction modes indicated that *D. bissetiana* in Korea appears to be agamosporous with diploid or triploid chromosome numbers. However, *D. saxifraga* is sexual diploid or agamosporous triploid, and the other taxa are agamosporous triploid. *Dryopteris bissetiana*, *D. saxifraga* and *D. saxifragi-varia* are similar in major morphological characteristics, but show differences in attachment and shape of rachis scales. The results also suggest that agamosporous triploid *D. saxifragi-varia* was probably derived from hybridization between sexual diploid *D. saxifraga* and *D. bissetiana.*

P0909. When and where Polystichum s.l. originated? Evidences from molecular data

C. Li[1], S. Lubinski[2], Q. Yang[1];
[1]State Key Laboratory of Palaeobiology and Stratigraphy of Nanjing Institute of Geology and Palaeontology, Chinese Academy of Science, Nanjing, China, [2]Institute of Ecology and Geobotany, Yunnan University, Kunming, China.

Polystichum Roth is a nearly worldwide genus with its diversity center in southwest China and adjacent regions. In this study, 60 *rbc*L sequences of *Polystichum* species, including 23 new sequences from southwest China, were used to assess the phylogenetic relationships within the genus; on the basis of estimated evolution rate of *rbc*L and the relative-rate tests results, the divergence time between major clades were further estimated. The phylogenetic results reveal that all species of *Polystichum* s.l. in this study (including *Cyrtomium* and *Cyrtomidictyum*) form a monophyletic group. The basal split in *Polystichum* s.l. separates a clade with all Asian members from a clade containing other species from all over the world. The divergence time estimation results suggest that *Polystichum* s.l. originated in Asia in the late Late Cretacous (å76 Ma) and migrated into other places in the world in early Eocene (å46 Ma).

P0910. Phylogenetic Relationships of the Neotropical Species of *Polypodium* (Polypodiaceae) based on Morphology evidence

J. D. Tejero-Díez[1], L. Pacheco[2], T. Terrazas Salgado[3];
[1]Universidad Nacional Autónoma de México. Facultad de Estudios Superiores Iztacala. Carrera de Biología., Tlalnepantla, Estado de México, Mexico, [2]Universidad Autónoma Metropolitana-Iztapalapa. Depto. de Biología-Área de Botánica Estructural y Sistemática Vegetal, México, D. F. (City), Mexico, [3]Colegio de Posgraduados, Programa de Botánica, Montecillo, Estado de México, Mexico.

In this study a list of 65 characters and character states were used to fulfill a cladistic analysis of 35 *Polypodium* species based on morphological, anatomical and spore characters using PAUP version 3.1. These characters were unordered and unweighted. The sequence of random addition was done using MULPARS. The polarization of the characters was assessed using the standard procedure of outgroup comparison with *Polypodium californicum.* The analysis obtained produced 192 cladograms with a consistency index of 0.52, a homoplasy index of 0.062 and a retention index of 0.683. All the cladograms agreed on the following points: to reorganize the several groups of the genus, therefore to realize that we are naming *P. colpodes* group with 5 species, *P. plesiosorum* group with just 3 species, *P. dulce* group with *P. martensii* and relatives and *P. fraternum* group with *P. echinolepis* and relatives. We indicate the taxonomic affinity of *P. fallax*, *P. feuillei*, *P. kunzeanum*, *P. pleurosorum* and *P. rhachipterygium*. As well as we suggested the redefinition of *Pleopeltis* and *Phlebodium* genus.

P0911. Phylogenetic relationships in Pteridaceae inferred from chloroplast *rbcL* nucleotide sequences

M. L. F. Salatino[1], **J. Prado**[2], A. Salatino[1];
[1]Universidade de São Paulo, São Paulo, Brazil, [2]Instituto de Botânica, São Paulo, Brazil.

Pteridaceae are ferns distributed worlwide, with most genera centered in the tropics, usually with adaptations to xeric habitats. Most fern phylogenetic studies have relied upon *rbcL* sequences. In the present investigation *rbcL* sequences of Pteridaceae species native in Brazil and representative of *Acrostichum*, *Adiantopsis*, *Adiantum*, *Cheilanthes*, *Doryopteris*, *Eriosorus*, *Hemionitis*, *Pellaea*, *Pityrogramma*, *Pteris* and *Vittaria* (Vittariaceae) were obtained. These sequences and GenBank *rbcL* data from representatives of *Anogramma*, *Ceratopteris*, *Coniogramma*, *Jamesonia*, *Microlepia* (Dennstaedtiaceae), *Notholaena*, *Platyzoma*, *Taenitis* and *Trachypteris* were analyzed using parcimony and *Microlepia strigosa* as outgroup. The results indicate that Pteridaceae *sensu* Tryon et al. is paraphyletic, Pteridoideae, Cheilanthoideae *sensu* Tryon et al. and *Pteris* are polyphyletic. Adiantoideae, Ceratopteridoideae and Taenitidoideae are monophyletic. *Pteris cretica* from the Old World is sister to most neotropical *Pteris* species, while *Pteris vittata* clades with *Platyzoma*. *Acrostichum* (Pteridoideae) clades with *Ceratopteris* (Ceratopteridoideae).

P0912. A systematic study of the fern genus Polystichum (Dryopteridaceae) in Japan

M. Nagamoto[1], A. Ebihara[2], K. Iwatsuki[3], S. Lin[1];
[1]Dept. Biological Science, Shimane University, Matsue, Japan, [2]Graduate School of Arts and Science,University of Tokyo, Tokyo, Japan, [3]Museum of Nature and Human Activities, Hyogo, Japan.

Hybridization and polyploidization play the important roles in species diversification and reticulation in the fern genus *Polystichum.* In this study, morphological, cytological and electrophoretic investigations were undertaken in eleven Japanese *Polystichum* species. The polyploidy and genetic patterns of four diploid species and seven tetraploid species were determined. The spore morphology showed the distinct characters in each diploid species, but intermediate among tetraploid species. Electrophoretically, the species-specific marker alleles were detected in four loci of PGM, PGI, SkDH, LAP enzymes in each of four diploid species *P. fibrilloso-paleaceum, P. igaense, P. retroso-paleaceum, P. otomasui.* Electrophoretic variants were detected in the tetraploid species *P. longifrons*, *P. tagawanum* and *P. polyblepharum* (all of them were allopolyploids). Further, six triploid hybrids and five tetraploid hybrids were examined morphologically and erectrophoreticlly, and the putative parents of these hybrids were confirmed. Based on the above, the reticulate evolution of the Japanese *Polistichum* is discussed.

P0913. Phylogenetic studies in the genus *Doryopteris* J. Sm. (Cheilanthoideae-Pteridaceae)

J. C. Yesilyurt[1,2];
[1]Royal Botanic Gardens, Kew, Surrey, United Kingdom, [2]The Natural History Museum, London, United Kingdom.

Doryopteris is the fourth largest genus of Cheilanthoideae-Pteridaceae. A number of species appeared to be congeneric mainly on the basis of soral condition and some of them proved difficult to classify within the genus or in related genera (*Cheilanthes*, *Pellaea* and *Notholaena*). The research was carried out in order to elucidate interspecific relationships within *Doryopteris* and to formulate evolutionary hypothesis of its relationships with the related genera. Data from cpDNA sequences (*trn*L-F and *rbc*L) and morphology were analysed independently and in combination using maximum parsimony. *Doryopteris* is paraphyletic according to the molecular data and polyphyletic with the combined analysis. However, the topologies are congruent with the two sections recognised by Tryon. Cytological data indicate that hybridisation and polyploidy are also playing a role in the evolution of this genus.

P0914. The study of morphology, sporology and anatomy of the species of the genus: *Athyrium*, along with introducing the new species: *Athyrium distentifolium* in Iran

S. Haghighi, A. Mazooji, F. Fallahian;
IAU-Roodehen branch, Roodehen, Islamic Republic of Iran.

The genus *Athyrium* belongs to *Athyriaceae*. Distribution of this genus in Iran is mainly in humid woodlands regions of Caspean Sea coasts in Hyrcanian phytogeographical region and sometimes within rock slots in timberline.

Wendelbo(1976) introduced a species of this genus named *Athyrium filix-femina*.

In current study on the ferns of Northern Iran, the species *Athyrium distentifolia* Tausch ex., is introducing in Iran for the first time.

Noting to morphology, anatomy, sporology - and partly echological - characteristics, could have been differentiated this specis with its neighboring species.

The species *A. distentifolium* contains orbicular sour, without indosium - or soon lost - and spinuluse spores. In transverse sectioning, petiole is siphonostele with six meristele.

The anatomy, sporology and morphology of this genus in Iran are studied and distribution map and determination key for its species are provided.

P0915. Palinology of twenty five species of the genus *Diplazium* (Woodsiaceae).

L. Pacheco, A. Sánchez Morales, M. B. Jarquin Pacheco, S. Mendoza Mociño;
Universidad Autónoma Metropolitana-Iztapalapa. Departamento de Biología-Área de Botánica Estructural, México, D. F., Mexico.

The palinology of *Diplazium* species is studied as a contribution to the knowledge of the genus to ascertain its utility for the delimitation of close species and study the possibility to segregate groups or subgenus of *Diplazium*. Some of the spores were collected in the field, some others were taken from herbarium sheets. The spores were set on a coal tape and this one on a small aluminum stick. Some of the spores were broken to see the spore structure, later on they were covered with coal dust and gold. The micrographs were taken using a Scanning Jeol 35CF microscope. *Diplazium* spores are monolete, 25-75 µm, with a linear aperture 2/3 to ¾ their length. The aperture, however, is often obscured by broad perisporal wings. In most species these wings have irregular margins, but in others are almost entire to fimbriate. Sometimes, the perisporal wings make a wide reticulate, in other times are irregular or make a cristate pattern. The exospore is plain. The perispore usually is of two layers, the lower of which has small papillae, whereas the upper layer is thinner and fragile. The elements between the folds are part of the perispore and they are variable between species.

P0916. Anatomy of Thirty Species of *Diplazium* (Woodsiaceae)

S. Mendoza Mociño, **L. Pacheco**, M. B. Jarquin Pacheco, A. Sánchez Morales;
Universidad Autónoma Metropolitana-Iztapalapa. Departamento de Biología-Área de Botánica Estructural, México, D. F., Mexico.

The anatomical studies of thirty Neotropical species of *Diplazium* are providing to contribute to the knowledge of the genus and to ascertain its utility for the delimitation of species. Roots of all the species are diarch, with a dictyostelic rhizome, a petiole with three possible xylem strands shapes: hippocampus, elliptical or walking sticks; in the distal petiole or in the rachis the strands are united in a single strand with rounded U or squared U shape. There are mucilage cavities in the xylem parenchyma of the leaf trace. The cortex of the root, rhizome and stipe has starch grains; cells with dense brown content are disposed near or around the meristeles, leaf traces, veins or medulla are present in almost all the species studied. In general the data show that the species present similar anatomy, each one can be differentiated from the others by its shape of the leaf trace, number of caulinar meristeles and distribution of brown content cells. The conclusions confirm the usefulness of anatomical and histochemical characters to delimitate species.

P0917. To a question on systematization *Ducampopinus krempfii* (Lecomte) *A. chev.* (Pinaceae)

T. Arseneva;
Botanical institute RAS, Saint-Peterburg, Russian Federation.

The structure of bark Ducampopinus krempfii till now remained unexplored. We carried out studying anatomy of young branches of this plant. Investigated by us taxon finds out similarity to Pinus, Keteleeria and Pseudolarix, however on the majority of attributes of a structure of a bark is closer only to first two. Third rather strongly differs on a lot of attributes: the form of cells of epidermis - ellipse; the form of cells of hypodermis; presence in an initial bark sclereids; under the form of cells of phellem in periderm-rectangular or square and some to other attributes. At the same time, at both genus's in a bark is absent resiniferous system and dominate numerous slime idioblastes, quantity crystal parenchyma unsignificantly and is absent typical aerenchyma that specifies doubtless related affinity of these two genus's. Most precise difference Ducampopinus from relatives to it of sorts Pinus and Keteleeria is absence in an initial bark resin ducts and homogeneous phellem of periderm. Results of our anatomic research Ducampopinus represents close, but independent taxon in a rank of independent genus Ducampopinus.

P0918. Were Mesozoic Ginkgophytes Shrubby?

W. A. Green;
Department of Geology, Yale University, New Haven, CT, United States.

Data on leaf morphology in the Mesozoic of North America shows a proportional increase of bifurcated, Ginkgo-like leaves during the middle of the Jurassic. This ginkophyte acme is correlated with a decreased proportion of the leaf forms associated with herbaceous or shrubby pteridophytes, and with no substantial change in the proportion of leaf forms associated with canopy gymnosperms. The increase in Ginkgo-like foliage at the same time as fern-like forms decreased in relative abundance suggests replacement of some part of the forest understory by early ginkgophytes. That is, early ginkgophytes were competing for space in the understory rather than in the canopy. This data suggests that most Mesozoic ginkgophytes were not canopy trees like the surviving Ginkgo biloba, but shrubs, and may support the argument that has already been made from sedimentological data, that to a much greater extent than do individuals of Ginkgo biloba now cultivated around the world, many ancestral ginkgophytes pursued ruderal or early-successional strategies.

P0919. Young crown groups in *Gnetum* and *Ephedra* - reconciling molecular age estimates and fossils in Gnetales

H. Won[1,2], S. S. Renner[3];
[1]University of Missouri-St. Louis, Department of Biology, St. Louis, MO, United States, [2]Seoul National University, School of Biological Sciences, Seoul, Republic of Korea, [3]Ludwig Maximilians University Munich, Munich, Germany.

Gnetales comprise *Gnetum* (35 spp.), *Welwitschia* (1 sp.), and *Ephedra* (35+ spp.). An *rcbL* clock gave an age of 32-8 my for the initial divergence among living species of *Ephedra* (Huang & Price 2003), yet fossils with modern reproductive characters existed 110 mya (Rydin et al. 2004; Yang et al. 2005). Using slow-evolving *rbcL* and fast-evolving *matK* for dense species samples, we estimated the ages of the initial divergences in *Ephedra* and *Gnetum*. Both genes, regardless of seed plant topology and clock approach used, yield basal divergences in *Gnetum* of 22-14 my and in *Ephedra* of 16-2 my. The ca. 35 species in each genus appear the result of recent radiations from ancestors that kept certain morphological traits (unknown for *Gnetum*), while congeners went extinct. This seems as plausible as extant species being of Mesozoic age (Rydin et al. 2004). If true, the ages of the *Gnetum* clades (S American (African, Asian)) imply that the genus reached its distribution across water (n.b., some *Gnetum* have buoyant seeds). Recent speciation esp. in Asia would explain the limited morphological divergence, overlapping distribution ranges, and incomplete concerted evolution in rITS.

P0920. Phylogeny within Cupressus L. with morphological data

P. Knopf, C. Schulz, T. Stützel;
Special Botany, Ruhr-University, Bochum, Germany.

Recent studies on the phylogeny of Cupressus L. are mostly based on molecular data. Even if morphological data are considered then they are often incomplete and sometimes even not correct, because they are based on outdated information. Moreover, none of these trees includes all species of the genus. The understanding of evolution requires careful morphological interpretation of such phylogenetic trees. For the present study, a cladogram was calculated including each Cupressus species (incl. Xanthocyparis FARJON & HIEP) for the first time. This cladogram is based on a matrix of characters resulting from new morphological investigations and critical literature analysis as well. The topology resulting from this study fits well to the spatial patterns of the species. The two species of Xanthocyparis (Xanthocyparis vietnamensis FARJON & HIEP, Xanthocyparis nootkatensis (D. DON) FARJON & HARDER syn. Chamaecyparis nootkatensis (D. DON) SPACH) appear in different positions within Cupressus, therefore the genus has to be included in Cupressus.

P0921. Jurassic *Araucaria*from the sauropod dinosaur bonebed at Howe Ranch, Wyoming: the power food of the giants?

C. T. Gee[1], M. Clauss[2,3], J. Hummel[4,2];
[1]Institute of Paleontology, University of Bonn, Germany, [2]Institute of Animal Physiology, Physiological Chemistry and Animal Nutrition, University of Munich, Germany, [3]Division of Zoo Animals and Exotic Pets, University of Zurich, Switzerland, [4]Institute of Animal Nutrition, University of Bonn, Germany.

Nearly all specimens of a new flora from a dinosaur bonebed (G Quarry, Howe Ranch, Wyoming) in the Late Jurassic Morrison Formation pertain to various plant organs of *Araucaria.*Large, squat cones with partially fused ovuliferous scale-bract complexes which are shed at maturity represent the ovulate strobili. The ligulate, unwinged, single-seeded nature of the cone-scale complexes and the detached unwinged seeds show similarities to the extant species *A. bidwillii,*Section *Bunya.*Slender cones with long-bristled cone scales are likely microstrobili. Branches and twigs bearing rhomboidal, scale-like leaves of the form genus *Brachyphyllum*represent araucarian foliage and hint at locally arid conditions. Coniferous wood is also present in large quantities. Fermentation experiments with material from extant *Equisetum,*ferns, tree ferns, conifers, and selected basal angiosperms indicate that modern leaves of *Araucaria*spp. have a comparatively high energy content and nutritional value for browsing herbivores. Virtually the only fossil plant at the site, *Araucaria*may have played a major--if not exclusive--role in the diet of these gigantic sauropods.

P0922. Genetic variation of *Ginkgo biloba* based on RAPD, ISSR and PCR-RFLPs

Y. X. Qiu, W. Gong, C. X. Fu;
Lab of Systematic and Evolutionary Botany, College of Life Sciences, Zhejiang University, Hangzhou, China.

Ginkgo biloba is referred as a “living fossil” plant. As a wild species, it is native to China. Patterns of cpDNA variation were studied in 220 individuals from 15 populations inside and outside China. Six populations in China were selected to analyze population differentiation using ISSR and RAPD markers. Results show *PPB* = 73.86% in ISSR and *PPB* = 68.04% in RAPD. Combined data indicated relatively high H_E = 0.2408, *H*o =0.3599 in species level. Possible natural populations possessed higher genetic diversity. Differentiation among populations is 28%. Restriction analysis of PCR-cpDNA fragments was employed to identify the distribution of haplotypes. There were 19 haplotypes in two combinations. Hapotype A was the most frequent haplotype, found in all populations. Haplotype B, G and H represented 11.4%, 16% and 5% of the total samples. Other 15 haplotypes were very rare, but some of them were informative. Distribution of haplotypes revealed diversity center lies in Guizhou and Congqing of Southern China, possible natural populations. Combined ecological and genetic data, Two conservative strategies are proposed.

P0923. Fine morphology of peculiar reticulate pollen from the Permian of Russia

N. Zavialova[1], A. Gomankov[2];
[1]Paleontological Institute of the Russian Academy of Sciences, Moscow, Russian Federation, [2]V. L. Komarov Botanical Institute, Russian Academy of Sciences, St.-Petersburg, Russian Federation.

The morphology of dispersed pollen of Reticulatina from the Permian of the Russian Platform was studied. We found individual pollen grains showing reticulate pattern both under LM and SEM (group 1) and a different set of specimens (group 2) with the inner reticulum visible only under LM. With SEM, group 1 exhibits a coarser reticulum in the center of the pollen grain and a finer peripheral reticulum. The ectexine includes perforated tectum, spongy infratectum with rather regular short partitions, and foot layer. The thick endexine appears nearly homogeneous, but at places lamellate structures are distinguishable supporting that the endexine might have been ontogenetically lamellate. Group 2 shows a continuous and smooth tectum that completely hides the underlying layers when examined with SEM. Differing in the ultrastructure of ectexine, they are similar to group 1 in the endexine morphology. Although the pollen grains are of gymnospermous affinity, the similarity between the surface of Reticulatina (group 1) exine and that of Cretaceous angiosperm pollen is fascinating. The study is supported by the RFBR, no. 03-04-49611.

P0924. Morphology and development of seeds of *Zamia amblyphyllidia* D.W.Stev. (Cycadaceae) and *Ginkgo biloba* L. (Ginkgoaceae)

J. Obermann, T. Stützel;
Special Botany, Ruhr-University, Bochum, Germany.

Our investigations about the female reproductive structures of *Zamia ambliphyllidia* D.W.Stev. and *Ginkgo biloba* L. were focused on the initiation and the development of seeds. Studies were done by SEM and LM to compare the results with previous studies in other gymnosperms. These results show various similarities within all members of Cycads and *Ginkgo*, but several differences to the morphogenesis of seeds in most Conifers. The differentiation of the integument in a stony sclerotesta and a fleshy sarcotesta in *Ginkgo* and Cycads has been mostly regarded as a derived feature. A detailed comparison of these two taxa should show whether this resemblance is a homology or not, and if it has to be regarded as a plesiomorphic or an apomorphic character within gymnosperms. It is apparent that the sarcotesta in both Cycads and *Ginkgo* is not homologous to the sarcotesta in *Cephalotaxus*. The latter appears to be homologous to the aril in other Taxaceae.

P0925. A comparative study of the sarcotesta of *Cephalotaxus* Sieb. & Zucc ex Endl. and the aril of Taxaceae

I. B. Mundry, T. Stützel;
Lehrstuhl für Spezielle Botanik, Bochum, Germany.

The outer fleshy layer of the seed of *Cephalotaxus* was mostly regarded to be a sarcotesta and therefore as a structure completely different from the aril of Taxaceae. Therefore, the monogeneric family of Cephalotaxaceae was placed within the classical conifers distinct from Taxaceae, which was placed in their own order Taxales. In contrast to this view, recent molecular analyses group the Cephalotaxaceae and the Taxaceae as sistergroups within classical conifers. For a better understanding of these groups, we have studied the morphogenesis, the morphology and the anatomy of the female reproductive structures of both groups by SEM and light microscopy to search for morphological homologies which support the high affinity of both families in molecular analyses.

We found that the sarcotesta of *Cephalotaxus* exhibit a striking similarity to the aril of *Taxus* L. and *Torreya* Arn.*,* while the sarcotesta of *Zamia* and *Ginkgo* differs markedly from the fleshy layer of *Cephalotaxus*. Therefore, the clustered position of *Cephalotaxus* and the rest of Taxaceae is also supported by morphological characters and *Cephalotaxus* might be best included in Taxaceae.

P0926. Early lignophyte trees

A. Decombeix, B. Meyer-Berthaud, J. Galtier;
CIRAD, Montpellier, France.

Early evolution of the tree habit in the lignophyte clade is poorly understood and patterns of diversification of the trees that replaced the progymnosperm genus *Archaeopteris* around the Devonian/Carboniferous boundary remain obscure. We focussed our research on woody axes from the marine deposits of Thuringia (Germany) and Montagne Noire (France) dating from the basal Mississipian (Tn2b-Tn3a). Such deposits are known to yield plant remains from a wide range of environments from lowlands to well-drained elevated areas. The axes show a broad diversity of stelar and wood anatomy and some represent new taxa. Genera previously described from younger deposits of northwestern Europe (i.e. *Protopitys*, *Eristophyton*) are also present, which widens their recorded occurrence stratigraphically to the basalmost Carboniferous, and geographically to the northwestern border of Gondwana. These results shed more light on the diversity of arborescent lignophytes soon after the D/C boundary, suggesting that they originated in the late Devonian while *Archaeopteris* was still flourishing.

P0927. On the systematic importance of the morphology and anatomy of the vegetative and reproductive organs in the Pinaceae

L. V. Orlova;
Komarov Botanical Institute RAS, St. Petersburg, Russian Federation.

Studies of different genera of Pinaceae have shown that various (partly new) morphological and anatomical characters (1) of both vegetative and reproductive organs are of great systematic value. In Pinus, these 1 include needles (their dimensions, number per brachyblast (2), shape (3) in cross-section and apex, degree of marginal dentation), sheaths of 2 and scale-like leaves (3 and color, arrangement on axis, morphology (4) of marginal fringes etc.), prophylls of 2 (sizes and 3, 4 of their carina), apical buds (dimensions and 3) and their scales (4 of marginal fringes), young shoots (thickness, hairiness, color etc.), microstrobili and microsporophylls (size and 3 of clusters of microstrobili and of each microstrobilus, 4 of supra-connective and connective), cones and their scales. Based on dehiscence type of paired microsporangia, genera of Pinaceae are referable to 3 groups: - a) dehiscence along transverse suture (Abies, Keteleeria, Tsuga, Pseudolarix), - b) along longitudinal-medial (Larix), and - c) along longitudinal ones (Pinus, Cedrus, Pseudotsuga, Picea). Within Pinaceae Pine species have the most specialized microsporophyll structure.

P0928. AFLP Phylogeny *versus* fossil evidences within genus Araucaria

V. M. Stefenon[1], O. Gailing[2], R. Finkeldey[2];
[1]Universidade do Planalto Catarinense, Lages, Brazil, [2]University Georg-August, Göttingen, Germany.

The genus *Araucaria* (Araucariaceae) includes four sections (19 extant species) restricted to the Southern hemisphere. The fossil register indicates that this genus was widespread also in the Northern hemisphere and denotes *Eutacta* and *Bunya* as the oldest sections. About 670 polymorphic AFLP markers were applied to analyse the phylogenetic relationships of seven species from three sections within genus *Araucaria* with a cladistic (parsimony) and a phenetic (NJ with Nei and Li genetic distance) approaches. Phylogenetic trees obtained from AFLP data are collinear with a *rbcL* tree and support the classification in sections according to morphological characters. Sections *Eutacta*, *Araucaria* and *Bunya* are supported as monophyletic groups by high bootstrap values in the AFLP analysis. In accordance with the fossil record section *Eutacta* has a basal position within genus *Araucaria*. However, section *Bunya* diverged latter and is sister to section *Araucaria*.

P0929. Cone and seed structure of *Thuja sutchuenensis*

A. V. F. Bobrov[1], M. S. Romanov[2,1];
[1]M. V. Lomonosov Moscow State University, Moscow, Russian Federation, [2]Main Botanical Garden nm. Tcitcin N. V. RAS, Moscow, Russian Federation.

Morphology and anatomy of cones and seeds of *Thuja sutchuenensis* (critically endangered endemic of south-west China) were studied in compare with other species of the genus. Mature cone is brownish, up to 1 cm; cone scales (8-10; 4-6 medial are fertile) up to 6.5 mm with 1-2 axillar seeds. Seed body is ellipsoidal lightly brown, up to 5 mm, with two equal lateral crescent-shaped wings. Seed coat is formed by exotesta (typical epidermis of cells with tannins in walls and pale lumens), mesotesta with resin ducts (12-13 layers of pale isodiametric cells with thickened unlignificated walls) and endotesta (1 layer of cells with thickened unlignificated walls and tannins in lumens). The structure of female fructifications of *Th. sutchuenensis* implies basal position of the species in the genus. Other *Thuja* species are characterized by more advance features of female fructifications, especially in the structure of seed coat (e.g. reduced number of cell layers of mesotesta). Supposedly, *Th. sutchuenensis* inhabits the ancient refugium of the genus, from where other representatives of *Thuja* distributed.

P0930. The genofund of conifers in Azerbaijan and the questions of its diagnostics.

Z. Gumbatov;
Azerbaijan Agricultural Academy, Ganja, Azerbaijan.

The conifers in Azerbaijan are represented with ancient relict and endemic taxons, which are similar but always complemented by scientific material. The high stability in different ecological conditions and conservatism of the conifers structures appeared during the evolution process.The paleobotanical researches conducted in Azerbaijan demonstrate that in the past geological epochs conifers took the dominant location.Our researches showed, in order to establish species characteristic of conifers, it is necessary to collate complex diagnostic elements including paleobotanical and phylogenetical data. Some ancient species (Taxus) require ultrastructural and morphophysiological researches as well as the diagnostical data. Based on the complex researches of the conifers of Azerbaijan the 3 species of Pinus, 7 species of Juniperus and 2 species of Taxus with new described species for science (T.talyschensis Gum.) have been established. The population of T. talyschensis is located on the upper border of the wood in Talish and there are about 100 of them. Their age is 1200-1400 years and they are in the process of degradation.

P0931. Assembling the tree of life for angiosperms

A. Atol-group;
University of Florida, Gainesville, FL, United States.

Angiosperms are the largest and economically most important group of green plants. Despite enormous progress, several major nodes remain unresolved. The Angiosperm ATOL (Assembling the Tree of Life) consortium will attempt to clarify relationships at 12 problematic nodes. Targeted sequencing of 17 genes (~25,200 nt), representing the three plant genomes, for 370 species will provide a backbone tree, and entire plastid genome sequences for 30 angiosperms will be combined with published data to resolve relationships among major clades. Four large clades_Malpighiales, Ericales, Lamiales, and campanulids_will be examined intensively. We will compare supertrees with trees obtained through analyses of supermatrices. A “Botany Browser” will serve as a portal to an informatics infrastructure that will bring varied data resources together on a user’s desktop. The Angiosperm MorphBank will archive annotated images of morphological features and will facilitate the diagnosis of clades, analyses of character evolution, and integration of fossils. This project will lay the groundwork for collaboratively building the tree of all 12,000 genera of angiosperms.

P0932. Cytotaxonomic congruence with five major clades in the Resedaceae based on ITS sequences.

S. Martín[1], M. Luceño[1], V. Valcárcel[1], **P. Vargas**[2];
[1]Universidad Pablo de Olavide, Sevilla, Spain, [2]Real Jardín Botánico, Madrid, Spain.

The Resedaceae (6 genera and c. 70 species) is widely distributed in the Old World, with some species in the New and a major center of diversity in the Mediterranean basin. Phylogenetic analysis of 62 ITS sequences reveal that *Reseda* (c. 60 species) is not a monophyletic group since two of the five major clades of Resedaceae include species of *Reseda* together with those of *Randonia* and *Oligomeris*. Two independent clades are in turn formed by *Sesamoides* and *Caylusea*. Three basic chromosome numbers (x = 5, 6, 7) and morphological characters served historically to circumscribe five sections in *Reseda*, taxonomic treatment mostly in agreement with the ITS phylogeny. Naturalness of smaller groups in *Reseda* implies: (1) monophyly of most conspecific populations; (2) three endemics to different Iberian mountain ranges (sect. *Glaucoreseda*). At least three independent dispersal events may have been involved in *Reseda* colonization and differentiation in the Canary Islands: *R. luteola* (Old World), *R. lancerotae* (endemic), and *R. scoparia* (endemic).

P0933. Revision of Butia (Becc.) Becc. (Butiinae, Cocoeae, Palmae)

A. C. Marcato, J. R. Pirani;
Instituto de Biociências, Universidade de São Paulo - IBUSP, São Paulo, Brazil.

Butia (Becc.) Becc. (Butiinae, Cocoeae, Palmae) is a neotropical genus composed by small to medium-sized palms that can be distinguished within other genera of the subtribe Butiinae by its strongly arched leaf rachis, smooth to sligthly striate peduncular bracts, which sometimes are densely tomentose, and for the endocarp pores located nearly to or slightly below to its equator it. *Butia* occurs mainly in the grasslands and open fields from Brazil to Argentina, Paraguay and Uruguay, a few of them reaching the Atlantic lowlands, in coastal forest and sand dunes. Eleven species are here recognized: *B. archeri*, *B. campicola*, *B. capitata*, *B. eriospatha*, *B. leiospatha*, *B. leptospatha*, *B. microspadix*, *B. odorata*, *B. paraguayensis*, *B. purpurascens* and *B. yatay*. Two new combinations and 4 synonyms are proposed. The study includes a taxonomic key to the species, illustrations and color plates of the habits, morphological details and leaflet anatomy of the species. On a conservational perspective, the majority of the species in the genus can be considered endangered, as they occur at places under strong pressure of land use interests

P0934. Asian origin, Mediterranean differentiation and back-colonization of ivies (Hedera L., Araliaceae)

V. Valcárcel[1], P. Vargas[2];
[1]Pablo de Olavide University, Seville, Spain, [2]Botanical Garden of Madrid, Madrid, Spain.

Placement of Hedera in molecular phylogenies, embedded in Asian lineages of the Araliaceae and the finding of the oldest Hedera macrofossil in Asia, supports the argument of Asia as the center of origin for ivies. The most relevant diversity center is in the Mediterranean, as revealed by morphology, ploidy variation -four ploidal levels in Mediterranean vs only diploids in Asia-, and chloroplast diversity -four chlorotypes (I, II, III, IV) in the Mediterranean vs one (III) in Asia. A comprehensive trnT-L chloroplast study, with special emphasis in Asian populations, confirms that the most ancient Hedera chlorotype (cpI) is confined to W Mediterranean basin; and the presence of a single, derived chlorotype (cpIII) in Asia. These results lead us to hypothesize a diploid (cpI) Asian Hedera colonizing the Mediterranean. Once established here, a profound morphological, cytogenetic and molecular diversification took place. In parallel an extinction of Asian ivies occurred. After this, diploid ivies with cpIII recolonized Asia producing a most limited diversification.

P0935. Plastid DNA phylogeny and the classification of palms

C. B. Asmussen[1], J. Dransfield[2], W. J. Baker[2];
[1]The Royal Veterinary and Agricultural Univeristy, Copenhagen, Frederiksberg, Denmark, [2]The Royal Botanic Gardens, Kew, London, United Kingdom.

During the last ten years a number of phylogenies have been published for the Arecaceae. We build upon these studies and include all genera of palms in a cladistic analysis of plastid DNA sequences. One species from each genus was included as placeholder and for most monogeneric tribes and subtribes several species were included. Ten species from the Commelinid clade of monocots were included as outgroups. Four plastid DNA regions were sequenced for all 220 species, *rbc*L, *trn*L-*trn*F, *rps*16 intron, and *mat*K. The parsimony analysis of the combined data sets resulted in a phylogeny with good resolution at the subfamily, tribal, and subtribal level. The results corroborated previous molecular phylogenies and resolved five subfamilies, Calamoideae, Nypoideae, Coryphoideae, Ceroxyloideae (including Phytelephantoideae), and Areoideae as monophyletic. Additionally, the tribes and subtribes within Calamoideae supported the classification of Baker et al.; the Coryphoideae and the Ceroxyloideae were well resolved at the tribal and subtribal level; leaving Arecoideae well-resolved at the tribal level but needing additional attention at the subtribal level.

P0936. Is the Straight of Gibraltar an effective barrier to gene flow in the wind-pollinated species Carex helodes Link (Cyperaceae)?: a molecular and cytogenetic approach.

M. Escudero[1], **V. Valcárcel**[1], P. Vargas[2], M. Luceño[1];
[1]Pablo de Olavide University, Seville, Spain, [2]Botanical Garden of Madrid, Madrid, Spain.

Carex helodes Link, previously thought to be endemic to SW Iberian Peninsula, has been recently found in a recent field campaign in northern Morocco. Phylogenetic reconstructions based on ITS and matK sequences, including populations of C. helodes from both sides of the Straight of Gibraltar, reveal its monophylly and agree with its circumscription in sect. Spirostachyae. Distribution of genetic diversity estimated from results of an AFLPs analysis does not allow establishing two different evolutionary lineages (Iberian vs. Moroccan populations). However, one exclusive character has been detected for Moroccan populations in the analysis of the ITS sequences. Furthermore, from a cytogenetic point of view, Moroccan populations have stabilized a single chromosome number 2n=74, whereas Iberian's most frequent cytotype is 2n=72. This suggests that the current geographical distribution of C. helodes is the result of a relatively recent dispersal event between SW Iberian Peninsula and N Africa, but reproductive and genetic gene flow between both sides of the Straight of Gibraltar cannot be ruled out.

P0937. Molecular markers help clarify morphological-based taxonomic studies of the UK National Willow Collection

S. O. Trybush[1], I. V. Belyaeva[2], A. Karp[1];
[1]Rothamsted Research, UK, Harpenden, United Kingdom, [2]Ural Botanical Garden, Russian Academy of Science, Ekaterinburg, Russian Federation.

The understanding of relationships between species of the genus *Salix* and their identification is key to efficient utilisation of willows as bioenergy crops. The current taxonomy of the genus *Salix* is very complex and is being continually revised.

The National Willow Collection (NWC) was originally established in 1920 as a repository for disappearing willows used for basketry. Now it is the only National Collection of *Salix* comprising more than 150 species and hybrids from all over the world. We are undertaking a thorough characterisation of the Collection using traditional botanical knowledge and modern molecular techniques to provide improved knowledge of germplasm available. Morphological assessment carried out on the NWC and herbarium material demonstrated that key characters used for the identification of some species were unreliable due to the large intra-specific variation, especially within species of the section *Vimen*. Amplified Fragment Length Polymorphism (AFLP) analysis carried out on DNA extracted from 64 species of *Salix* was successful in differentiating between species and supported known species relationships.

P0938. Evolution and Biogeography of Geraniaceae

O. Fiz-Palacios, M. Alarcon, J. GarcÃia, P. Vargas, J. J. Aldasoro;
Royal Botanic Garden of Madrid, Madrid, Spain.

Geraniaceae is a monophyletic family included in the Geraniales (basal Rosids) together with four families (*Vivianiaceae, Francoaceae, Greyaceae, and Melianthaceae*). Geraniaceae s.l. consists of six genera (*Hypseocharis, Pelargonium, Monsonia, Erodium, Geranium* and *California*), which form a natural group with *Hypseocharis* sister group to the remaining genera. It has been proposed that an early Geraniaceae divergence occurred after the separation of South America and Africa. A limited distribution in central Andes and accumulation of primitive characters lead us to interpret a relict status of *Hypseocharis*.

A phylogenetic, biogeographic, and molecular study is herein presented to assess previous taxonomic treatments, to infer the historical distribution, to find out patterns of diversification, and to explore the rates of nucleotide substitution related to morphological differentiation. In this study we describe the patterns of genera diversification already described by Price & Palmer (1993) as well as a basal position of *California* in the Geraniaceae . We have also found one of the highest substitution rates in *rbc*L in angiosperms.

P0939. Systematics of Pseudotrimezia (Trimezieae, Iridaceae)

J. Lovo[1], R. Mello-Silva[2];
[1]Universidade de São Paulo, Sãoo Paulo, Brazil, [2]Universidade de São Paulo, São Paulo, Brazil.

Pseudotrimezia (Iridaceae) is an endemic genus from Espinhaço Range, Minas Gerais State, Brazil. It comprises about 20 species, with an interesting distribution pattern. The species, which are difficult to delimit, occurs isolated, sometimes to a single locality, being a good model for biogeographic studies. The genus has never been subject of phylogenetic analysis. Previous studies were made with *Pseudotrimezia* and related genus*, Trimezia* and *Neomarica* (tribe *Trimezieae*) by Rudall, using anatomical data, but not in a cladistic approach. The present preliminary phylogenetic analysis of *Pseudotrimezia* and tribe Trimezieae was based on morphological characters from literature, herbarium collections, and fresh material, as the collections of Iridaceae are almost always fragmentary. Differently from the previous analysis, the results show *Neomarica* as a clade within *Trimezia*, and *Pseudotrimezia* as a monophyletic group.

P0940. Revision of species of genus Coccoloba P.Browne nom. cons. (Polygonaceae) of Brazil

E. Melo;
Universidade Estadual de Feira de Santana, Feira de Santana, Brazil.

A taxonomic revision of the genus Coccoloba from Brazil is presented. It is a Neotropical genus with about 400 species, distributed from the Southern United States (Florida) to Uruguai. The taxonomic treatment included nomenclatural revision, synonymizations, typifications, morphological descriptions, analysis of the geographical distribution patterns, comments and illustrations to Brazilians species. They were recognized 45 species; 18 new synonyms were proposed and 10 new occurrence of species from Brazil were recorded; 7 lectotypes and 2 neotypes are being designated here, and 2 species were re-established. This study includes an identification key, descriptions, illustrations, data of flowering and fruiting periods, general comments and analysis of distribution patterns of the taxa. Among the 45 species recorded at presente, 20 occur exclusively in Brazil. In relation to geographical distribution patterns 16 species presented wide distribution; 19 species have restric distribution; 4 species present disjunct distribution pattern; and 6 species have an endemic distribution within Brazil.

P0941. Revision of Aegiphila Jacq.(Lamiaceae) and its sistematic position

F. França;
Universidade Estadual de Feira de Santana, Feira de Santana, Brazil.

A revision of the Neotropical genus Aegiphila (Lamiaceae) is presented. Its taxonomic history is detailed and some morphological structures are re-evaluated. A palynological study is presented using both light and scanning electron microscopy. The geographical distribution is presented in ecoregions and the genus has 44 endemic species. The positioning of the genus at ordinal level as well as the positioning of the species in the genus are discussed using cladistic analysis based on morphological characters. The taxonomic revision resulted in the recognition of 102 species from the universe of 355 names previously cited for the genus. These species are classified in the two sections here recognized, whose delimitation, composition and monophily are defined and discussed. 74 new synonyms are proposed and one species is excluded from Aegiphila. The study of the nomenclatural types resulted in the designation of 49 new lectotypes, 8 epitypes and 3 neotypes. It is provided a dicotomic key for sections and species. For each species it is presented a list of synonyms, descriptions, distribution maps and discussion about its taxonomy and typification.

P0942. What-if anything-is Escalloniaceae?

J. Lundberg;
Dept of systematic botany, EBC, Uppsala, Sweden.

Escalloniaceae have traditionally been treated as a taxonomical dustbin. As a subfamily in Saxifragaceae sensu Engler 1928 it contained 16 genera, but have recently been slimmed down to only five genera (APG II), although their relationship with several of the genera formerly placed in Escalloniaceae are still uncertain.

Using a broad sample with several representatives from all major campanulid clades, combined with Bayesian inference, a well-supported and monophyletic Escalloniaceae includes *Anopterus*, *Eremosyne* (formerly Eremosynaceae), *Escallonia*, *Forgesia*, *Polyosma* (formerly Polyosmaceae), *Tribeles* (formerly Tribelaceae), and *Valdivia*, but not *Quintinia*. This latter genus should together with *Sphenostemon* be transfered to Paracryphiaceae. Furthermore, preliminary results indicates that *Valdivia* and *Forgesia* might be included in *Escallonia*.

The age and biogeography of Escalloniaceae and its position within the campanulids is briefly discussed.

P0943. Morphological and Taxonomic Studies of the Genus *Tradescantia* L. (Commelinaceae) in Brazil

R. C. Barreto;
UFPE, Recife, Brazil.

This work reports a part of the studies about Brazilian Commelinaceae species. The study was based on a comparative morphological analysis of specimens obtained from herbaria and cultivated materials. Identification keys were made to species level. Descriptions and comments related to taxonomy, morphology, phenology and geographical distribution are included, as well as plates of flowering branches and floral morphology. Eight species were identified: *Tradescantia ambigua*, *T. anagallidea*, *T. blossfeldiana*, *T. cerinthoides*, *T. crassula*, *T. fluminensis*, *T. umbraculifera* and *T. zanonia*. *Tradescantia blossfeldiana* represents the first reference to Brazil. New occurrences to Brazilian regions are indicated: *T. ambigua* and *T. crassula* to Southeast, *T. umbraculifera* to South, *T. zanonia* to North, Northeast and South regions. The geographical distribution of *Tradescantia* species is more concentrated in the Southeast and South regions; however, *T. ambigua* occurs in the Northeast and Middle-West while *T. zanonia* has been found in the North and Northeast regions.

P0944. Morphological phylogeny of *Anthurium* Schott (Araceae)

L. G. Temponi[1], R. Mello-Silva[1], S. J. Mayo[2], M. B. Cattai[1];
[1]Universidade de Sao Paulo, Sao Paulo, Brazil, [2]Royal Botanic Gardens, Kew, United Kingdom.

A partial cladistic analysis of *Anthurium* was conducted in order to define monophyletic groups and understand the evolution of morphological characters within the group. We studied 95 morphological characters in 30 species of *Anthurium* plus one species of five other genera of Araceae (i.e., *Asterostigma, Monstera, Philodendron, Pothos*, and *Spathicarpa*) that were used as outgroups. The species sampled represent a significant proportion of the morphological diversity of the genus and of the sections currently recognized in *Anthurium*. A parsimony analysis revealed two major groups within *Anthurium*, those of which were supported by a series of characters, including: the overall shape of the petiole and lamina, the shapes of the base and apex of the lamina, the number of cell layers in the palisade parenchyma, the position of the spathe, the sessile spadix, and berry color. On the other hand, important characters supporting minor clades included: the number and prominence of the 2ary veins and the number and presence of basal veins. Our results suggest that the currently recognized sections and series within the genus are not monophyletic. Cnpq, Fapesp.

P0945. Philogenetic analysis of Fouquieriaceae based on morphological and molecular data

N. B. Medina Jaritz, C. F. Vargas Mendoza, O. Hernández Montes;
Escuela Nacional de Ciencias Biológicas, México, D.F., Mexico.

Chloroplast DNA was obtained from ten taxons of *Fouquieria* (*F. burragei, F. columnaris, F. diguetti, F. fasciculata, F. ochoterenae, F. purpusii, F. splendens, F. splendens* ssp. *breviflora* and *F. splendens* ssp. *splendens*) and one from outgroup (*Arbutus glandulosa*). Segments of 2,500 bp were amplified using trnKe1 and trnKe2 primers. PCR products were restricted with 8 endonucleases; and separated by horizontal electrophoresis, then documented for phylogenetic analysis; also morphological characters were documented to perform phylogenetic analysis. Analysis were performed using only the molecular data, or the morphological data, or both kind of data together (total evidence); methods of phylogenetic analysis were unweightted maximum parsimony and neighbor joining, with branch support tested with a 1000 resampling bootstrap. Phylogenetic trees obtained show a monophyletic origin for the Fouquieiriaceae and just one genus: *Fouquieria*, which includes the woody and the fleshy species. *F. burragei* is a nearby species of *F. splendens*, so we can conclude that the division of the *Fouquieria* subgenus is not natural.

P0946. Modern approaches to the differentiation and taxonomy of genus *Anemone* L. (*Ranunculaceae* Juss.)

S. N. Ziman[1], Y. Kadota[2], C. S. Keener[3], E. V. Bulakh[1], O. N. Tsarenko[1];
[1]N.G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kiev, Ukraine, [2]National Science Museum, Ibaraki, Japan, [3]The Pennsylvania State University, University Park, PA, United States.

In a re-examination of the evolution and taxonomy of *Anemone* L. (Ziman et al., 2004), we utilized several additional essential characters including chromosome numbers and pollen grain types, carpel morphology (sessile or stalked, styles distinct or indistinct, stigmas linear or dilated), stamens (filaments filiform or dilated), tepals (deciduous or persistent, monomorphic or dimorphic, venation including anastomoses), staminodes, germination, roots (taproots or adventitious), shoots above ground (mono- or sympodial, semi- or un-rosetteous) or underground (caudices, rhizomes or bulbs), basal leaves (petioles basally narrow, vaginated or sharply dilated, blades monomorphic or dimorphic, developing before or after anthesis) and involucral leaves (petiolate or sessile, similar or dissimilar to basal ones). As a result of the 150 species studied in this research, we are recognizing 4 subgenera, 23 section, 4 subsections and 26 series, and we described subgenus *Stolonifera*, section *Rosulantes*, subsection *Somalienses*, and 14 series (*Nikoenses*, *Deltoideae*, *Trullifoliae* and others).

P0947. Phylogenetic relationships among Gagea and Lloydia (Liliaceae)

A. Peterson[1], J. Peterson[2];
[1]Biozentrum der Martin-Luther-Universität Halle-Wittenberg, D-06120 Halle/Saale, Germany, [2]Landesamt für Umweltschutz Sachsen-Anhalt, D-06116 Halle/Saale, Germany.

As higher level relationships of the monocots are resolved, the need increases for comprehensive, lower level, generic and species studies employing rigorous phylogenetic and morphological character analyses. The systematics of *Gagea* and *Lloydia* species has long been considered difficult because only a few phenotypic features within both genera exist and as a result of hypothesized interspecific hybridisation; the latter we could shown for G. *pomeranica* which represents a hybrid of *G. pratensis* and *G. lutea*. In the present study we report on the utility of intergenic regions in the plastid DNA (*trn*L-*trn*F) and of the internal transcribed spacer region of nuclear ribosomal DNA (ITS1, 5.8S rRNA, ITS2) to assess interspecific and generic relationships. Our cpDNA sequence data, the initial morphological analysis as well as the literature study, all indicate that the taxonomic position of *Lloydia* as an independent genus within the Liliaceae seems to be doubtful. However, a clear understanding of relationships among *Gagea* and *Lloydia* will require data from other DNA regions and additionally a more complete taxon sampling of both genera.

P0948. Ancestral types of minor vein phloem for subclasses of dicotyledonous plants

D. R. Batashev, Y. V. Gamalei;
V.L. Komarov Botanical Institute RAS, St. Petersburg, Russian Federation.

Comparative study of the minor vein ultrastructure has been performed by TEM in leaves of 1500 species from evolutionary “advanced” and ”primitive” (according to Takhtajan, 1997) families of dicots. Significant differences in organization of minor vein phloem have been revealed between evolutionary “young” and “ancient” families. Several characteristics delimit the “primitive” ancestral and the specialized types of minor vein phloem: (1) symmetry of companion cell-sieve element (CC-SE) complexes; (2) the number of CC-SE complexes per a minor vein; (3) the number of CC per SE; (4) the presence and size of plasmodesmal fields at the CC/bundle sheath interface; (5) type of plastids in CC. Only a small number of dicot families has specialized minor vein phloem, while their majority have no traits of minor vein specialization. We conclude that the ancestral field of non-specialized minor vein phloem comprises the basic taxa of several subclasses of dicots, and that specialized types have evolved several times in course of the evolution of dicots.

P0949. Morphological and molecular diversity in different Asparagus species (Asparagaceae) of Sri Lanka

D. M. D. Yakandawala[1], R. Samuel[2], E. Grasserbauer[2];
[1]Univeristy of Peradeniya, Peradeniya, Sri Lanka, [2]Deparment of Systematics and Evolution of Higher Plants, Vienna, Austria.

Morphological and rDNA ITS sequence studies were carried out to evaluate the number of different Asparagus that occur in Sri Lanka. Data were analysed independently and in combination and all analyses resulted in five distinct groups. Two of these groups unequivocally agreed with A. gonoclados Baker and A. falcatus L. Asparagus included under A. racemosus Willd. contributed to the remaining clusters and each could be supported by unique character combinations; Asparagus with shorter and sickle shaped cladodes with tapering base of higher elevation and lower elevation versus Asparagus with longer, straight cladodes of lower elevation. Worldwide Flora treatments for A. racemosus Willd. parallels well with shorter cladodes that occur in the low country. Asparagus that occur in the higher elevations is possibly A. zeylanicus (Baker) Hook. f. and needs to be resurrected. The study proclaims Asparagus described under A. racemosus Willd. is an assemblage of different species. Floral morphology for all these groups are under investigation. Further, fast evolving plastid regions will be sequenced construct phylogenetic relationships within this genus.

P0950. YABBY gene expressions in lateral organs of basal angiosperms

T. Yamada[1], Y. Hirayama[2], R. Imaichi[2], M. Ito[3], M. Kato[3];
[1]National Science Museum, Tokyo, Japan, [2]Japan Women's University, Tokyo, Japan, [3]University of Tokyo, Tokyo, Japan.

Most YABBY genes (CRABS CLAW, FILAMENTOUS FLOWER, INNER NO OUTER, YABBY2, and YABBY3) are expressed on the abaxial side of lateral organs, such as leaves, and are involved in the establishment of abaxial tissue identity in core eudicots (Brassicaceae, Solanaceae, and Plantaginaceae). On the contrary, some YABBY genes are not expressed limitedly in the abaxial tissues of lateral organs in Poaceae. Here we report the expression patterns of YABBY genes in the lateral organs of the early branching angiosperms. We find that YABBY2-homologue of Amborella trichopoda (Amborellaceae) is expressed in the adaxial tissues of the carpel and leaf, in contrast to abaxial expression in core eudicots. In addition to this, YABBY5-homologue of Cabomba caroliniana (Cabombaceae) is also expressed in the adaxial tissues of the carpel. This difference indicates the abaxially-limited expression pattern of the YABBY genes evolved in the course of angiosperm evolution.

P0951. Asexual genetic variability in Agavaceae

D. J. Infante, J. R. Demey, S. Molina, E. Gamez;
Centro de Biotecnologia, IDEA, Caracas, Venezuela.

Agaves are succulent monocot plants rich in fibers, sugars and other important compounds. Molecular markers (AFLP and ISTR) were used to study genetic diversity in different Agavaceae plant samples. The comparison of the banding pattern between the mother plant and sucker derived daughter plants showed that genetic variability is also introduced during asexual reproduction in these species. Phylogenetic relationships among the Agave species were investigated using Bayesian inference with 3,000,000 generations, 4 independent Markov chains run, tree sampling every 100 generations and burnt after 300 trees. The Maximum Posterior Probability (MPP) tree shows the existence of four different taxonomic groups, with indication about the need of reclassification of some agaves. This asexual variability open the possibility for genetic improvement, as has been done in henequen.

P0952. Flowering inducers and repressors in rice

G. An, D. Jeong, S. Lee, H. Yoon, J. Yoo, Y. Kim, C. Ryu;
POSTECH, Pohang, Republic of Korea.

Rice is a short day flowering plants. During the most of the vegetative growth phase, light acts as a repressor of flowering. We are investigating regulatory pathways that control the flowering signal pathways in rice. A MADS box gene, *OsMADS50,* is an inducer of flowering, acting very early stage of the plant development and the induction is long day dependent. Another MADS box gene *OsMADS56* is appeared to be a repressor of flowering signal. They act to control expression of *OsMADS14*, which is a key transcription factor that induces flowering in rice. In addition to these MADS box genes, CO-like genes also play critical roles in controlling flowering time. *Hd1* is known to function for a repressor under long days and an activator under short day. We isolated a constitutive repressor *COL4*, which displays a circadian expression pattern opposite to that of *Hd1*. We also identified another CO-like gene, *COL8*, which acts as a flowering inducer. We are investigating interactions between these regulatory elements and how they control the downstream gene *Hd3a*.

P0953. *OsDAPD3*, a double AP2 domain gene, plays a major role in development of spikelet in rice

D. Lee, G. An;
National Research Laboratory of Plant Functional Genomics, Pohang, Republic of Korea.

In higher plants, the aboveground structure is determined by the two antagonistic functions of the shoot apical meristem (SAM), the maintenance in an indeterminate state and the successive organ formation. In this study, we report identification of the *OsDAPD3* gene as the main regluator in spikelet meristem transition to floral meristem. The gene encodes a putative transcription factor carrying two AP2 domains. The gene is expressed in the all the tissue examined. In *DAPD3* knockout plants, transition from spikelet meristems into floral meristems was delayed, resulting in production of more rudimentary glumes in alternative phyllotaxy. In addition, the empty glumes were transformed into the lemma/palea-like organs due to the increased expression of the *OsMADS1* gene. The lodicules were altered into the lemma/palea-like organs. These results indicate that *OsDAPD3* play a major roles in the transition of spikelet meristem to floral meristem and in floral organ specifications.

P0954. Petal Organ-Identity Genes Are Expressed in Petaloid Bracts of Dogwood

N. Maturen[1], J. Hu[2], M. W. Frohlich[3];
[1]The University of Michigan, Ann Arbor, MI, United States, [2]National Taiwan University, Taipei, Taiwan Republic of China, [3]The Natural History Museum, London, United Kingdom.

The Dogwood tree *Cornus kousa* is known for its specialized bracts that surround the inflorescence and recall the bright, attractive petals of a large flower, even upon anatomical inspection. Genes from three classes (A, B and E) work in combination to specify a petal according to the ABC(DE) model of flower development, which is especially well-supported among the eudicots, of which *Cornus* is a member. Moreover, overexpression of an A and/or E class gene along with the two B class genes has been shown to be sufficient to convert vegetative leaves into petals in *Arabidopsis.* We have isolated members of these highly-conserved classes of petal-organ-identity genes from *C. kousa:* the A-class gene *CkAP1*, the B-class genes *CkPI* and *CkAP3,* and the E class gene *CkSEP.* We used RT-PCR to detect gene expression in bracts, leaves (negative control) and flowers (positive control). All four of these *C. kousa* genes are expressed in flowers, and none are expressed in leaves. In petaloid bracts, at least the A-class and two B-class genes are expressed, suggesting that these petal genes are turning leaves into 'petals' in this species.

P0955. An EST library from developing fruits of a Hawaiian endemic mint, *Stenogyne rugosa* (Lamioideae, Lamiaceae): characterization and resources

C. Lindqvist[1], A. Scheen[1], M. Bendiksby[1], M. Yoo[2], P. Grey[2], D. G. Oppenheimer[2], D. E. Soltis[2], P. S. Soltis[2], V. A. Albert[1];
[1]Natural History Museum, Oslo, Norway, [2]University of Florida, Gainesville, FL, United States.

The morphologically diverse Hawaiian endemic mints include two genera with unusual fleshy fruits. An EST library was constructed from developing fleshy fruits of *Stenogyne rugosa* to develop genetic markers for lamioid mint research, as well as for comparison with Floral Genome Project and other unigene sets. 628 unigenes were derived from 904 high quality ESTs. Many unigenes were putative homologues of genes involved with reproductive development, e.g, *CAF*-like DEAD box, *EIN2*, *FCA*, *GI*, *LD*, *LUG*, *SYD*, *TFL1*, *UFO*, and *YABBY1*. Interestingly, *FCA*, *GI*, and *LD* are timing genes that promote flowering, whereas *TFL1* is a flowering inhibitor. Among the unigenes, >40 microsatellites (SSRs) were identified of which >50% were trinucleotide repeats. 8 SSRs could be annotated to reproductive development, 7 to RNA and protein processing, and 3 to transcription factors. Given that allelic repeat length variation in developmental genes of other organisms has been linked with morphological evolution, these SSRs may be useful for analyses of phenotypic differences of lamioid mints.

P0956. MADS about perianth morphology in Impatiens and Marcgravia

K. Geuten[1], P. Caris[1], A. Becker[2], K. Kaufmann[3], G. Theissen[3], **E. Smets**[1];
[1]Laboratory of Plant Systematics, Leuven, Belgium, [2]Monash University, School of Biological Sciences, Clayton, Australia, [3]Lehrstuhl für Genetik, Jena, Germany.

The balsaminoid Ericales consist of the families Balsaminaceae, with its core genus Impatiens, Marcgraviaceae and Tetrameristaceae. Judging from the long branch lengths, Balsaminaceae and Marcgraviaceae have probably evolved independently over a long period of time. This has hampered the robust reconstruction of the relationships in the balsaminoid clade and leaves us without clear morphological evidence of their evolutionary relations. Comparisons of the genes controlling flower development in Impatiens and Marcgravia can help to bridge the morphological gap between the two lineages. Impatiens has a petaloid sepal spur and Marcgravia umbellata has greenish sepals and petals. According to the quartet model of floral development, AP1, AP3, PI and SEP MADS-domain proteins control petal development in Arabidopsis. We have cloned several putative orthologues of the corresponding genes in Impatiens hawkeri and Marcgravia umbellata, and we report on their molecular evolution and functional diversity as indicated by expression patterns. We integrate these data with phylogenetic analysis of the balsaminoid clade, and observations of floral ontogeny.

P0957. AGAMOUS-like Genes Suggest Staminal Origin for the Perianth of Lauraceae

A. Chanderbali, S. Kim, M. Buzgo, D. Soltis, P. Soltis;
University of Florida, Gainesville, FL, United States.

The perianth of Lauraceae typically consists of two whorls of morphologically similar tepals. One frequent exception is a dimorphic perianth due to reduction in the size of the outer tepals. To determine whether orthologues of A, B, and C-class MADS-box genes have played a role in this morphological shift, their expression levels were compared across the dimorphic perianth of Persea borbonia and the more typical perianth of Persea americana. Our results indicate that A- and B-class orthologues are expressed at comparable levels in both perianth whorls of the two species, but AG (C-class) and SEP3 (E-class) orthologues are absent from the outer tepals of Persea borbonia. Based on our results, we hypothesize: 1. A role for AG- and SEP3-like genes in shaping perianth morphology is indicated by the coincident shift to a dimorphic perianth with loss of their expression in the outer tepals of Persea borbonia. 2. In Persea, sepaloid outer tepals and petaloid inner tepals are likely specified through action of A+B and A+B+C+E class genes, respectively. 3. The gene expression profile of the petaloid tepals of Persea, and perhaps other Lauraceae, suggests staminal derivation.

P0958. A comparison of floral morphology and physiology genes in an adaptive radiation

K. Esfeld, M. Thiv;
Staatliches Museum für Naturkunde, Stuttgart, Germany.

We aim at testing the impact of flower morphology versus physiology genes in the process of speciation in the Macaronesian Sempervivoideae as a classic example of an island radiation. Substitution patterns of genes affecting the phenotype, e.g., flower morphology genes (AP1, AP3) and physiology genes (e.g. PEPC, TIP), are analysed. Increased mutation rates are expected, when comparing the adaptively radiated island clade to its non-radiated mainland sistergroup. This would indicate positive selection acting upon these gene classes. Analysing these genes that are potentially involved in the evolution of floral morphological or physiological key characters enables us to distinguish between different forces driving speciation. The comparison of evolutionary rates between these genes presumably affecting reproductive isolation and physiological adaptation will yield an indirect measurement of the degree to which these forces are linked to species diversification in this plant group.

P0959. The Molecular Basis for Convergent Loss of Floral Anthocyanins in *Aquilegia* (Ranunculaceae)

J. B. Whittall, S. A. Hodges;
University of California, Santa Barbara, CA, United States.

Understanding whether phenotypic convergence extends to the molecular level is a basic question in evolutionary biology. Based on a highly resolved AFLP phylogeny for the North American *Aquilegia* clade, loss of floral anthocyanins (A-) has occurred independently at least seven times. These losses are usually associated with a transition to hawkmoth pollination and are inferred to be adaptive. We investigated whether variation in the expression of six structural and two regulatory genes in the anthocyanin biosynthetic pathway (ABP) could be responsible for the convergent (A-) phenotype in six species. We found evidence of expression in the first two enzymes in the ABP among the six A-species. Loss of expression in the remaining six genes however, varied among species and could account for the A- phenotypes. Most species showed different patterns of expression loss indicating that convergence usually does not extend to the molecular level during loss-of-function adaptations. These results emphasize the significance of variation in expression patterns for producing convergent adaptations during a rapid radiation.

P0960. Floral development in *Persea americana* (avocado): the male mystery in Lauraceae.

M. Buzgo, A. Chanderbali, Z. Zheng, S. Kim, D. G. Oppenheimer, D. E. Soltis, P. S. Soltis;
University of Florida, Gainesville, FL, United States.

Flowers of Lauraceae are small and consist of organs in distinct, **trimerous whorls,** with clearly **differentiated organ identities**. This syndrome is also found in other groups of magnoliids (e.g., Aristolochiaceae, Annonaceae) and in monocots. In Lauraceae, a **pair of nectar-secreting appendages** occurs at the base of the third whorl of stamens. Are they best considered accessory staminodes? Or are they additional pollen sacs, implying that the stamens are branched? The initiation sequence of the androecium and nectary-like or stamen-like structures outside of the androecium could help to answer these questions. The **delimitation of the androecium** towards the gynoecium and the perianth is discussed with respect to other basal angiosperms. The reliability of ***in situ* hybridization of an *AGAMOUS* homolog** (MADS-box gene required for the organ identities "stamen" and "carpel") is critically discussed. The expression of a single *AGAMOUS* homolog in the tepals may be insufficient to infer their homology with stamens, but may instead hint at the evolutionary processes of flower miniaturization and multiplication.

P0961. *TEPAL-LIKE BRACT* gene of *Fagopyrum esculentum* represents a new class of genes which states lower perianth boundary.

M. D. Logacheva[1], A. N. Fesenko[2], I. N. Fesenko[2], A. A. Penin[1];
[1]Faculty of Biology, Lomonosov Moscow State University, Moscow, Russian Federation, [2]All-Russia Research Institute of Legumes and Groat Crops, Orel, Russian Federation.

A genetic and morphological study of new mutant of *Fagopyrum esculentum* (common buckwheat) has been performed. *Fagopyrum* wild type plants have a cymose partial inflorescence bearing hyaline scale-like bracts. The flower consists of 5 petaloid tepals, 8 stamens and 3 carpels. The morphological change in mutant line concerns the bract structure; no other significant difference is found. The bracts of mutant plants resemble wild-type tepals, so the line is called *tepal-like bract* (*tlb*). The likeness of wild type tepals and *tlb* bracts is confirmed by scanning electron microscopy. This feature is inherited as a monogenic nuclear recessive trait. Following the modified ABC-model petaloid tepals are mediated by the combination of A and B class gene activity. The morphology of *tlb* lets us suggest that *TLB* represents a class of genes which restricts ectopic expression of floral meristem identity genes involved in tepal development. The mechanism of *TLB* action may be similar to the same of *SUPERMAN* in *Arabidopsis thaliana* which states an apical boundary of B class gene expression. The work is supported by RFBR No 04-04-49643, RPLSI No 1731.2003.4.

P0962. Cytoplasmic homeosis in wheat

K. Murai, T. Saraike, C. Hirabayashi;
Fukui Prefectural University, Matsuoka-cho, Japan.

Pistillody, homeotic transformation of stamens into pistil-like structures, has been reported in the cytoplasmic substitution (alloplasmic) lines of bread wheat (Triticum aestivum) with Aegilops crassa cytoplasm. The induction of pistillody is suppressed by the Rfd1 gene located on the long arm of chromosome 7B in wheat cultivar 'Chinese Spring' (CS). Because of the absence of Rfd1, the alloplasmic line of CS ditelosomic 7BS ((cr)-CSdt7BS) lacking the long arm of chromosome 7B exhibits pistillody in all florets, whereas the euplasmic CS ditelosomic 7BS (CSdt7BS) with normal cytoplasm forms normal stamens. The class B MADS box genes, WPI and WAP3, were expressed in the normal stamen primordia of CSdt7BS, but not in the pistil-like stamen primordia of (cr)-CSdt7BS, indicating that pistillody is caused by the change of the MADS box gene expression. To clarify the mechanism of the cross-talk between MADS box gene and cytoplasmic genome, we have identified genes specifically expressed in the young spike of the pistillody line by using the cDNA subtraction technique. As a result, a protein kinase gene was cloned as a player of the cross-talk.

P0963. The differentiation of perianth morphologies in monocotyledonous plants.

A. Kanno, T. Nakamura, M. Nakada, S. Kim, T. Fukuda, Y. Mashiko, P. Yun, T. Ochiai, T. Kameya;
Graduate School of Life Sciences, Tohoku University, Sendai, Japan.

The morphological transition of the first whorl from petaloid tepals into sepals occurs frequently during the diversification of angiosperms. The class B genes, *AP3* and *PI* in *Arabidopsis*, are required for the petal development in whorl 2, and its homologs have been isolated and characterized from various plants. A recent study on tulip indicates that the morphology of petaloid tepals in whorls 1 and 2 is consistent with the expansion of class B gene expression. To clarify the evolutionary transition between sepals and petals in monocots, we isolated class B genes from *Agapanthus*, *Muscari* and *Tricyrtis*, whose perianths consist of petaloid tepals in two whorls, and *Tradescantia*, *Commelina* and *Habenaria*, whose perianths are differentiated in sepals and petals. RT-PCR studies using dissected floral organs revealed the expansion of class B gene expression in whorl 1 in *Agapanthus*, *Muscari* and *Tricyrtis*, and a lack or low level of *DEF*(*AP3*)-like gene expression in whorl 1 in commelinaceous and *Habenaria* species. This suggests that *DEF*-like gene expression pattern may correlate with morphological transition from petaloid tepals into sepals in the first whorl in monocot.

P0964. The modified ABC model explains the development of the petaloid perianth of Agapanthus praecox ssp. orientalis (Agapanthaceae) flowers

T. Nakamura[1], T. Fukuda[1], M. Nakano[2], M. Hasebe[3], T. Kameya[1], A. Kanno[1];
[1]Graduate school of Life Sciences, Tohoku University, Sendai, Japan, [2]Niigata University, Niigata, Japan, [3]National Institute for Basic Biology, Okazaki, Japan.

The floral diversity of angiosperms has profoundly changed the terrestrial biosphere and it is of interest to identify the genes that are responsible for these heritable phenotypic differences. The class B genes, which belong to the MADS-box gene family, play important roles in regulating the development of petals and stamens in flowering plants. *Agapanthus praecox* ssp. *orientalis* (Agapanthaceae) has petaloid sepals in whorl 1. To understand the molecular mechanisms of floral development in *Agapanthus*, we isolated and characterized the homologs of the *Antirrhinum majus* genes *GLOBOSA* and *DEFICIENS* in this plant, designated by *ApGLO* and *ApDEF*, respectively. Expression analyses revealed that expression of *ApGLO* and *ApDEF* were observed in whorl 1 as well as in whorls 2 and 3. Moreover, the flowers of transgenic *Arabidopsis* plants that ectopically expressed *ApGLO* formed petal-like organs in whorl 1. We found that the class B genes of *Agapanthus* had the same expression pattern as those of tulip and lily. These observations indicate that the mechanism of flower development in *Agapanthus* follows the modified ABC model.

P0965. Diversity and evolution of Cycloidea-like genes in Papaveraceae.

C. Damerval[1], M. Le Guilloux[1], M. Jager[2], M. Manuel[2];
[1]UMR Génétique Végétale, Gif-sur-Yvette, France, [2]UMR 7138, Paris, France.

Floral symmetry in Angiosperm is supposed to have evolved as a response to specialized pollinators. Two main types of symmetry are recognized, actinomorphy or polysymmetry, and zygomorphy or monosymmetry. Zygomorphy would have evolved recurrently from actinomorphy, which rises the question of the homology of the molecular mechanisms involved.

Molecular developmental genetic studies in Snapdragon have shown that two paralogues, *Cycloidea* (*Cyc*) and *Dichotoma* were responsible for the zygomorphic wild-type flower. The molecular evolution of *Cyc*-like genes has been investigated in several Angiosperm derived taxa as related to floral symmetry. We present here a study of the evolution of *Cyc*-like genes in a primitive Eudicot taxon, the Papaveraceae that encompasses species with diverse floral symmetry. Two to three *Cyc*-like genes were found in 8 Papaveraceae species, corresponding to three homology groups. Homology of these genes with those of other taxa, and relationship with floral symmetry will be discussed.

P0966. Isolation of class B genes from *Muscari* and expression analysis using laser microdissection system

M. Nakada[1], T. Fukuda[1], T. Ochiai[1], M. Nakazono[2], N. Nishizawa[2,3], M. Nakano[4], T. Kameya[1], A. Kanno[1];
[1]Graduate School of Life Sciences, Tohoku University, Sendai, Japan, [2]Graduate School of Agricultural and Life Sciences, University of Tokyo, Tokyo, Japan, [3]CREST, Kawaguchi, Japan, [4]Faculty of Agriculture, Niigata University, Niigata, Japan.

In higher eudicot, the floral organs consist of four different whorls, containing sepals, petals, stamens and carpels. In contrast, the two whorls of perianths in many monocot flowers are almost identical petaloid organs, called tepals. To explain this flower morphology, the modified ABC model was proposed; two types of class B genes, *DEF*- and *GLO*-like genes, are expressed in whorl 1 as well as whorls 2 and 3, so that the organs of whorls 1 and 2 are the same petaloid structure. Although this model may apply to tulip and other Liliaceae as well, the class B genes were not expressed in whorl 1 in asparagus. In order to investigate whether the class B gene expression in asparagus is the common character in related species, we isolated and characterized the class B genes from *Muscari armeniacum* (Asparagales). We isolated two *DEF*- and three *GLO*-like genes from *Muscari* by RACE method. Total RNA was isolated from dissected floral organs by Laser microdissection system and RT-PCR was performed. The result showed that the class B genes were all expressed in whorl 1 as well as in whorls 2 and 3, which supports the modified ABC model in *Muscari*.

P0967. Pod and seed morphology in Iranian species of Sophora and related taxa

M. Noori, M. Noori;
University of Arak, Arak, Islamic Republic of Iran.

Pod and seed morphology are characters sets used to assess the relationships among Iranian species and subspecies of the tribe Sophoreae (Leguminosae: Papilionoideae).

In *Sophoreae* tribe fruits are extraordinarily diverse. In addition to obvious macro-morphological characters of pod and seeds such as size, shape, colour, wall thickness, positioning, type of pod opening and number of seeds per legume micro-morphological characters of pods and seeds can be useful for taxonomists.

In this study mature pods and seeds of each species and subspecies were collected from various geographic region of Iran. The morphology of the seeds and pods was studied using a zoom binocular light microscope and scanning electron microscopy. Photomicrographs were taken under different magnification. A number of macroscopic characters were also scored. The key summarized these data. Macro- and micro-morphological studies of pods and seeds of Iranian members of tribe *Sophoreae* showed some characters may support the identification of the species and varieties of *Sophora* and related genera.

Keywords: Leguminosae, pods, seeds, morphology

P0968. Verbenaceae

T. R. S. Silva, A. M. Giulietti;
Universidade de Feira de Santana, Feira de Santana, Brazil.

Brazilian species of *Lantana* are included in four sections. The genus can be defined by the presence of 1 or 2 pyreno per fruit and succulent mesocarp (Schauer 1847). Specimens from 65 herbaria were examined (B; BM; BR; CEN; CEPEC, G; HAL; HUEFS; IBGE; INPA; IPA; K; LINN; M; MBM; MG; NY; OXF; P; R; RB; SP; SPF; TEX; UB; UEC; US and W amont others). Cladistic and morphological analyses suggest that *Lantana sensu* Schauer (1847) is polyphyletic and the circumscription of Chamisso (1832) would be preferable. This latter circumscription includes species with only one pyreno per fruit and no infrageneric divisions. Of the 85 names originally described, 21 species were recognised, 16 taxa were excluded, 32 new synonyms were proposed, and 6 new combinations were made. Fifteen names were lectotypified, one neotypified; 4 nomina nuda were detected, 2 later homonyms and 1 superfluous name were found. Eastern Brazil was the region with higher species number (18, of which 9 endemics), and is the main centre of species diversity in the country. The Atlantic Forest is especially rich in endemics (5 out of 9 species). Twelve out of the 21 species are exclusive to Brazil.(CNPq, UEFS)

P0969. The reproductive strategies of Strobilanthes glandulifera (Acanthaceae)

H. Murata[1], T. Nakanishi[1], A. Inada[1], Y. Inatomi[1], K. Dohi[1], K. Ono[1], J. Murata[2];
[1]Faculty of Pharmaceutical Sciences, Setsunan University, Hirakata, Japan, [2]Botanical Gardens, The University of Tokyo, Tokyo, Japan.

Monocarpy and mass flowering are widely known in the tropical species of *Strobilanthes* sensu lato. *Strobilanthes glandulifera*, endemic to the Okinawa-jima Island is a single monocarpic species in Japan and a six years' mass flowering cycle was recognized. In the chance of mass flowering, which begun from November 2003, we examined reproductive strategies of the species, such as the ability of autogamy, duration of fruit maturation, seed germination rate and growth, viability of individuals after fruit set etc., using pot cultivated materials in the. Additional observation was carried out in the natural populations in the Okinawa-jima Island. As a result, individuals bagged with nylon net could produce fruits and the obtained seeds well germinated. The duration of fruits maturation was very variable. Most of the individuals were died after fruits set but the rest of them that left vegetative shoots survived and flowered in the following winter.

P0970. The genus *Lepiota* in Azerbaijan

A. S. Sadykhov, D. N. Aghayeva;
Institute of Botany, Baku, Azerbaijan.

The genus *Lepiota* (Basidiomycota, Agaricales) comprises approximately 400 species that produce epigeous mushrooms with lamellate hymenophores. Species of the genus are widespread and have been recorded in deciduous forests, meadows and parks. Based on herbarium materials and recent collection 23 species: *L. acutesquamosa*, *L. adulterina, L. brunneoincarnata*, *L. castanea, L. clypeolaria, L. cortinarius*, *L. cristata, L. cygnea, L. eriophora, L. felina, L. fulvella, L. helveola, L. lilacea, L. micropholis, L. oreadiformis, L. pulverulenta, L. rosea, L. serena, L. setulosa, L. subalba, L. subgracilis, L. tomentella, L. wichanskyi* were identified on morphology. Most of species were collected from south part of Azerbaijan. *Lepiota fulvella*, *L. tomentella* were predominant in the north of country. Some of species are edible, but they are not in use by population because of small carpophores. The species of *L. acutesquamosa*, *L. brunneoincarnata*, *L. cristata, L. lilacea* are poisonous. *Lepiota brunneoincarnata* is widely spread and many incidents of poisoning with this fungus have been reported in the country.

P0971. Biological peculiarities of introduced species of the genus Sedum L. (Crassulaceae DC.)

V. Berezkina;
Kyiv National University named by Taras Shevchenko, Kyiv, Ukraine.

The abstract submission is devoted to the study of biological properties of the species of the genus Sedum L. The collection of the genus Sedum L., including 40 taxons, has been created in the O.V. Fomin Botanical garden of the Kyiv National University named by Taras Shevchenko. The rhythms of seasonal development of plants in culture has been investigated. The data of the anatomical structure of the vegetative organs of the species of the genus Sedum L. are established for the first. The peculiarities of seed and vegetative reproduction were revealed. The anti-virus activity of the species of the genus Sedum L. has been investigated. The results of investigations on content of biologically active substances - lectins in the vegetative organs of representatives of the genus Sedum L. are given.

It has been determined that the majority of the species Sedum L. which have been studied are perspective for cultivation in the

Forest-Steppe and Wooded Districts of Ukraine. The species Sedum L. have been selected for the use in ornamental garaening and phytoreclamation.

P0972. Umbelliferae of Russia

M. G. Pimenov, T. A. Ostroumova;
Botanical Garden, Moscow State University, Russia, Moscow, Russian Federation.

Russia, world's largest country, occupies the area of 17075 thousand sq. km (~13 % of earth surface) in N & NE Eurasia. Diversity in Russian Umbelliferae (U) is not rich for such territory (109 genera, 298 spp., ~ 2.5% of country flora). In European Russia (50 genera, 87 native spp.; the biggest genera - *Seseli* - 9, *Chaerophyllum* - 6, *Bupleurum* - 5), and W Siberia (38 genera, 57 spp., excluding southern mountains; the biggest genera - *Bupleurum* - 6, *Seseli* - 5) widely distributed boreal Euro-Siberian U taxa prevail. More original U are distributed in N Caucasus (77 genera, 175 spp., the biggest genera - *Heracleum* - 17, *Bupleurum* - 15, *Chaerophyllum* - 11, *Seseli* - 9, *Pimpinella* - 7), Altay-Sayan mountains in Siberia (30 genera, 46 spp.), as well as in S part of Russian Far East, belonging to E Asian floristic region (34 genera, 65 spp.; the biggest genera - *Angelica* - 11, *Bupleurum* - 8, *Ostericum* - 5). The only endemic genus in Russian U is *Magadania*; genera *Arafoe*, *Mandenovia*, *Sajanella*, *Tamamschjanella*, *Symphyoloma* are subendemic; there are only 12 endemic species. Complete compatible descriptions, determination keys and dot maps were compiled for regional monographic treatment.

P0973. Molecular systematics of Campanulaceae subfam. Lobelioideae

A. M. Antonelli;
Botanical Institute, Göteborg, Sweden.

Relationships within Lobelioideae were inferred based on DNA sequence variation in the *rbcL* and *ndhF* genes, the *trnL-F* region including the *trnL* intron, and the *trnL-F* intergenic spacer. *Lobelia* appears as highly paraphyletic, reconfirming earlier studies. Giant lobelioids from Hawaii, Brazil, Africa and Sri Lanka form a strongly supported group. Some species of *Lobelia*, that were earlier referred to the genus *Pratia,* are clustered together with *Isotoma*. In order to make *Lobelia* monophyletic, the genus should only comprise some 30 species native to North America, Europe and the Antilles. Those species are sister to a clade comprising Central American and Antillean species of *Lobelia*, *Heterotoma* and *Hippobroma*. The analysis shows for the first time that the moss-like genus *Lysipomia*, native to the Andean Páramos, is sister to a group comprising the Neotropical shrubs *Burmeistera*, *Centropogon* and *Siphocampylus*. Moreover, *Centropogon* and *Siphocampylus* are not monophyletic. Evolutionary and biogeographical aspects are discussed.

P0974. New Caledonia: A hotspot for dioecy

M. A. Schlessman[1], L. B. Vary[1], J. Munzinger[2], P. P. Lowry II[3,4,4];
[1]Vassar College, Poughkeepsie, NY, United States, [2]Institut de Recherche pour le Développement, Laboratoire de Botanique, Nouméa, New Caledonia, [3]Missouri Botanical Garden, St. Louis, MO, United States, [4]Muséum National d'Histoire Naturelle, Paris, France.

The unusually rich flora of New Caledonia includes over 3,200 indigenous species of seed plants, of which approximately 80% are endemic. It appears to be a distinctive combination of relict Gondwanan lineages and more recently evolved ones. Using the literature, herbarium specimens, and field observations, we determined sexual systems for 98% of the indigenous seed plant flora. We found remarkably high incidences of dioecy. Of the 44 species of gymnosperms, 70% are dioecious and the remaining 30% are monoecious. The distribution of sexual systems among angiosperms (3,095 species) is 19.5% dioecious, 0.7% gynodioecious, 0.4% androdioecious, 13.6% monoecious, 4.1% andromonoecious, and 61.6% hermaphroditic. For angiosperms, dioecy is over-represented among endemics, woody and rainforest species, and the Gondwanan component of the flora. Almost 90% of the dioecious angiosperms have at least three of four ecological traits appear to enhance the success of dioecous lineages. With over 4% of the world’s dioecous species, the flora of New Caledonia provides a rich and important new source of information on the origins and maintenance of dioecy.

P0975. Biodiversity of the vascular plants on the Russian Far East

A. E. Kozhevnikov;
Institute of Biology and Soil Science, Vladivostok, Russian Federation.

The natural flora of the Russian Far East (RFE) covers 4347 species of the vascular plants from 979 genera and 176 families (Kozhevnikov, 2003). The indigenous species complex is presented by 3686 species from 789 genera and 169 families. The adventive (alien) species complex includes 661 species from 334 genera and 68 families.

Flora of RFE belongs to floras of Cyperaceae type. The Endemic element includes 470 species from 147 genera and 45 families. There are 7 endemic genera - Microbiota, Acelidanthus, Miyakea, Ermania, Astrocodon, Popoviocodonia and Magadania.The portion of main 10 families in indigenous species complex of RFE varies from 76-78% in arctic zone to 50% in nemoral zone. Adventive index changes from 6.1% in Magadanskaya District to 22.1% in Primorsky Territory.

According to structure of taxonomical spectrums two main groups of administrative areas on RFE were revealed. The first group situated in continental part of RFE and the second - in its maritime parts (Kamchtskaya and Sakhalinskaya Districts). The flora of Magadanskaya District has got intermediate position.

P0976. Two ivy (*Hedera* L., Araliaceae) species from the classic and geometric morphometrics points of view

A. B. Shipunov[1], D. D. Vasjukov[2], E. A. Kost[2], V. S. Rudakova[2];
[1]Institute of Information Technologies, Moscow, Russian Federation,
[2]Moscow South-West High School, Moscow, Russian Federation.

Two ivy species from Russia and Ukrainia, *Hedera helix* and *H. colchica* (Araliaceae), are noticeably different in ploidy and micromorphological characters (hairs), but hardly distinguished in field conditions if only morphological characters used. We employed the simultaneous multivariate analyses of 8 metric leaf characters and three different approaches in geometric morphometry (landmark analysis via thin-plate splines and two variants of the elliptical Fourier analysis of the leaf outlines, totally 810 plants were measured) to test if there is the differences between these species in morphology and which of these methods is most suitable for taxonomic purposes. Our results show that only landmark-based method could clearly distinguish these species. Several of localities contain the forms with intermediate characters, this could be evidence of introgression between these two species. The samples of ``*Hedera taurica*'' from Crymea do not show any differences from typical *H. helix*.

P0977. A study on the varietal differences in the vegetative morphology of Citrus spp

m. I. igwe;
nnamdi azikiwe university,awka, Along ziks avenue,awka anambra state, Nigeria.

Seven varieties of Citrus spp were sampled for studies to assess varietal differences in their vegetative morphology, and to develop a taxanomic key that will simplify the classification of this angipsperm plants.The seven varieties used included Nigerian Green Orange[Citurs sinesisL.Osbeck],Sasuma[Citurs nobilis Var Unshiu],Shaddock[Citrus maxima],Grape[Citrus paradisii Mact],Tangerine[Citrus reticulata Blanco],Tangelo[tangelo*pomello]and Rough lemon[Citrus limoni].A twig was cut from the tree of each variety under studies and 10 leaflets were abscised and randomly sampled for biometeric analysis.Length,width and petiole length of the leaflets were also measured and the data obtained were statistically analyzed..A taxanomic key was formulated for identification of the species studied using their morphological characters and the measured parameters.It is possible that a more detailed key could evolved with the study of all Citrus species and could be used in taxanomic studies of other angiosperm.

P0978. Genetic differentiation and relationship of populations in the *Aconitum delavayi* complex (Ranunculaceae)

F. Zhang, W. Chen, Q. Yang, S. Ge;
Institute of Botany,Chinese Academy of Sciences, Beijing, China.

RAPD markers were employed to examine the differentiation of 18 populations representing all species of the *Aconitum delavayi* complex distributed mainly in Hengduan Mountains of China. The PCO and UPGMA analyses of RAPD data indicate that the complex comprises three different clusters. The first cluster consists exclusively of *A. episcopale* populations, which indicates that *A. episcopale* is a very distinct species, in good agreement with our previous allozyme and ITS data. The second includes one *A. campylorrhynchum* population and all the *A. henryi* populations from the northern Hengduan Mountains and its neighbor areas. The third comprises the populations of *A. delavayi*, *A. stapfianum*, *A. tuguancunense* and *A. campylorrhynchum* from the southern Hengduan Mountains. The little genetic differentiation among populations of *A. stapfianum*, *A. delavayi* and *A. tuguancunense* suggests that they would batter be treated as a single species. The fact that *A. campylorrhynchum* populations appear in two different clusters demonstrates that *A. campylorrhynchum* should be treated as two different species.

P0979. Phylogeny of the genus *Anthurium* Schott (Araceae): Preliminary results

M. Carlsen[1,2];
[1]Missouri Botanical Garden, Saint Louis, MO, United States, [2]University of Missouri, St. Louis, MO, United States.

Anthurium, with approx. 700 species, all from the New World tropics, is the largest genus in Araceae, and is currently divided into 18 sections mainly distinguished by leaf morphology and habit. Species with lobed leaves have been placed in sections Schizoplacium, Semaeophyllium and Dactylophyllium, however, a molecular phylogeny using chloroplast markers shows that lobed leaves have evolved independently more than three times. Preliminary results also indicate that other sections may not be monophyletic whereas some tend to hold together (e.g. bird-nest *Anthurium*, section Pachyneurium). These data thus suggest that the current morphological sectional classification of *Anthurium* needs re-evaluation. Further molecular and morphological work is underway in order to develop a robust phylogeny for the genus on which a revised classification can be based. The phylogeny will also help clarify the evolution and diversification of this ecologically important genus.

P0980. Phylogeny of Anagallis

U. Manns[1], A. A. Anderberg[2];
[1]Department of Botany, Stockholm University, Stockholm, Sweden,
[2]Department of Phanerogamic Botany, Swedish Museum of Natural History, Stockholm, Sweden.

Anagallis (Myrsinaceae), with 31 recognised species, includes small herbaceous, erect or decumbent plants diagnosed by the presence of circumscissile capsules. Most species have a limited distribution, several in tropical East Africa, others in Madagascar, South Africa or the Mediterranean region. A few species are more widespread, e. g. *Anagallis arvensis* or "Poor man's weather glas". Previous molecular studies place *Anagallis* nested within *Lysimachia* but in two different clades, raising questions regarding the monophyly of the genus. Our present study of nuclear and cpDNA data supports *Anagallis* as a monophyletic group, but only if *Asterolinon* and *Pelletiera* as well as *Lysimachia nemorum* and *L. serpyllifolia* are also included. In *Anagallis* two monophyletic groups appear with strong support, the first supported by several unique morphological floral characters while synapomorphies for the second group are less obvious, despite an overall similarity between its species.

P0981. Multivariate morphometric analysis of the *Caltha palustris* L. complex from the representative parts of its European range

E. CieŜlak;
W. Szafer Institute of Botany, Polish Academy of Sciences, Kraków, Poland.

Taxonomical-chorological studies on the *Caltha palustris* L. complex were carried out based on the material of North and Central European provenance. Detailed analysis of the intra- and interpopulational variability, based on several morphological features of the specimens from various parts of the species' range, allowed to determine the limits of this variability and to assess a taxonomical status of the discerned morphotypes. Numerous morphologically intermediate forms were also revealed. Several techniques of the numerical analysis have been applied (PCA, CA, DA, ANOVA) to characterize the variability of the material studied. Based on the date obtained for the variability as well as on the geographical distribution of the whole complex, its taxonomical treatment was proposed and, for the taxa distinguished, the pattern of the horizontal and the vertical ranges was identified. As a result, the following taxonomy of the complex has been adopted:
C. palustris L. ssp. *palustris*
ssp. *cornuta* (Schott, Nyman & Kotschy) Hegi
ssp. *radicans* (T. F. Forst.) Syme
C. laeta Schott, Nyman & Kotschy

P0982. Reappraisal of Sectional Classification of *Anthurium* (Araceae)

T. B. Croat[1], M. Carlsen[2];
[1]Missouri Botanical Garden, St. Louis, MO, United States, [2]University of Missouri-St. Louis, St. Louis, MO, United States.

A total of 1024 species are now known in the genus *Anthurium* (Araceae). This represents a 235 % increase in numbers of species from the 305 treated in last revision of the genus by Engler in 1905. The current sectional classification of *Anthurium* distinguishes 18 sections, however this reappraisal has placed many more species in section *Porphyrochitonium*, eliminated section *Oxycarpium*, greatly modified the understanding of section *Urospadix*, added the new section *Decurrentia*, accepted *Tetraspermium*, *Dactylophyllium, Gymnopodium*, *Pachyneurium*, *Polyphyllium*, *Leptanthurium*, *Cardiolonchium*, *Chamaerepium*, *Calomystrium* and *Belolonchium* as seemingly natural sections, and suggests *Porphyrochitonium, Xialophyllium*, *Polyneurium*, *Urospadix*, *Episeiostenium*, *Digitinervium*, *Semaeophyllium* and *Schizoplacium* as sections in need of more investigation.

P0983. Taxonomic diversity and conservation of genus *Trichosanthes* in India

A. K. Pandey;
TM Bhagalpur University, Bhagalpur, India.

The genus *Trichosanthes* (Cucurbitaceae) is represented by 21 species in India. *Trichosanthes anamalaiensis* Bedd., *T. perrottetiana* Cogn., *T. villosula* Cogn., *T. cuspidata* Lam. are endemic to South India. *T. himalensis* var. *glabrior* Clarke, *T. ovata* Cogn. and *T. tometosa* Chakravarty are endemic to Khasi hills (Meghalaya), Sikkim and Nagaland respectively. *Trichosanthes* species are found in wild conditions except *T. cucumerina* var. *anguina* L. and *T. dioica* Roxb. which are cultivated as vegetable crops. Plants are extensive climbers. Most of the species are dioecious except *T. cucumerina* var. *anguina* and *T. horsfieldii* Miq. which are monoecious. Flowers are generally white and are characterised by the presence of frills. The pollen grains are spherical and triporate. Fruits are fleshy, globose, ovoid or fusiform, indehiscent and many seeded. *T. dioica* possess round and smooth seeds. *Trichosanthes* exhibits diversity at specific and infraspecific levels. This diversity needs to be conserved especially in *T. dioica* where varieties are known only under cultivation.

P0984. Phylogenetic relationships in Aponogeton (Aponogetonaceae) based on chloroplast DNA sequence data, with implications for the evolution of fenestrated leaves in lace plants

N. Tanaka[1], M. Ichiyanagi[2], J. Bogner[3], R. Imaichi[2];
[1]Tsukuba Botanical Garden, National Science Museum, Tokyo, Tsukuba, Japan, [2]Department of Chemical and Biological Sciences, Japan Women's University, Mejirodai, Tokyo, Japan, [3]Arbeitskreis Wasserpflanzen Baden-Wurttemberg, Gersthofen, Germany.

A phylogenetic analysis of the chloroplast DNA of Aponogeton species was undertaken. The Aponogetonaceae includes only Aponogeton, which is an aquatic genus with about 45 species distributed throughout the tropical and subtropical regions of Africa, Asia, and Australia. The lace plant, Aponogeton madagascariensis, is characterized by fenestrated leaves. Our anatomical observations suggest that its three varieties are divided into two types according to the process involved in perforation formation. This study examined the phylogenetic relationships in Aponogeton to reveal the evolution of fenestrated leaves. In the molecular phylogenetic tree constructed using the chloroplast genes rbcL and matK, the three varieties of lace plant do not form a monophyletic group. Therefore, fenestrated leaves arose more than once in Aponogeton. In addition, leaf morphology and geographic distribution are discussed based on character-state reconstruction.

P0985. Taxonomic studies in Indian *Curcuma* L.: what causes such confusion in the genus?

J. Skornickova[1,2], O. Sida[3], T. Fer[1], M. Sabu[2], K. Marhold[1];
[1]Charles University, Prague, Czech Republic, [2]Calicut University, Calicut, India, [3]National Museum, Prague, Czech Republic.

The genus *Curcuma* L. (Zingiberaceae) with over 100 species is distributed in tropical Asia with the highest diversity in India and Thailand. About 30 species have been previously recognized in India, but the number of published names has been neglected and over 60 names have been published for Indian taxa. Many of these names may be synonyms, but some of the earlier proposed synonyms are incorrect and need critical reconsideration. Several species were described 200 years ago and their true identity is not always clear. Substandard descriptions, lack of type specimens, the need to study fresh flowering material, the overall resemblance of many species and high intra-population variability of seed-setting species with a wide distribution makes the study difficult. This poster presents preliminary results of our extensive fieldwork conducted between 2000-2004 as part of a revision of this economically and ornamentally important genus for India.

P0986. The carpology and systematic relationships of the subfamily *Hydrocotyloideae (Apiaceae)*

A. I. Konstantinova;
Moscow State University, Moscow, Russian Federation.

As a result of our comparative morphological and anatomical study of fruits in numerous representatives of the subfamily *Hydrocotyloideae* (*Apiaceae*), tentative corrections to Drude's system were proposed. These changes mainly relate to the size of tribes and subtribes: thus, we consider advisable to elevate South African endemic *Hermas*, possessing a fruit with a special secretory system type, to tribal rank. We also propose to exclude Australian genus *Actinotus* from the *Apiaceae***,** because the way of ovary development in it and some structural traits of its highly specialised one-seeded indehiscent fruit are absolutely uncharacteristic for this family. On the basis of significant carpological differences between the subfamily *Hydrocotyloideae* and subfamilies *Saniculoideae* and *Apioideae*, as well as the analysis of available data on palynomorphological, embryological, biochemical features, the concept of *Hydrocotyloideae* as a separate family *Hydrocotylaceae* Hylander seems thoroughly acceptable.

P0987. Phylogenetics relationships of Ebenaceae : inferred from four regions of plastid and *ncp* glutamine synthetase

S. Duangjai[1], R. Samuel[1], B. Wallnoefer[2], M. Chase[3];
[1]Institute of Botany, Vienna, Austria, [2]Natural History Museum, Vienna, Austria, [3]Royal Botanic Gardens, Kew, London, United Kingdom.

Phylogenetics relationships in Ebenaceae were investigated by parsimony analysis of combination of DNA sequences of plastid *matK*, *trnK* intron, *trnLF* region, *trnSG* spacer and *ncpGS*. Preliminary results clearly show that Ebenaceae are monophyletic. *Lissocarpa* is sister to *Euclea* and *Diospyros*. Member of *Diospyros* section *Royena* are grouped together with *Euclea* as a separate clade. In *Diospyros*, subgeneric status of subgen. *Hierniodendron* with *D. maingayi* is confirmed, and is also supported by morphological evidence. However except this subgenus and the section *Royena*, all other species of *Diospyros* form a unresolved clade containing subgenera *Maba*, *Eudiospyros* and other species from Asia minor, North America and Africa. One African *Diospyros* species (*D*. sp. Eb205) is sister to this unresolved clade without a good support. Within subgen. *Eudiospyros* our results give better resolution at sectional level for sections *Capanulata*, *Ebenaster*, *Glutinosa*, *Kurzella*, *Lotus*, and *Ptychocylix*.

P0988. Reappraisal of *Diplolabellum coreanum* (Orchidaceae)

S. M. Eom[1], T. Yukawa[2], J. V. Freudenstein[3], Y. Luo[4], **N. S. Lee**[1];
[1]Department of Biology, College of Natural Science, Ewha Womans University, Seoul, Republic of Korea, [2]Tsukuba Botanical Garden, National Science Museum, Amakubo, Tsukuba, 305-0005, Japan, [3]Department of Evolution, Ecology and Organismal Biology, Ohio State University Herbarium, Columbus 43212, OH, United States, [4]Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences, Beijing, 100093, China.

The taxonomic treatment of a monotypic genus, *Diplolabellum*, which was described by Maekawa in 1935 based on *Oreorchis coreana* Finet, has been in dispute by various authors. Since the distribution of this plant is very limited in Jeju Island of the South Korean Peninsula, the species has not been well studied. To reappraise *Diplolabellum coreanum*, ITS, *trnT-trnL* and *trnL-trnF* sequences were obtained from *D. coreanum,* several species of *Oreorchis* and related genera. In the sequence analysis, *Diplolabellum coreanum* was revealed to be closely related to one group of *Oreorchis,* which consists of *O. patens* and *O. fargesii*. Molecular data therefore suggest that the species should be treated as *Oreorchis coreana* rather than *Diplolabellum coreanum*, even though this species is distinct from the other taxa of *Oreorchis* in morphological characters such as callus, pedicel, column and caudicle.

P0989. Phylogenetic trends in fruit structure of Apiaceae

P. M. Tilney[1], B. Van Wyk[1], M. Liu[2];
[1]Department of Botany and Plant Biotechnology, University of Johannesburg, South Africa, [2]Department of Biology, Harbin Normal University, China.

With recent advances in molecular systematics of the Apiaceae at suprageneric level, it has become possible for the first time to interpret the remarkable diversity of fruit structure in a new way. The evolution of dorsally compressed fruits, vittae, loss of rib oil ducts and crystals, and reduced lignification of the endocarp appear to be unique events which help to define large groupings of genera within the family. There is great variability with regard to the shape of the two mericarps comprising the fruit, the configuration of wings (if present), the presence or absence of outgrowths on the mericarps, the shape of epidermal cells, the number of vascular bundles, the configuration of the rib oil ducts and vittae (if present), the presence or absence of crystals and their positions, the degree or lack of lignification of the endocarp, and the carpophore (and ventral bundle) configuration. This variability limits the diagnostic utility of many of the features (homoplasy seems rampant) but several general trends can clearly be distinguished.

P0990. The systematic significance of seed morphology in *Stenocereus* (Cactaceae)

G. Arroyo-Cosultchi[1], T. Terrazas[1], H. J. Arreola-Nava[1], S. Arias[2];
[1]Colegio de Postgraduados, Montecillo, Mexico, [2]Jardín Botánico, Instituto de Biología, UNAM, Mexico city, Mexico.

Seed morphology of 24 species of *Stenocereus sensu* Barthlott and Hunt was examined by scanning electron microscope. Quantitative and qualitative features were evaluated using phenetic analysis in order to identify groups of species. Two groups of species were distinguished based on morphological variations of seed size, luster, multicellular sculpture, cell-size, sculpture of periclinal walls, microrelief, position relative to rim and shape of hilum and micropyle complex. All studied species are keeled with isodiametric cells. *Stenocereus alamosensis*, *S. kerberi* and *S. beneckei* are unique among species of *Stenocereus* in having seeds with flat relief and lacking micro-relief. *Stenocereus aragonii* and *S. eichlamii* also have seeds with large size, glossy appearance, and lack of micro-relief as most *Pachycereus* species. *Stenocereus dumortieri* shares with the other *Stenocereus* species most seed characters, specially the coarse striated cuticle in all periclinal walls with *S. martinezii* and *S. quevedonis*. Congruence and discordance among characters for species groups in *Stenocereus* are discussed.

P0991. Phylogenetic analysis in Rhynchosporae (Cyperaceae)

A. C. Ana Claudia[1,2], W. Thomas[2];
[1]Universidade do Vale Itajai, Itajai, Brazil, [2]New York Botanical Garden, New York, NY, United States.

Rhynchospora is the most diverse sedge genus in the Neotropics. Kükenthal's revision recognized two subgenera (each of which was divided into 2-3 supra-sectional taxa called "pars"), 28 sections, and placed *Pleurostachys* outside of *Rhynchospora*. A phylogenetic analysis of the plastid gene *trn*L-F was conducted in order to evaluate phylogenetic validity of the separation of *Pleurostachys* from *Rhynchospora*, the monophyly of the subgenera, and the soundness of the "pars" level groupings. *Cladium mariscus* was used as the outgroup in this analysis of three species of *Pleurostachys* and 22 of *Rhynchospora*, representing 11 of Kükenthal's sections. Preliminary results indicate that *Pleurostachys* is distinct from *Rhynchospora* and that, possibly, some species of *Rhynchospora* (i.e., *R. splendens*) should be placed in *Pleurostachys*. Within *Rhynchospora*, a large clade comprising most sections of subgenus *Haplostylis* is distinct. Subgenus *Rhynchospora* and the remaining sections of subgenus *Haplostylis* are poorly resolved but show some evidence of clustering into clades resembling some of Kükenthal's supra-sectional groupings.

P0992. Japanese Oenanthe javanica contains two biological speices: evidence from chloroplast DNA

A. Seo, N. Murakami;
Graduate School of Science, Kyoto University, Kyoto, Japan.

Oenanthe javanica (Blume) DC. is a perenial herb well known as "Seven Spring Herbs" in Japan since Heian period of 8th century. Some morphological characters (leaf shape, length of umbel rays and so on) of O. javanica shows large intrtaspecific variation. However, this plant species has been treated as one species due to continuous morphological variation, especialy in leaf shape. In Japan, some taxonomists recognized two subspecies, subsp. javanica and subsp. linearis in O. javanica based on their difference in leaf shape. We analyzed noncoding regions of cpDNA, rps16 intron and trnG (UCC) intron, of these intraspecific taxa growing in Japan and also observed their flowering period, habitat, and leaf shape. Two haplotypes of cpDNA were found in this species two ecological traits (flowering period, habitat) and morphological trait (cauline leaf shape) were observed in each haplotypes. These results showed that Japanese O. javanica can be divided into two independent species. O. javanica is widely distributed in Southeastern Asia, Taiwan, and China. We should investigate plant samples in these areas as well.

P0993. Biological varieties of plants in South Caucasus and their protection

V. Novruzov, Z. Ismayilova;
Ganja State University, Ganja, Azerbaijan.

The problem of flora protection in South Caucasus has become more pressing. Periodicity of processes has become sharp and the results of it have become irresistible. As human affects to natural flora more increasingly, the problem of the protection of genofund is becoming more vital.

It was defined that 460 species out of more than 4500 in the flora need to be protected. Every tenth variety in the flora is endangered.

We must note with regret that the habital of 28 species out of 140 that have been included in the "Red Book" is in Garabagh.

The only place that endemic species like Scoroteria pulchra, Anemone kuznetzovii, Qladiolus halophilus exist in nature is Garabagh. On the other hand Stellaropsis maqakyanii, Salsola tamamschyane lactuca takthadzianii are spread only in 2 places in nature-Nakhchivan and Armenia. The biological diversity of Caucasus can be protected by the joint efforts of the Caucasian scientists.

P0994. Studies on interspecies relationship of *Smilax china complex* based on Karyotypes and molecular data analysis

C. X. Fu, A. L. Wang, H. H. Kong;
Lab of Systematic Botany, College of Life Sciences, Zhejiang University, Hangzhou, China.

Smilax china and their relativities distributed in Chi. Kor. and Jap., including 12 populations of *S. china* (one 2X, three 4X and eight 6X) and 8 relativities of *S. polycolea(4X)*, *S. ferox*(6X), *S. lebrunii*(6X), *S. davidiana*(2X), *S. trinervula*(2X), *S. chingii*(2X), *S. glauco-china*(2X), *S. scobinicaulis*(2X) and *S.biflora*(4x) are studied using ITS, matK and isozyme. Results show *S. davidiana, S. trinervula* and *S. china* in Hubei have close relationships to polyploid species of the group and maybe diploid parents. *S. davidiana & S. trinervula*, *S. biflora & S. polycolea,* and *S. ferox & S. lebrunii* should be clear into the complex. *S. lebrunii* are more closer to *4X* Jinfu *S. china* and *S. polycolea* distributed in same area. *S. china var. kuru* and *S. biflora* distributed in Okinawa islands are close to *S. trinervula* of China, however, 4x population in Jap. is sister to 4x and 6x populations in China. It is suggested *S.glauco-china* and *S. scobinicaulis* of black fruits are more different from *S.china* complex of red fruits. It is considered that polyploidy of the complex is of multiple origins and is allopolyploidy. A possible evolution and speciation are given in the paper.

P0995. Improving growth and productivity desert plants: Laticiferous plants.

A. Kumar;
Biotechnology LAB. Department of Botany, Jaipur, India.

The semi-arid and arid regions of the world have vegetation rich and latex which helps it to overcome drought conditions on one hand and prevent browsing from the stray cattle. Arid region of India lies between 24 degree and 29 degree latitude and 70 degree and 76 degree longitude and covers 3,17,090 km square spread over seven states of Indian Union. Ninety percent if arid region about 2,85,580 km square is confined to north west India, covering most of the western Rajasthan. The present investigations were undertaken to characterise the plant species appearing at different stages of vegetation development. The vegetation of non-saline wastelands was determined and potential renewable sources of bio-energy were identified. Several plants had uses in traditional medicines. The detailed investigation of selected plants were carried out and different factors like nutrients and growth regulators affecting growth and productivity of desert plants were determined with special reference to laticiferous plants. Details shall be presented.

P0996. Immunological investigations of relationships of taxa within Apioideae (Apiaceae): correspondence and disagreement with DNA sequence data.

V. S. Shneyer;
Komarov Botanical Institute RAS, Sanct-Petersburg, Russian Federation.

The results of the immunological comparison of storage seed proteins and of DNA sequence analysis of *Apioideae* (*Apiaceae*) taxa mostly correlate with each other and revealed the pattern of evolution within the subfamily that poorly supports earlier suggested classifications based on morphological characters. Among main lineages within *Apioideae* supported by results received by both methods are: *Physospermum*-group; *Parasilaus-Komarovia-Hansenia-Notopterygium* group; *Caucalideae-Scandiceae-Dauceae-Thapsieae* group; *Smyrnium* group; Apioid-superclade; among smaller groups are *Apium-Anethum-Foeniculum-Petroselinum* group; *Heracleum-Pastinaca-Zosima* group and some other. But the inclusion of some taxa in the Apioid-superclade by DNA analysis was not confirmed by immunological data and *vice versa,* as well as the subdivision of the superclade. Discordant results were received concerning relationships and/or phylogenetic position of *Carum*, *Smyrnium*, *Ferula, Conioselinum, Ligusticum scoticum* and some other taxa.

P0997. Taxonomic treatment of *Salvia* Section *Incarnatae* (Lamiaceae)

S. I. Lara-Cabrera;
Facultad de Biología, Morelia. Michoacan, Mexico.

Salvia is a not well understood genus despite its economic and ecological importance. For a thorough understanding of the systematics and phylogeny of *Salvia* it is necessary to have taxonomic treatments of as many groups as possible, particularly those with taxonomic or nomenclatural problems. Of the 94 sections that Epling recognized in 1939 for subgenus *Calosphace*, 34 are mainly Mexican in distribution, but only section *Sigmoideae* has been recently studied. Section *Incarnatae* is treated, including its two species, *S. elegans* and *S. cinnabarina*, and their varieties status is discussed. *Incarnatae* has petiolate leaves, 3 to 6 flowers per semiwhorl, upper calyx lip five veined, corolla tube sulcate longitudinally near the base in *S. cinnabarina*, and exserted stamens from the corolla's upper lip. *S. elegans* distributed from the north of Mexico into Oaxaca and *S. cinnabarina* from Oaxaca into Central America. Several nomenclatural problems have been found particularly in *S. elegans*.

P0998. Phylotaxonomy of genus Scabiosa (Dipsacaceae) in East Asia.

C. Suyama, K. Ueda;
Division of Life Sciences, Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan.

Genus *Scabiosa* is distributed mainly in temperate zone of Europe, Africa and Asia, and comprises ca. 90 spp. In Japan, *S. japonica s.l.* and *S. jezoensis* occur widely in seaside to alpine areas throughout the Japanese archipelago. The taxonomical review in Japanese *Scabiosa* revealed that *S. japonica s.l.* and *S. jezoensis* have to be classified into different sections, though they have been treated as varieties of the same species until quite recently. *S. japonica* s.l. is classified into section *Scabiosa* by its cylindrical, deep and narrowly 8-sulcated epicalyx. This is the unique taxon among the East Asian species in this respect, and the species of the same section are distributed in Europe, Africa and central Asia, but never in East Asia. *S. jezoensis*, on the contrary, shows the same characteristics as in the section *Prismakena* that is distributed only in East Asia.

We reexamined the former taxonomic systems in *Scabiosa* based on morphology and habitat, and molecular analyzing using cpDNA and nDNA gave the new insights for speciation and dispersion of E-Asian *Scabiosa*. Furthermore we will discuss the phylotaxonomy of *Scabiosa* in East Asia and of Dipsacaceae in the world.

P0999. Genetic diversity of an endangered slipper orchid, *Cypripedium macranthos* var. *rebunense* and the impact of a sympatoric relative, *C. calceolus*

T. Kawahara[1], T. Izawa[2], H. Takahashi[3], K. Inoue[4];
[1]Forestry and Forest Products Research Institute, Sapporo, Japan, [2]Graduate School of Agriculture, Hokkaido University, Sapporo, Japan, [3]The Hokkaido University Museum, Hokkaido University, Sapporo, Japan, [4]Shinshu University, Nagano, Japan.

An endangered species, Cypripedium *macranthos* var. *rebunense* is distributed in the most northern small island in Japan. This species used to be collected illegally and is fragmented to several populations. We estimated genetic diversity of these populations using 13 allozyme loci. Genetic diversity in a small population is not different from those in large. The gene differentiation index (Gst) is 8.4%. These results show fragmentation of the populations would have occurred recently enough that genetic diversity has not decreased even in small population and genetic differentiation has not occurred among the populations. Eight plants of *C. calceolus* grow sympatorically in the protected area of *C. macranthos* var. *rebunense*. These plants doubt to be planted. We identified their hybrids using 8 allozyme loci, ITS2 and 4 cpDNA sequences. Six putative hybrids had both specific markers derived from two species. Judging from the result of cp DNA markers, *C. macranthos* was their mothers. Two plants have homozygotes of *C. macranthos* specific alleles in MNR and EST-3 respectively. It is indicating the backcross hybridization may have occurred with *C. macranthos.*

P1000. Carpoanatomy supports polyphyly in *Podistera* (Umbelliferae/Apiaceae) and generic status of *Orumbella*

M. G. Pimenov, **E. A. Zakharova**;
Botanical Garden, Moscow State University, Russia, Moscow, Russian Federation.

Sun, Downie & Hartman showed recently, on the basis of molecular analysis, that many N American Umbelliferae genera are not monophyletic. This refers to *Podistera*, the genus of dwarf alpine and arctic perennial polycarpic herbs. The systematics in American Umbelliferae was traditionally based on different morphological characters, and was developed without detailed analysis of inner fruit structure. American monographers even rejected the taxa which they referred to “carpological genera”. Our carpological analysis of 3 *Podistera* species (*P. nevadensis*, the type of genus’ name, *P. eastwoodae*, and *P. macounii*) revealed essential differences among the species in mericarp transaction form, rib form and structure, in the absence/presence of parenchyma cells with lignified pitted walls and in absence/presence of rib sectretory ducts, as well as in style structure. For instance, Beringian (Alaska & Chukotka) endemic *P. macounii* differs considerably from *P. nevadensis*. The genus *Orumbella* Coult. & Rose is to be restored for this species. Russian and American *O. macounii* have similar fruit structure. In this case, carpological and molecular data are congruent.

P1001. Evolutionary patterns in the transition between the terrestrial and epiphytic habit in Orchidaceae

K. M. Cameron;
The New York Botanical Garden, Bronx, NY, United States.

Multi-gene phylogenies of Orchidaceae show that the terrestrial habit is plesiomorphic in the family. Four of the five orchid subfamilies are almost exclusively terrestrial, as are the tribes of "lower" Epidendroideae. Only within the "higher" Epidendroideae (which constitutes ca. 80% of all orchid species) do we find entirely obligate epiphytic lineages, and this habit defines 88% of those genera and 92% of their species. But, there are a few higher epidendroid lineages that have secondarily reverted to a terrestrial lifestyle. To explore one example of this phenomenon, ITS and *matK* sequences were collected for 71 taxa of Malaxideae (a tribe containing both epiphytes and terrestrials) in order to develop a phylogenetic hypothesis for the genera and species. Highly resolved and supported cladograms indicate that the tribe is split into one clade of terrestrials and another of epiphytes, documenting that the reversal to terrestrial habit has occurred only once in Malaxideae. Whether or not a similar unilateral pattern is characteristic of other orchid clades remains to be investigated within the framework of robust phylogenetic hypotheses.

P1002. Phylogenetic and Biogeographic Relationships in Polyscias s. lat. (Araliaceae)

G. M. Plunkett[1], P. P. Lowry II[2];
[1]Virginia Commonwealth University, Richmond, VA, United States,
[2]Missouri Botanical Garden, Saint Louis, MO, United States.

“*Polyscias* s. lat.” unites the paraphyletic genus *Polyscias* (~150 spp.) to 6 other genera of Araliaceae. Analyses using molecular data suggest an Australian-Malesian origin of the clade, but most species have insular Pacific or Indian Ocean distributions, and diversity is highest in New Caledonia and Madagascar. Thus, *Polyscias* s. lat. affords an opportunity to compare dispersal patterns between these two ancient, floristically-rich, continental islands. Results suggest multiple, independent dispersals to land masses in both oceans. In the Indian Ocean, independent dispersals led to separate Seychelles and Malagasy lineages, with secondary dispersals from Madagascar to the Mascarenes, Comoros, and continental Africa. In the Pacific, three independent dispersals from Australasia to New Caledonia can be inferred, with subsequent dispersals to other Pacific islands (e.g., Fiji, Vanuatu, Lord Howe Is.) in one of these radiations. At least two additional dispersals into the Pacific have been identified that do not include New Caledonian representatives.

P1003. Floral structure of *Ditassa burchellii* var. *burchellii* (Apocynaceae, Asclepiadoideae) with emphasis on glands

M. d. M. Castro[1], L. S. Kinoshita[1], L. Ascensão[2];
[1]Depto. de Botânica, Universidade Estadual de Campinas, Campinas, Brazil, [2]Centro de Biotecnologia Vegetal, Depto. de Biologia Vegetal, Faculdade de Ciências, Universidade de Lisboa, Lisboa, Portugal.

The purpose of the present work is to show the floral structure of *Ditassa burchellii* Hook. & Arn. var. *burchellii* with special reference to the observed glands. It is a liane growing in mesophytic forest edges that bears tiny white flowers producing a characterist scent. Inflorescences were collected, and mature flowers investigated using scanning electron microscopy and histological serial sections. Different types of glands were observed: **1. bracteolar and calycine colleters** are emergences exsuding a sticky substance that lubricate and protect the developing floral buds; **2. papillose epidermis** are covered by non-glandular trichomes in the upper surface of the petals; **3. secretory palisade-like epidermis** of the gynostegium produces the translators; **4. secretory epidermis** also occurs on the filaments at special regions of the gynostegium and corona; **5. laticifers** are widely distributed on the floral organs - from sepals to gynostegium - forming a continuous system dispersed among the ground tissue. The glands variety reinforces the floral complexity presented by species of Asclepiadoideae. (CNPq)

P1004. Pyrrolizidine alkaloids in Apocynaceae

M. Boppré;
Forstzoologisches Institut, Freiburg i.Br., Germany.

Pyrrolizidine alkaloids and/or their N-oxides (PAs) are secondary compounds typical for several Asteraceae (e.g., *Senecio*, *Gynura*), Boraginaceae (e.g., *Heliotropium*, *Echium*), and Fabaceae (*Crotalaria*). However, several types of PAs have also been reported from a few species of Apocynaceae *s.l.*

Relationships of "PA-insects" (e.g., certain butterflies and moths) with Apocynaceae indicate that further taxa of Apocynaceae also contain PAs. These are reviewed and results of new chemical analyses are provided. Although they are insufficient to provide a conclusive picture on the distribution PAs in Apocynaceae, they suggest that studying further species seems rewarding; more comprehensive knowledge on the presence of PAs in species of Apocynaceae not only helps elucidating the evolution of insect-PA relationships but likely will contribute to the systematics of Apocynaceae.

P1005. Gynostegium morphology of Mesechiteae (Apocynaceae, Apocynoideae) based on species of *Forsteronia, Macrosiphonia, Mandevilla* and *Mesechites.*

L. S. Kinoshita[1], A. O. Simões[2,3], M. C. S. Rio[2], M. d. M. Castro[1];
[1]Depto. de Botânica, Universidade Estadual de Campinas, Campinas, Brazil, [2]Pós-Graduação em Biologia Vegetal, Universidade Estadual de Campinas, Campinas, Brazil, [3]Institute of Systematic Botany, Zürich, Switzerland.

In order to investigate morphological patterns in Mesechiteae and test the new circumscription of the tribe, the gynostegium structure of eight species belonging to *Forsteronia*, *Macrosiphonia*, *Mandevilla* and *Mesechites* as well as two species from *Secondatia* (as outgroup) were comparatively studied. The gynostegium of *Forsteronia*, *Macrosiphonia*, *Mandevilla* and *Mesechites* all have the same basic pattern: a proliferation of parenchyma cells in the style-head forms five projecting ribs that are united either only at their base or along their entire length to the stamens via cellular fusion. In *Secondatia*, on the other hand, the style-head has no projecting ribs and union is via unicellular trichomes of the connective, which are inter-digitated with the secretory epidermis of the style-head, without cellular fusion between the parts. The observed differences between the gynostegium morphology of *Secondatia* and that of the other genera agree with the new circumscription of Mesechiteae, supporting the inclusion of *Forsteronia* in the tribe and the transfer of *Secondatia* to Apocyneae. (FAPESP, CNPq)

P1006. Molecular Phylogeny and Biogeography of the Secamonoideae (Apocynaceae s.l.)

R. Lahaye[1], J. Klackenberg[2], M. Källersjö[2], L. Civeyrel[1];
[1]Laboratoire de Dynamique de la Biodiversité, Toulouse, France,
[2]Swedish Museum of Natural History, Stockholm, Sweden.

The poorly known Secamonoideae are nested in the Apocynaceae s.l. in which they are sister group to the subfamily Asclepiadoideae. This palaeotropic subfamily is represented by 7 genera with about 200species showing an extensive morphologic diversification and an interesting Gondwanan distribution pattern. Madagascar is the main centre of radiation of this subfamily with about half of the known species occurring; the other taxa are distributed in Africa, Asia and Australia. Relationships within Secamonoideae are investigated by maximum parsimony and Bayesian inferences of molecular sequence data from the plastid trnL intron, trnL-F spacer, and the matK gene with its first trnK spacer. From this largest phylogeny of the Secamonoideae ever presented, we particularly put emphasis on phylogenetic relationships of the main genus Secamone. The next largest genus, Toxocarpus, appears to be closely related to Secamone. The biogeography of the Secamonoideae is also discussed for the first time showing no clear vicariance patterns between continents and islands, but instead repeated supposed long distance dispersals.

P1007. Phylogenetic analysis of the Cascabela-Thevetia complex (Plumerieae;Apocynaceae) based on morphology.

L. O. Alvarado-Cárdenas, **H. Ochoterena**;
Instituto de Biología, UNAM, Mexico, Mexico.

Cascabela, Cerbera and Thevetia have a convoluted taxonomic history and controversial generic circumscription. Two solutions to this dispute have been proposed: 1) recognition of two genera, Thevetia (including Cascabela) and Cerbera, or 2) recognition of three genera, Cascabela, Cerbera and Thevetia.

A morphological cladistic analysis was conducted aiming to solve this controversy. This analysis incorporated 12 genera and 22 species, including all species of Cascabela (4) and Thevetia (4), three species of Cerbera and at least one species of each of the remaining genera in tribe Plumerieae (sensu Endress & Bruyns). The matrix has 53 morphological characters, several of which are used here for the first time. The consensus of the most parsimonious trees supports the monophyly of Cascabela, Cerbera and Thevetia only if T.pinifolia is transferred to Cascabela. Since Cascabela and Thevetia share a most recent common ancestor, the results of this analysis are inconclusive regarding the recognition of one or two genera, but given the characters that support these clades we prefer to recognize two genera.

P1008. An evaluation of Matelea subgenus Poicilla (Apocynaceae - Asclepiadoideae - Gonolobinae): Parsimony analysis based on morphology

A. Krings;
Herbarium (NCSC), Raleigh, NC, United States.

The circumscription of *Matelea* (Apocynaceae - Asclepiadoideae) and submerged genera, such as *Poicilla*, *Poicillopsis*, and *Ptycanthera*, has been particularly complicated. Although many subgenera are likely ill-conceived and some submerged genera were recently re-instated, tests of the subgeneric concepts in *Matelea* have not been published. This study sought to test the monophyly of *Matelea* subgenus *Poicilla* sensu Woodson based on parsimony analysis of morphological characters and to evaluate the systematic implications. A data matrix was produced by appropriately scoring character states for thirty-two species based on study of herbarium specimens and the literature. The data matrices were analyzed using parsimony methods in PAUP 4.0*. Results of analyses showed *Matelea* subgenus *Poicilla* sensu Woodson to be paraphyletic. The narrower generic concepts of other authors, such as Grisebach and Schlechter, also appeared non-monophyletic, although additional resolution is needed.

P1009. Molecular Systematics of *Oxypetalum* R.Br. (Asclepiadoideae, Apocynaceae).

M. A. Farinaccio, R. Mello-Silva;
Universidade de São Paulo, São Paulo, Brazil.

The subfamily Asclepiadoideae is one of the largest in the Apocynaceae. The group is mainly tropical and subtropical, with a centre of diversity in South America. *Oxypetalum*, a group centred in Brazil, is the largest Neotropical genus of the subfamily (ca. 130 species). The genus is generally recognised by a combination of characters that include a rostrated gynostegium, and caudicles of the pollinaria with reticulated membranes and lateral teeth. Several systems of classification within Asclepiadoideae are highly artificial. Yet Oxypetalinae is the best circumscribed and characterized group within the subfamily. However, the infrageneric classification of *Oxypetalum*, remains problematic and with several artificial groupings being recognized. This project intends to redefine *Oxypetalum*, test the monophyly of subgenera within *Oxypetalum*, and study relationships among subgenera. In addition, the relationship between *Oxypetalum* and some of its close relatives, such as *Calostigma* and *Schistogyne* will also be investigated. FAPESP

P1010. Pollinator foraging behavior and effectiveness on sympatric *Asclepias* species

K. E. Theiss[1], S. R. Kephart[2], C. T. Ivey[3];
[1]Chigago Botanic Garden, Glencoe, IL, United States, [2]Willamette University, Salem, OR, United States, [3]Illinois Natural History Survey, Champaign, IL, United States.

Mechanical and ethological factors can provide pollinator-mediated floral isolation capable of reinforcing species barriers. We examined experimental and natural populations of three sympatric species of *Asclepias* for differences in pollinator effectiveness: *A. syriaca*, *A. incarnata* and *A. verticillata*. Previously we had detected significant variation in the frequency, constancy, and behavior of major pollinators on these species. Mechanically, pollinia attach differentially to the aroliar pad of insect legs in *A. syriaca*, but to tarsal hairs in the other species. Based on single visit removal and deposition of pollinia, as well as pollinium load on captured insects, we analyzed the relative effectiveness of insect visitors. Effectiveness fluctuated by species and by site. Major pollinators varied in their behavior for factors including the amount of time spent on umbels, number of flowers visited, and mode of contact with individual flowers. Overall, pre-mating barriers provide a potentially effective means of reducing interspecific pollen flow among plants visited by generalists.

P1011. Apocynacean floral ontogeny - gynoecium development patterns

S. M. Gomes[1], L. S. Kinoshita[2], M. d. M. Castro[2];
[1]Pós-Graduação em Biologia Vegetal, Universidade Estadual de Campinas, Campinas, Brazil, [2]Depto. de Botânica, Universidade Estadual de Campinas, Campinas, Brazil.

The floral ontogeny of 34 species of Apocynaceae was studied using SEM and results for five species are presented. The most relevant ontogenetic characteristics are: sepal initiation may be dextrorse, sinistrorse or both within the same inflorescence; congenital connation of the corolla tube basal region; reduction or absence of the corolla tube superior region; synchronous or assynchronous initiation of the petals and stamens; congenital adnation of the stamens with the corolla tube; postgenital adnation of the stamens with the style-head; appendicular origin of the nectaries. Four patterns of gynoecium development are proposed: congenital syncarpy (*Lacmellea arborescens* Markgr., Rauvolfioideae), mixed syncarpy (*Allamanda blanchetii* A. DC., Rauvolfioideae), hemisyncarpy initiated as a concavity (*Malouetia arborea* Miers, Apocynoideae and *Ceropegia woodii* Schltr., Asclepiadoideae) and hemisyncarpy initiated as a dome (*Rhodocalyx rotundifolius* Müll. Arg., Apocynoideae). FAPESP, CNPq and LNLS.

P1012. The genus *Oxypetalum* R. Br. (Asclepiadoideae-Apocynaceae) in the state of Rio de Janeiro, Brazil

N. M. F. da Silva[1], **J. Fontella-Pereira**[2], M. C. Valente[1];
[1]Instituto de Pesquisas Jardim Botânico do Rio de Janeiro, Rio de Janeiro, Brazil, [2]Museu Nacional, Rio de Janeiro, Brazil.

A synopsis of *Oxypetalum* R. Br. species from the state of Rio de Janeiro, Brazil, is presented, with an identification key, a short description of each species, illustrations, flowering and fruiting periods, and other observations. *Oxypetalum* R. Br. is a Neotropical genus with c. 131 species. The 25 taxa found in Rio de Janeiro are climbers with the exception of *O. patulum* E.Fourn., which is a sub-erect shrub. Most taxa occur in secondary Atlantic Forest and other are from sandy coastal plain (restinga) vegetation. Some taxons occur in high altitude grasslands, such as *O. costae* Occhioni and *O. patulum* E.Fourn. Some species are endemic to Rio de Janeiro, such as *O. lutescens* E.Fourn. and *O. schottii* E.Fourn. Two species are cited here as new records for the state of Rio de Janeiro: *O. molle* Hook. & Arn. and *O. pannosum* Decne. Some species are proposed as new synonyms, such as *O. sobralii* Occhioni and *O. mourai* Hoehne. *O. appendiculatum* Mart., *O. molle*, *O. pannosum* , *O. sublanatum*, *O. wightianum* Hook. & Arn., and *O. banksii* subsp. *banksii* are widely distributed, the first five reaching Paraguay and Argentina, while *O. banksii* subsp. *banksii* is limited to Brazil.

P1013. Phylogeographic investigation in *Biscutella* L. *(Brassicaceae)* based on morphological, genome size and molecular (ITS) data

C. König[1], A. N. Müllner[2];
[1]Institute of Botany, Department of Systematic and Evolutionary Botany, University of Vienna, Vienna, Austria, [2]Jodrell Laboratory, Royal Botanic Gardens, Kew, Surrey, United Kingdom.

The genus Biscutella comprises about 50 species, mainly found in Central and Southern Europe. Species delimitation is difficult, because most of the morphological differences are only quantitative. Several polyploidy series exist with tetraploids and hexaploids. In a cladistic analysis of 40 species 30 morphological characters were recorded and ITS 1 and 2 sequence variation was analysed. Phylogenetic trees show clear separation of the three main groups *Iondraba, Thlaspidium,* and *Laevigatae*, while resolution within the biggest group *Laevigatae* is quite low. *B. frutescens* and *B. megacarpea* are found at the basis of this clade, while *B. coronopifolia* and *B. laevigata* are in the most derived position. There can be observed a phylogeographic trend within the *Laevigatae* clade: phylogenetic development and spreading of the species seems to take place in a certain direction: from South-Western to Central Europe. This observation is also supported by flow cytometry measurents: genome size shows the lowest values of 0,78 pg (1C) in Southern Spain, increasing over 0,92 pg in Southern France up to finally 0.98 pg in the Southern Alps.

P1014. A preliminary investigation of phylogenetic relationships and species limits among diploid taxa of *Boechera* (Brassicaceae)

L. Allphin[1], M. D. Windham[2], C. D. Bailey[3], I. Al-Shehbaz[4];
[1]Brigham Young University, Provo, UT, United States, [2]Utah Museum Natural History, Salt Lake City, UT, United States, [3]New Mexico State University, Las Cruces, NM, United States, [4]Missouri Botanical Gardens, St. Louis, MO, United States.

Boechera was proposed by A. Löve and D. Löve (1976) as a North American segregate of cosmopolitan *Arabis*. Although separated by chromosome base number (x = 7, *Boechera* vs. x = 8, true *Arabis*), morphological distinctions are subtle and treatment of *Boechera* as a genus is not widely accepted. Recent studies using chloroplast and nuclear genes indicate that *Boechera* is phylogenetically isolated from *Arabis* and more closely related to *Halimolobus, Capsella,* and *Arabidopsis*. Consequently, most North American *Arabis* have been transferred into *Boechera*. We initiated detailed studies of this group and found a taxonomic complexity rarely encountered among higher plants. Molecular data indicate that *Boechera* appeared rather recently (< 3 mya). Subsequently, divergent speciation has produced >70 morphologically distinct, sexual diploids. Reproductive isolation has not kept pace with morphological divergence and diploid *Boechera* appear to hybridize in sympatry. Hybridization has given rise to a diverse array of facultatively apomictic diploids and obligately apomictic triploids and tetraploids, obscuring morphological distinctions among sexual diploids.

P1015. Infraspecific differeniation of *Arabidopsis halleri* based on AFLP and morphological data

M. Kolník[1], K. Marhold[1,2];
[1]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia, [2]Department of Botany, Charles University, Prague, Czech Republic.

Three or four subspecies have been usually recognized in *Arabidopsis halleri*: E Asian subsp. *gemmifera*, C and SE European subsp. *halleri* and subsp. *ovirensis*, and sometimes also somewhat doubtful subsp. *tatrica* from the W Carpathians. We studied 32 populations originating from the Carpathians and Alps in Europe, and from Japan, using morphometric and AFLP (amplified fragment length polymorphism) approach. Fifteen additional population samples were included in morphometrics only. As a result, four genetically well-defined groups can be delimited, corresponding to subsp. *gemmifera*, subsp. *tatrica*, subsp. *ovirensis* from Austria, and populations assigned to subsp. *ovirensis* from Romania. Romanian populations, although previously treated within subsp. *ovirensis*, represent a clearly distinct lineage. Within subsp. *halleri*, which is on the basis of AFLP markers only weakly supported, genetic differentiation between the Carpathians and Alps can be observed. Morphometric analyses confirm morphological differentiation among the groups as resolved by AFLP data.

P1016. A floral homeotic variety of *Capsella*: evolutionary aspects

P. Nutt[1], B. Neuffer[2], G. Theißen[1];
[1]Genetics Department, University of Jena, Germany, [2]Department of Systematic Botany, University of Osnabrück, Germany.

Homeotic mutants have been invaluable to understand plant development, but their role in evolution is controversial. To better understand the evolutionary significance of homeotic mutants we are studying a floral homeotic variety of *Capsella bursa-pastoris*. In the aberrant *Capsella* all petals are completely transformed into stamens. This variety is growing in several natural populations in the wild in Europe and Central Asia and it shows no obvious reduction in fitness. This ‘Staminoid petals’ (*Spe*) *Capsella* thus qualifies as a drastic morphological variant with the potential to establish a new evolutionary lineage. It hence serves as a suitable model to investigate the role of non-gradualistic structural changes during the evolution of the flower. We report the first results on the inheritance of the mutant phenotype and the isolation and phylogenetic evaluation of some candidate genes. Ongoing study efforts on the expression of candidate genes and on map based cloning are discussed.

P1017. Worldwide phylogeography of the genus Draba (Brassicaceae): Distribution patterns of genetic diversity.

M. Koch, **I. Hase**;
Heidelberg Insitute of Plant Sciences, Heidelberg, Germany.

The genus Draba includes about 350 species, which are distributed primarily in the northern hemisphere with some 70 species in South and Central America, 115 species in N America, 45 species in China, 90 species in the former USSR, and 45 species in Europe. Many species are hardly distinguishable morphologically, and hybridization and reticulation is thought to have played a major role during its evolution and diversification. We studied DNA-sequence variation of the plastidic trnL-trnF-region to reconstruct the phylogeographic history of the genus Draba, which is distributed primarily in high-montane and alpine regions.

Our data strongly support hybridization and reticulation in this old genus and confirms Eurasian Arabis as closest sistergroup and herein we shortly present a generic circumscription.

First phylogeographic results favour the hypothesis of multiple immigration into North America from both amphi-beringean pleistocene refugias with subsequent hybridization between representatives from both areas. Further research is focused on Central and East Asian Drabas as one diversity center with taxa from elevations higher than 5500 m a.s.l.

P1018. Molecular basis and evolutionary consequences within the change in self-incompatibility system in the genus *Diplotaxis* (Brassicaceae)

C. Laschke, H. Hurka;
Department of Systematic Botany, University of Osnabrueck,
Osnabrueck, Germany.

In the Brassicaceae, cross fertilisation is forced by a sporophytic self-incompatibility-system (SI), which has been intensively studied in the model plant *Brassica*. We focus on the diploid species pair *Diplotaxis tenuifolia/Diplotaxis cretacea*, which are closely related to *Brassica*. *D. tenuifolia* is strictly out-crossing, a successful coloniser and native to south and central Europe. The closely related *D. cretacea* is highly selfing, not colonising and locally restricted to the Northern Ukraine and adjacent parts of Russia. The distribution areas are separated by a gap of several hundred kilometres. The breakdown of the SI-system in *D. cretacea* might be correlated to its peripheral geographic position compared to the selfincompatible and widespread *D. tenuifolia*. The aim of the project is to reveal the molecular basis for the transition from SI to SC and characterise S-haplotypes in natural populations of both species mentioned.

P1019. Natural hybridization between *Cardamine raphanifolia* and *C. pratensis* (*Brassicaceae*) in NW Spain

J. Kuļ era[1], J. Lihová[1], M. Perný[1], K. Marhold[1,2];
[1]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia,
[2]Department of Botany, Charles University, Prague, Czech Republic.

Sympatric occurrence of two polyploids, *Cardamine raphanifolia* Pourr. and *C. pratensis* L. (s. str.), was found on several localities in the Cordillera Cantabrica Mts. (NW Spain), together with morphologically intermediate individuals. Combined karyological, morphometric and molecular (AFLP, amplified fragment length polymorphism) approach was used to confirm assumed hybridization between these two species. Individuals from pure populations of both species were comparatively examined with individuals from putative hybrid populations. The results reveal extensive interspecific hybridization and introgression going-on on several sites. Detailed sampling on one locality shows the role of habitat disturbance for successful hybrid establishment and persistence. Although hybridization between *C. pratensis* and *C. raphanifolia* does not seem to be rare, the type herbarium specimen of a previously described hybrid of these two taxa, *C.* ×*larambergiana* Rouy et Foucaud, deposited in herbarium P, undoubtedly belongs to *C. raphanifolia*.

Financial support: Grant Agency of the Czech Republic, project no. 206/03/0228 (to KM).

P1020. The system for determination of pests and pathogens based on shown symptoms in cruciferous plants.

V. áļ ek;
University of South Bohemia, Faculty of Agriculture, Ļ eské BudŊjovice, Czech Republic.

The system is created for the model of the family *Brassicaceae* as an example of an important agricultural group of plants. In some constituents of this family there are described symptoms which are caused by diseases and pests. In this project the taxonomic revision of the family *Brassicaceae* was made. This system was created using Php and MySgl software. Plants, pests and fungal pathogens are sorted according to Bayer's codes in the databases. The system contains taxonomical description in pests and pathogens, also their characteristics, bionomical data and exact definition of symptoms. The advantage of this system is the displaying of one particular symptom in particular plant caused by different pathogens. The system has a section for administrators where were inserted new plants, pests, diseases and types of symptoms. The relationships between new inserted data are created using sets of forms. In the whole system is used the correct scientific terminology with description of these terms therefore this system serves for the education and thanks to the used database MySql it is easy to update it.

P1021. Phylogeny and biogeography of *Cardamine flexuosa* (Brassicaceae) and close relatives

J. Lihová[1], K. Marhold[1,2], H. Kudoh[3], M. Koch[4];
[1]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia,
[2]Department of Botany, Charles University, Prague, Czech Republic,
[3]Department of Biology, Faculty of Science, Kobe University, Kobe, Japan, [4]Biodiversity and Plant Systematics, Heidelberg Institute of Plant Sciences, University of Heidelberg, Heidelberg, Germany.

Based mainly on morphology, 10-15 species have been associated with two Eurasian species, tetraploid *Cardamine flexuosa* and diploid *C. hirsuta*. They include mostly autogamous annuals and biennials, with both diploids and polyploids represented. In the present study we aim to infer phylogenetic relationships within this group of taxa, using nuclear and chloroplast DNA sequence data. The results of both data sets are largely congruent and show several supported clades. Some of the main results can be summarized: 1) European *C. flexuosa* is different from populations in E Asia assigned to this species; E Asian populations represent a distinct lineage most likely of allopolyploid origin, as a weed invading Australia and America; 2) low genetic diversity is found in *C. flexuosa* and *C. hirsuta* across their large geographic area; 3) in contrast, E Asian tetraploids *C. scutata* and *C. niigatensis* show large haplotype diversity just within the small area of Japan; 4) N American diploid *C. oligosperma* often confused with *C. hirsuta* is distinct from the latter; 5) polyploids and diploids are separated in distinct clades, thus the origin of most polyploids remains unclear.

P1022. Molecular phylogeny of the tribe Brassiceae (Brassicaceae)

S. I. Warwick, C. Sauder;
Agriculture and Agri-Food Canada, Ottawa, ON, Canada.

Evolutionary relationships of the tribe Brassiceae (Brassicaceae) were examined using sequence data from the ITS region and *trn*L intron and cpDNA restriction site polymorphism data. The tribe (ca. 50 genera) is distinguished by the presence of conduplicate cotyledons and/or heteroarthrocarpic fruit. cpDNA restriction site data and ITS and *trn*L sequence data were obtained for 22, 104, and 94 taxa in the tribe, respectively. Maximum parsimony analyses of the cpDNA and ITS sequence data showed a monophyletic origin for the tribe, with the inclusion of controversial members *Calepina*, *Conringia* and *Orychophragmus*. Molecular ITS clades corresponded to taxonomic subtribes: Vellinae, Zillinae, and Savignyinae; but as with cpDNA data, there was little support for subtribes Brassicinae, Raphaninae and Moricandiinae. Taxa from these three subtribes were previously assigned to either the Rapa/Oleracea or Nigra cpDNA lineages. Although there was no support for these two lineages, many cpDNA subclades within each of them were evident in the ITS-based phylogeny. The *trn*L data provided no resolution of tribal limits or relationships within the tribe.

P1023. Molecular Systematics of the Central Asian genus *Dontostemon* (Brassicaceae)

B. Oyuntsetseg[1], W. Bleeker[2], D. German[3], N. Friesen[2], B. Neuffer[2], H. Hurka[2];
[1]Department of Botany, National University of Mongolia. Ulaanbaatar, Mongolia, [2]Department of Systematic Botany and Botanical Garden, University of Osnabrück, Germany, [3]South Siberian Botanical Garden, Altai State University of Barnaul, Russian Federation.

The genus *Dontostemon* is a Central and East Asian genus distributed primarily in Mongolia, Russia and China and comprising twelve species. *Dontostemon* species prevail in arid regions, mainly steppe, desert and mountain habitats. Genetic relationships within *Dontostemon* and phylogenetic position of the genus within the family Brassicaceae are unknown. We started a molecular analysis (ITS; *trn*L intron and *trn*L-F spacer) to trace the phylogenetic roots of this characteristic Central Asian - Far East floristic element. Data argue for a close relationship between *Dontostemon* and *Clausia* which formed a monophyletic clade. It would appear that *Matthiola* is closer related to this clade than *Hesperis*. Phylogenetic relationships between the *Dontostemon* species are not clearly resolved. However, three well supported clades are obvious: An eastern Asian clade, a clade with species from South Siberia, Mongolia and northern China, and a clade with species from western Mongolia and northern China.

P1024. Phylogenetic relationships of Brassicaceae genera from Northern Asia

D. German[1], N. Friesen[2], B. Neuffer[2], H. Hurka[2];
[1]South Siberian Botanical Garden, Altai State University of Barnaul, Russian Federation, [2]Department of Systematic Botany and Botanical Garden, University of Osnabrück, Germany.

Central Asia and the Russian Far East experienced a paleoenvironmental history different from that in Europe and in North America. The loss of biodiversity during the Ice Ages has been less dramatic than in Europe. Consequently, Siberia is of high biogeographic significance for the postglacial history of the European flora as is the Far East for North America. About 70 genera of Brassicaceae are reported from northern Asia, a considerable amount of which being endemic to this region. Two thirds are mono- to oligotypic genera, and only ca. 20 genera comprise three or more species. This taxanomic situation and the paleoenvironmental history let us to assume that some of the present day Brassicaceae in northern Asia represent preglacial elements, and others may have evolved recently in postglacial times. We study molecular phylogenies (ITS and non-coding cpDNA) to elucidate phylogenetic relationships, origin and age of northern Asian Brassicaceae taxa.

P1025. The role of lignification patterns in dehiscent and indehiscent fruits in Brassicaceae: a comparative anatomical approach

K. Mummenhoff, A. Polster;
Spezielle Botanik, Osnabrück, Germany.

Controlling seed dispersal remains an important challenge for growers of many agricultural crops worldwide. Scientists are beginning to understand the regulatory networks underlying the dehiscence (opening) of fruits. In *Arabidopsis* (Brassicaceae) only a few genes seem to control fruit dehiscence and promote the lignification of fruit valve margin cells. To evaluate the impact of lignification on the dehiscence process, we have examined the lignification patterns of valve margin cells in both dehiscent and indehiscent fruits of wild Brassicaceae species. Our first results indicate that in dehiscent fruits a strip of 1-2 longitudinal rows (parallel to the septum) of unlignified cells is left at each side of the replum (a thin structure that separates the fruit valves), functioning as a layer separating the valves from the replum, i.e. the dehiscence zone. In the indehiscent fruits lignification of parenchymatous tissue is uninterrupted and, therefore, no dehiscence zones are formed.

P1026. Darwin's finches with four petals: Diverse endemic Capeverdean *Diplotaxis* (Brassicaceae) are monophyletic and radiated recently

A. Franzke, K. Mummenhoff, B. Neuffer, B. Sharif Samani, H. Hurka;
University of Osnabrück, Osnabrück, Germany.

It has recently been postulated that the Capeverdean flora including its endemic elements is in contrast to previous beliefs very young, probably not older than a few hundred thousand years. To test this hypothesis we are studying molecular phylogenetics (ITS and non coding cpDNA) associated with a molecular clock approach analyzing representatives of *Diplotaxis* and allies (Brassicaceae). Nine *Diplotaxis* taxa, characterized by a very high level of morphological diversification, are endemic to the Macaronesian Cape Verde Island. Our data provide evidence for monophyly of the endemic Capeverdean species and a North African origin. DNA sequence differences among the Capeverdean species indicate diversification of the endemic Capeverdean taxa in Quartenary times, 0.6 to 1.2 million years ago. This adds to the emerging pattern that the present Macaronesian flora is of quite recent origin.

P1027. Rare *Camelina* weeds (*Brassicaceae*) in Slovakia

P. Eliás, jun., T. Baranec, I. Ikrenyi;
Slovak Agricultural University, Nitra, Slovakia.

The genus *Camelina* included four annual or winter annual weedy species in Slovakia: *C. alyssum*, *C. microcarpa C. rumelica* and *C. sativa*. *C. microcarpa* is relatively widespread, other three species were classified as critically endangered (*C. rumelica* and *C. sativa*) or extinct species (*C. alyssum*). Two subspecies of *C. alyssum* were found - subsp. *alyssum* and subsp. *integerrima.* Both taxa were already rare in the past; we recorded only 22 and 12 localities, respectively. Only 10 localities of *C. rumelica* were recorded at all, some of them were not native. Two new localities near Kamenica nad Hronom and Bajtava (southwestern Slovakia) were found in our field research. Herbarium samples of *C. sativa* involved two taxa - subsp. *sativa* (11 localities) and subsp. *zingerii* (5 localities). The most recent data of distribution of subsp. *zingerii* on southern Slovakia, Chlaba (1999) and Hajnácka (2001), were not confirmed in our study. Subsp. *sativa* is still infrequently cultivated.

P1028. Breakdown of self-incompatibility and speciation in *Capsella* (Brassicaceae)

M. Paetsch, S. Mayland-Quellhorst, B. Neuffer;
Department of Systematic Botany, University Osnabrueck,
Osnabrueck, Germany.

The transition from a self-incompatible (SI) to a self-compatible (SC) mating system is a widespread phenomenon in the Brassicaceae and is often associated with colonising success. The breakdown of the SI system might be a key event in evolutionary processes in the Brassicaceae. Aim of the project is to uncover the molecular basis for the switch from SI to SC, moving out from the knowledge in the model plant *Arabidopsis* to wild genera in the Brassicaceae. Focus is on the diploid taxa *Capsella grandiflora*, a non-colonising outbreeder endemic to the western balkan and on *C. rubella*, an inbreeding worldwide coloniser of mediterranean climates. We identified S-genes, tested for dominance of SC over SI and for linkage of S-genes, so far. Additional screening of a BAC library (coll. J. Kroymann) will unmask complete genes. Subsequent comparative analysis of the S-genes in wild populations of SI and SC taxa in *Capsella* will help to understand the genetic background of the breakdown of SI.

P1029. Phylogeography of *Schivereckia podolica* (Brassicaceae) and Ice Ages in East Europe

M. Markov[1], N. Friesen[2], B. Neuffer[2], H. Hurka[2];
[1]University of Tver, Department of Geography, Russia, Tver, Russian Federation, [2]University of Osnabrueck, Department of Systematic Botany and Botanical Garden, Osnabrueck, Germany.

Schivereckia podolica is endemic to eastern Europe where it is distributed from the Ukraine in the West to the Ural Mts. in the East. It is confined to rocky outcrops and has a disjunctive distribution area. RAPD data argue that this disjunction is the result of fragmentation of a formerly continuous distribution belt which is interpreted as a subarctic steppe along the periglacial environments of the last glacial period. DNA sequence divergence and RAPD data together with the present distribution of *Schivereckia podolica* argue for a recent origin of the disjunction, between 300,000 and 150,000 years BP (middle Pleistocene, Oka glaciation, to young Pleistocene, Dnjepr glaciation). Molecular analyses also revealed that the genus *Schivereckia* (two species are currently recognised) is monophyletic and nested within *Draba*, some arctic/subartic and/or alpine *Draba* species forming a sister clade. This supports the interpretation of *Schivereckia podolica* as a glacial relic.

P1030. A Revision of the Genus Isatis (Brassicaceae) in Iran

S. Sajedi, F. Sharifnia;
Tehran Islamic Azad University, Tehran, Islamic Republic of Iran.

Although widely spread in Irano-Turanian region, the extremely difficult genus *Isatis* L. has not been adequately covered by floristic and other studies, mainly due to exceptional variability of the species, inadequate material and illustrations, and lack of cross-cutting research.

The present paper attempts to revise this genus in Iran with a combination of morphologic and anatomic studies. The available specimen of the 14 reported species in the major herbaria and the fresh samples gathered from various provinces were examined in the light of the major flora of the region and the microscopic images of the anatomy of stem, leaves and fruits.

As a result, a revised description of the taxons and their geographic distribution and a new key to the genus in Iran were prepared. Three new records were made for Iran, and the status of some taxons was revised.

Adequate morphologic (including whole plant, fruits and characteristics leaves) and anatomic (stems, leaves and fruits) images and illustrations of all species were prepared.

P1031. Inflorescence architecture of Brazilian species of *Aechmea* subg. *Chevaliera* (Gaudich. ex Beer) Baker, Bromelioideae - Bromeliaceae

M. L. Wanderley[1], G. M. Sousa[2], M. V. Alves[3];
[1]Instituto de Botânica, São Paulo, Brazil, [2]Universidade federal do Piauí, Teresina, Brazil, [3]Universidade Federal de Pernambuco, Recife, Brazil.

Inflorescences in Bromeliaceae are indeterminate, supported by a terminal scape of various size, and have bracts of various position, number, color, shape and texture. *Aechmea* is the most diverse genus of Bromelioideae (ca.220 spp) presenting large inflorescence and variation in size and shape. *Aechmea* subg. *Chevaliera* comprises 21 taxa throughout Central and South America mainly distributed in eastern Brazil. A morphological inflorescence study of 15 Brazilian species is presented. The study was based on living specimens and herbarium materials with the inflorescence architecture observed at different developmental stages. This study describes the architectural form of the inflorescences at full-flower or with at least half of the flowers open, because fruit development may produce architectural changes in the axis. The inflorescence in the subgenus ranges from simple to compound. Spicate inflorescence is the basic pattern, and capitulum is here recorded for the first time in Bromeliaceae. Compound inflorescences are the rarest form in the subgenus, being represented by racemes of spikes. Descriptions, illustrations, and schematics are presented.

P1032. Phylogenetic inference involving some Bromelioideae genera, using *rps*16 and *atp*B-*rbc*L sequences and morphology.

J. V. Coffani-Nunes[1], M. G. L. Wanderley[2], L. B. Motta[3], M. L. F. Salatino[3], A. Salatino[3];
[1]Agronomia - UNESP - Registro, Registro, Brazil, [2]Inst. de Botanica de Sao Paulo, Sao Paulo, Brazil, [3]Inst. de Biociencias - USP, Sao Paulo, Brazil.

Among the three subfamilies of Bromeliaceae, Bromelioideae (ca. 30 genera) is the poorest known. *Portea* Brongn. ex K. Koch, a Bromelioideae genus endemic to Brazil, comprises nine species distributed in Northeast and Southeast Brazil. Usually, it is regarded as closely related to *Aechmea*. A phylogenetic analysis was carried out based on morphology (gross morphology, leaf-anatomy, palinology) and cpDNA sequences (*rps*16, *atp*B-*rbc*L). *Quesnelia arvensis* was used as outgroup and the analysis involved three species of *Aechmea* (*A. bromeliifolia*, *A. disticantha*, *A. nudicaulis*), two of *Canistrum* (*C.* aurantiacum, *C.* pickelii) and seven of *Portea* (*P. alatisepala*, *P. grandiflora*, *P. kermesina*, *P. leptantha*, *P. nana*, *P. petropolitana*, *P. silveirae*). Parsimony analysis of the combined data indicates that 1) *Portea* is monophyletic, 2) *Canistrum* is paraphyletic, 3) *Canistrum* is closely related to *Portea* (bootstrap value 98), and 4) *Aechmea* is polyphyletic.

P1033. The Effect of Speciation and Extinction Rates on Phylogenetic Branch Lengths in Bromeliaceae subfamily Bromelioideae

T. M. Evans[1], G. K. Brown[2], E. M. C. Leme[3], T. Wendt[4];
[1]Hope College, Holland, MI, United States, [2]University of Wyoming, Laramie, WY, United States, [3]Herbarium Bradeanum, Rio de Janeiro, Brazil, [4]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

Members of Bromeliaceae subfamily Bromelioideae exhibit their greatest diversity and are considered keystone species within the Atlantic Forest region of eastern Brazil. The Atlantic Forest has been subject to extensive reduction and fragmentation and is recognized as one of the most endangered biomes on the planet. Phylogenetic analyses of molecular and morphological data in Bromelioideae have consistently yielded a pattern in which terminal branches of the phylogeny are significantly longer than internal branches. Two hypotheses are proposed to explain this discrepancy in branch lengths: 1) members of Bromelioideae have recently derived stronger isolating mechanisms among closely related species than they possessed during earlier periods in their evolution; 2) the subfamily has recently experienced an increase in extinction rate that is not accompanied by a comparable increase in speciation rate. The latter hypothesis is consistent with simulation studies of variable speciation/extinction rates, and the elevated extinction rate is hypothesized to be a direct result of extensive habitat loss due to destruction of the Atlantic Forests of Brazil.

P1034. Towards a molecular population genetics of four Alcantarea species (Bromeliaceae) adapted to inselbergs in the Atlantic Rain Forest of Brazil

T. Barbará[1,2], C. Lexer[1], M. F. Fay[1], S. Mayo[1], G. Martinelli[3];
[1]Royal Botanic Gardens Kew, Richmond, United Kingdom, [2]Open University, Milton Keynes, United Kingdom, [3]Instituto de Pesquisas Jardim Botanico do Rio de Janeiro, Rio de Janeiro, Brazil.

The inselbergs of the Brazilian Atlantic Rain Forest form terrestrial "islands" that are isolated from the surrounding forest by steep gradients in humidity, temperature and irradiation, and by drastic changes in soil substrates. Bromeliads (Bromeliaceae) are particularly well represented among plants adapted to the extreme growing conditions on inselbergs. We have launched a research project to study the population genetics of four members of the genus Alcantarea endemic to inselbergs of coastal Atlantic Brazil, Alcantarea imperialis, A. geniculata, A. glaziouana, and A. regina. Our aim is a comparative study of genetic variability at nuclear DNA microsatellite and plastid DNA markers. We address fundamental questions regarding the evolution of genetic diversity within and among these four species. First results of this work will be presented, including a set of novel polymorphic microsatellites for Alcantarea spp.

P1035. Phylogenetic relationships of Sodiroa (Guzmania, Bromeliaceae) based on morphological and molecular data

R. E. Arevalo[1], J. Betancur[2], K. M. Cameron[3];
[1]Laboratorio de Botanica y Sistematica, Universidad de los Andes, Bogota D.C., Colombia, [2]Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Bogota D.C., Colombia, [3]The New York Botanical Garden, Bronx, NY, United States.

Sodiroa s.l. (Bromeliacae) is a group of species traditionally included in Guzmania, and made up of two species complexes: Massangea and Sodiroa s.s.. Previously considered separate genera, Sodiroa s.s. comprises 7 species and Massangea 11. The species are found from south Central America to northern Peru, with the greatest diversity occurring in the Pacific region of Colombia. Preliminary analyses of morphological data suggest that Sodiroa s.l. is a monophyletic group, whereas Massangea is paraphyletic. We sequenced DNA from 16 species of Bromeliaceae, in order to test this hypothesis, using separate and combined analyses of chloroplast genes (matK, ndhF, trnL intron, trnL-trnF intergenic spacer) and morphological characters. Additional sequences were taken from GenBank. Individual analyses show that trnL-trnF provides the best resolution, and Sodiroa s.l. is monophyletic. The combined molecular analysis recovers a monophyletic group that includes Sodiroa s.l. and two other Guzmania species. We intend to code additional morphological characters for all the species in order to initiate a total evidence analysis for this group of Bromeliaceae.

P1036. Molecular systematics of *Fosterella* (Bromeliaceae)

M. Rex[1], P. L. Ibisch[2], K. Weising[1];
[1]Institute of Biology, University of Kassel, Germany, [2]Faculty of Forestry, University of Applied Sciences Eberswalde, Germany.

The majority of species of the neotropical genus *Fosterella* (Bromeliaceae) are found in semiarid to humid habitats of the Andean slopes and valleys of Bolivia. Numerous new taxa have been described in the past decade, raising the number of known *Fosterella* species to about 30. *Fosterella* plants are mesophytic terrestrial herbs with small and inconspicuous flowers. Morphological differentiation of species is difficult due to a paucity of characters, and little is known about the intrageneric phylogeny. Traditionally, *Fosterella* is included in the subfamily Pitcairnioideae, but recent molecular data have challenged this classification. Whereas the monophyly of the genus is generally accepted, sister group relationships of *Fosterella* within Bromeliaceae are ambiguous. To analyze the phylogeny of

Fosterella at the species and genus level, we have initiated a molecular phylogenetic study based on AFLP markers and comparative sequencing of non-coding chloroplast DNA. Here we present preliminary results.

P1037. Phylogenetic analisys of *Vriesea* (Bromeliaceae) based on morphological data

A. F. Costa[1], M. G. L. Wanderley[2];
[1]Museu Nacional, Rio de Janeiro, Brazil, [2]Instituto de Botânica, São Paulo, Brazil.

The tillandsioid genus *Vriesea* includes 230 species, in two sections - *Vriesea* (100spp.) and *Xiphion* (130spp.). In this study, a partial cladistic analysis of the genus was done based on morphological data to evaluate the relationships within several groups of species and trace the phylogenetic relationship of the sections. Sixty eight *taxa* were selected for the ingroup, two species of *Catopsis* as outgroup; and 68 characters. Three hundred and sixty four equally parsimonious trees were produced in 734 steps (CI 0.219, RI 0.576 and RC 0.126). Two major clades were formed based on type of inflorescence branching. The two sections emerged as polyphyletic. However, several other clades emerged made up of *taxa* of one or the other of the sections. Some of the characters which supported the clades are used traditionally to separate sections. Other characters emerged as new traits, potentially important in genus taxonomy. Future analyses should include as many representatives of the tillandsioid group as possible to sustain a new interpretation of the subfamily Tillandsioideae.

P1038. Stem and leaf anatomy of Bromeliaceae from the cerrado of São Paulo State, Brazil

S. L. Proença, M. Sajo;
Instituto de Biociências - UNESP, Rio Claro/SP, Brazil.

The Brazilian cerrado vegetation (savanna) is one of the most unique biomes, covering around 23% of the country and comprising a diverse flora with over 6,000 species. Despite its importance, agriculture has been developed in the cerrado causing massive destruction. In the cerrado of São Paulo State there are 15 terrestrial and epiphytic species of Bromeliaceae. In these plants, the rhizomes and the floral scape have a parenchymatous cortex that in some species is limited from the central cylinder by a ring of sclerified cells (pericycle). Intracortical roots and leaf traces are commonly found in the cortex of the rhizome. The leaves are hypostomatic and bear peculiar stalked scales and silica bodies on their epidermis. Some features of the leaves, such as the presence of adaxial palisade parenchyma, extra-vascular fibers and/or secretory cavities in the mesophyll, are restricted to particular species. In addition, the location of water storage tissue, the nature of the thickness of the epidermal cells, the presence or absence of a mechanical hypodermis and the stomata position, vary between species and may characterize them.

P1039. Leaf anatomy of Fosterella (Bromeliaceae)

K. Patzolt[1,2], K. Schulte[1,2], M. Rex[3], K. Weising[3], P. L. Ibisch[4], G. Zizka[1,2];
[1]Forschungsinstitut Senckenberg, Frankfurt, Germany, [2]J. W. Goethe-Universität, Frankfurt, Germany, [3]Universität Kassel, Kassel, Germany, [4]Fachhochschule Eberswalde, Eberswalde, Germany.

The genus *Fosterella* comprises 30 species, principally distributed in arid and semihumid habitats and extending from Mexico to Argentina. Its center of diversity is located in the Andes of Bolivia. Some species are morphologically quite similar and their delimitation remains problematic.

The leaf anatomy of 24 species and 41 accessions of the genus was studied. Transverse sections of the leaf-blade were made from unstained fresh material by hand. Microtome sections were obtained from material fixed in FAA and embedded in HEMA, and stained with toluidine. The analysis included digital measurements, e.g. of tissue areas in comparison to the whole section.

Several characters, especially related to the epidermis, chlorenchyma and the position of vascular bundles proved to be of taxonomic value. Groups of species characterised by similar leaf anatomy are presented and compared to groups based on molecular data. Abstract will be improved to get to the minimum number of characters.

P1040. Water storage tissue patterns in the leaves of Bromeliaceae

N. S. Lazareva, Y. V. Kosenko;
The Botanic Gardens of Moscow State University, Moscow, Russian Federation.

Almost all the species of Bromeliaceae have succulent features, one of the most important is water storage tissue. The study of 9 species which belong to 3 subfamilies and 4 life forms (terrestrial xerophyte and mesophyte, tank and aerial epiphyte) showed different patterns of water storage tissue. The most massive water storage tissue have terrestrial xerophytes and aerial epiphytes, tank epiphytes and mesophytes have thin layers of this tissue. We recognised 3 different groups in investigated species that are based on water storage tissue patterns. The first group is with the layer of chlorenchyma under the layer of water storage tissue. The second one has 2 layers of water tissue and a layer of chlorenchyma between them. The third group without abruptly differentiated tissue layers: chlorophyll cells organised in the net with water storage cells inside. These 3 groups mark 3 trends of evolution and analysis of anatomy allows to suppose that the first pattern is the most primitive.

P1041. Circumscribing Vellozia hirsuta and V. tubiflora (Velloziaceae)

R. Mello-Silva[1,2];
[1]University of Sao Paulo, Sao Paulo, Brazil, [2]Fapesp, Cnpq, Brazil.

Vellozia hirsuta and *V. tubiflora* belonged to *Vellozia* sect. *Radia*, a poliphyletic taxon, although *V. hirsuta* and *V. tubiflora* emerge as close related in some analyses. From the 21 species admitted in the last revision of the section, I only recognise three. This reflects different choices of characters for delimiting the species. Authors choosed the indument, the dimensions of the pedicel and of the hypanthium tube to distinguish species within the section, but these characters may vary within species and populations. Better characters distinguishing them are that also used in cladistic analyses. *V. hirsuta* is circumscribed by one phloem strand and solitary flowers; *V. tubiflora* by smooth subsidiary cells in stomata, aquiferous hypodermis extending to bundle sheaths and furrows, vanishing integument of empty cells in seeds, and a sclerified belt in pedicels. The hypanthial tube always longer than ovary, and deciduous in fruit, distinguishes *V. hirsuta* and *V. tubiflora* from all other Velloziaceae. Although consistently delimited, both species exhibit wide intraspecific variation. Thus, *V. hirsuta* encompasses four taxonomic synonyms, and *V. tubiflora*, 19.

P1042. Revision of *Hohenbergia* Schult. & Schult.f. subgenus *Hohenbergia* (Bromeliaceae)

G. S. Baracho[1], M. F. Agra[1], S. J. Mayo[2];
[1]Laboratório de Tecnologia Farmacêutica, João Pessoa, Paraíba, Brazil, [2]Herbarium, Royal Botanic Gardens, Kew, United Kingdom.

Hohenbergia Schult. & Schult.f. subg. *Hohenbergia* is a neotropical group of bromeliads found mainly in altitudes from sea level to about 800 m elev. The mains morphological characters distinguishing this group are the 3-4-pinnate inflorescences, peduncled spikes, purple, green or yellow corollas, and caudate ovules. The subgenus is treated based on a morphological study of field-collected material and herbarium specimens. Forty-five epithets have been applied to the species of these group, and fifteen are recognized as synonyms. In this work the subgenus *Hohenbergia* consists of 30 species and occurs from Trinidad and Tobago to Venezuela and east coast of Brazil. All species are found in Brazilian territory, including *H. stellata* Schult. & Schult.f., the unique species with disjunct distribution. The principal center of diversity of the subgenus is the Brazilian State of Bahia with 28 species recorded (93% of the total). Of these, 23 species (77%) are endemic and found from Center-South to South of Bahia distributed through semiarid areas locally denominated “Caatinga” to remaining coastal rainforests in seaside direction. Sponsored by CAPES, IMSEAR-CNPq.

P1043. Phylogenetic analysis of the tribe Salsoleae (Chenopodiaceae) using ITS rDNA sequencing in connection with systematics and reconstruction of morphological evolution character

N. A. Poyarkov[1], T. A. Feodorova[1,2], C. M. Valiejo-Roman[2], T. H. Samigullin[2];
[1]Lomonosov Moscow State University, Moscow, Russian Federation,

[2]N.A. Belozersky Institute, Lomonosov Moscow State University, Moscow, Russian Federation.

The tribe Salsoleae includes approximately 30 genera distributed in ancient Middeterannean region. Regretfully, almost all morphological features used in tribe Salsoleae taxonomy do not reflect their phylogenetic relationships and can be probably a result of genetic assimilation of similar ecological modifications. A revision of morphological features taxonomical value for tribe Salsoleae systematics is necessary as well as search of new significant characters. The comparison of morphological and molecular features will allow to evaluate the significance of the former. We report a preliminary analysis of the phylogenetic relationships among Salsoleae genera using ITS 1-2 rDNA sequencing. The distribution of tribe Salsoleae genera contradicts to standart subdivision of the tribe into subtribes and genera. ITS phylogeny supports a sister-group relationship between Climacoptera and Halimocnemis, Ofaiston and Petrosimonia (100% bootstrap support). The possibility of treelike life forms and aphylly independent occurrence in different taxa is discussed in connection with aridity of the climate.The project is supported by RFBR grant 04-04-49010.

P1044. Taxonomical importance of testa micromorphology in the American taxa of *Sarcocornia* A.J. Scott (Chenopodiaceae)

M. Alonso, A. Juan, M. B. Crespo;
Instituto Universitario de Investigación-CIBIO, Alicante, Spain.

Sarcocornia A. J. Scott (Chenopodiaceae) includes shrubs succulent, erect to prostrate and sometimes creeping, with seeds smooth or hairy and lacking perisperm. Other morphological characters such as size, habit, succulency, inflorescence, etc., are strongly convergent and taxa identification is usually difficult. In the Americas up to 20 taxa have been described based on weak morphological vegetative differences. Moreover, different nomenclatural treatments are available from different authors, as taxa of *Sarcocornia* have not yet been studied as a whole in the Americas. Seed testa micromorphology has revealed however as an important character to differentiate taxonomic entities in that genus. In the present contribution, the taxonomical importance of testa indument is discussed, and a morphological characterization of the accepted American taxa is reported.

P1045. Morphology and practical identification of *Chenopodiaceae* pollen (taxa occurring in Ukraine)

Z. M. Tsymbalyuk, S. L. Mosyakin, L. G. Bezusko;
M. G. Kholodny Institute of Botany, National Academy of Sciences of Ukraine, Kyiv (Kiev), Ukraine.

Identification of *Chenopodiaceae* pollen below the family level was often considered impossible or highly unreliable. We present here the results of integral studies (using optical and scanning electron microscopy) of pollen morphology of more than 80 species of *Chenopodiaceae* occurring in Ukraine and adjacent areas. The main objective of the study was to develop reliable identification approaches and tools (keys and descriptions) to be used for taxonomy and pollen analysis. We propose a new identification manual for fossil pollen of *Chenopodiaceae*, which is based on our data and the principle of character correlation (shape and outline, pollen grain and pore diameter, distance between pores, number of pores, exine peculiarities). For the first time we propose to use for identification some basic qualitative characters (sculpture and texture of the exine). The problems and tasks of species-level and group-level identification of *Chenopodiaceae* pollen in pollen spectra of the Pleistocene and Holocene of Ukraine are considered. Palynological peculiarities and traits of selected natural phylogenetic groups of *Chenopodiaceae* are discussed.

P1046. Phylogenetic analysis of the tribe *Salicornieae* based on *mat*K and *trn*L-*trn*F chloroplast DNA sequences

C. Pagliano[1], E. Negrisolo[2], S. Maistro[2], F. Andreucci[1], R. Barbato[1];
[1]Dipartimento di Scienze dell'Ambiente e della Vita, Università del Piemonte Orientale, Alessandria, Italy, [2]Dipartimento di Biologia, Università di Padova, Padova, Italy.

The systematic and phylogenetic relationships between the annual genus *Salicornia* and the allied perennial genera of *Salicornieae* (*Sarcocornia*, *Arthrocnemum, Halocnemum*) were investigated by applying a molecular approach.

Two plastidial markers, the *mat*K gene and the non-coding *trn*L-*trn*F interspacer, were sequenced from 40 samples belonging to 12 species and representing 4 genera of the tribe *Salicornieae*. The same sequences from *Spinacia oleracea* L. (subfamily *Chenopodioideae*) and *Suaeda maritima* (L.) Dumort. (subfamily *Suaedoideae*) were used as outgroups.

Samples were collected in different sites of Mediterranean and Atlantic European coasts and identified according to standard analytical keys.

Phylogenetic analyses were performed using PAUP 4.0, according to maximum likelihood and maximum parsimony methods.

Our main results strongly favour: 1) a monophyletic genus *Salicornia;* 2) a clear separation between the annual and perennial genera, a finding supported also by a peculiar six-bases insertion in the *mat*K gene of the annual forms; 3) a sister group relationships between the genus *Sarcocornia* and the genus *Salicornia*.

P1047. The Chenopodiaceae of Armenia- taxonomical investigation

J. A. Akopian;
Institute of Botany of NAS, Yerevan, Armenia.

The Chenopodiaceae are represented in Armenia with 89 species of 32 genera. All these genera are known from the Caucasian flora, accept Microcnemum, present in Armenia. The complex genera in our area includs the following sections: Beta (4 species) - Vulgares, Corollinae; Chenopodium (14 species) - Ambrina (adv.), Botryoides, Eublitum, Degenia, Pseudoblitum; Atriplex (11 species) - Dichrosperma, Teutliopsis, Sclerocalymma, Obione; Kochia (3 species) - Pterocarpus, Semibassia; Suaeda (7 species) - Schanginia, Lachnostigma, Conosperma, Heterosperma; Salsola (14 species) - Coccosalsola, Salsola, Caroxylon, Malpighipila, Belanthera, Physurus; Anabasis (2 species) - Adenophora, Euanabasis. Habitats and distribution - arid, salty, clayey, sandy and rocky areas, from 700 up to 1200 (2000) m, for the most part in the Yerevan and Meghri floristic regions of Armenia.

P1048. Diversification in Camphorosmeae (Chenopodiaceae)

J. F. Cabrera, G. Kadereit;
Institut für Spezielle Botanik und Botanischer Garten, Johannes Gutenberg-UniversitÃ¤t, Mainz, Germany.

Camphorosmeae are a monophyletic tribe of Salsoloideae comprising subshrubs or shrubs that mainly occur in semi-deserts, deserts, and steppes. Molecular data show three major lineages within the tribe: 1. C Asia/Australia (13 gen., c. 150 spp.), 2. Eurasia/S Africa (3-9/c. 30), and 3. a lineage of five widely disjunct species (N Am., S Afr., Eurasia). After their origin in Eurasia in the Oligocene, the three lineages evolved along different tracks: The C Asian/Australian lineage entered Australia in the late Miocene where it experienced a steep increase in diversification rate in the newly forming arid landscapes of W and C Australia. In contrast to this, no shift of diversification rate took place in the Eurasian/S African lineage although this lineage evolved C4 photosynthesis with a high diversity of C4-leaves. We explore the possibility that this difference is due to stronger competition by other equally well-adapted steppe and semi-desert inhabitants in Eurasia and S Africa. The high genetic and leaf anatomical diversity of the five species of the third lineage suggests that these are remnants of old Camphorosmean lineages that have largely gone extinct.

P1049. Reproductive isolation between sympatric species of the northern European Salicornia (Chenopodiaceae) species complex

P. Teege, G. Kadereit;
Institut für Spezielle Botanik und Botanischer Garten, Johannes Gutenberg-Universität, Mainz, Germany.

Salicornia is notorious for taxonomic difficulties which have been explained with paucity of morphological characters, high phenotypic plasticity, frequent hybridization, and the inadequacy of dried material. Molecular studies based on sequence data and AFLPs, however, have shown that distinct clades can be recognized within the genus, and that substantial AFLP variation can be found among sympatric morphotypes/species.

Along the coast of northern Germany two diploid and two tetraploid morphotypes of Salicornia occur in close proximity. Although intermediate forms are known these morphotypes are stabile and probably reproductively isolated. To show that the morphotypes observed have a genetic basis, and to understand the prevalent mechanisms of their reproductive isolation, we 1. study their reproductive biology and breeding systems and 2. try to find matching AFLP genotypes. This detailed local analysis is supplemented with samples from the Atlantic coast of France and the English coast to obtain an idea of the distribution of morpho-/genotypes along the northern European coasts.

P1050. The flora of steppes and deserts of the South-East of European Russia: the current research state.

V. Sagalaev;
VSPU, Volgograd, Russian Federation.

The South-East of European Russia (Astrahan, Volgograd, Saratov regions, Kalmykia) are characterized by the arid climate, the absence of mountains, unique salt lakes and sand desert Naryn.

The researched flora consists of 952 species, belonged to 337 genuses and 59 families. The leading positions are occupied by species Asteraceae, Fabaceae, Poaceae, Chenopodiaceae, Brassicaceae, Caryophyllaceae, Liliaceae, and some genuses Astragalus, Allium, Artemisia, Euphorbia. Among them the leading positions belongs to the species of Mediterranean geoelements. About 60% percent of the flora have hear the verges of their areas. It is explained by its presence in the contact area of different climate zones. The presence of endemic kernel is its specific feature though it is not a characteristic of the plain flora. It can be explained by the complex geological history of the region. The transgressions of the Caspian Sea and intense glaciation in the North in Pliocene and Pleistocene garanteed the migrations and the isolation of the species, the formation of endemics.

P1051. Cytogenetic characterization of *Chenopodium quinoa* genom

B. Kolano[1], J. Maluszynska[1], B. R. Gardunia[2], E. N. Jellen[3];
[1]Department of Plant Anatomy and Cytology, University of Silesia, Katowice, Poland, [2]Dept. of Plant and Animal Sciences, Brigham Young University,, Provo, UT, United States, [3]Dept. of Plant and Animal Sciences, Brigham Young University, Provo, UT, United States.

Molecular cytogenetic analysis of *Chenopodium quinoa* was performed using fluorescent *in situ* hybridization (FISH) and flow cytometry. This Andean pseudocereal possess 2n=4x=36 very small chromosomes and its genome size was determined as 3,01 pg /2C. The sequences included in FISH analysis derived from conserved plant repetitive sequences (25S rDNA and 5S rDNA, telomeric) and isolated from *C. quinoa* genome disperse repeats.

Double FISH with 25S rDNA and 5S rDNA revealed that these sequences are located in a very few loci and allowed to distinguish only three homologue chromosome pairs. Hybridization signals of telomeric repeats were observed exclusively on chromosome termini.

Retroelement-like, transpozon-like sequences and disperse repetitive sequences without homology to mobile elements were detected as relatively weak, but discrete hybridization signals on every chromosome. In cases of mobile elements hybridization signals were preferentially localized in a pericentromeric region whereas loci of disperse sequence without homology to mobile elements were distributed throughout all chromosomes.

P1052. Polyploidy in subgenus *Brezia* (Moq.) Freitag et Schütze of the genus *Suaeda* (Chenopodiaceae)

M. Lomonosova;
Central Siberian Botanical Garden of the Siberian Branch of Russian Academy of Sciences, Novosibirsk, Russian Federation.

The subgenus *Brezia* includes about 30 species. The chromosome numbers of 16 species (including undescribed taxa) have been studied from 150 natural localities mainly in East Europe and North Asia. As the intrageneric taxonomy of the subgenus *Brezia* has not been established yet, the most records are listed according to the subclades separated by Schütze et al. (2003) on the basis of molecular data. **1** - “prostrata group”: diploids (2n=2x=18) *Suaeda prostrata* Pall., *S. olufsenii* Pauls., *S. heterophylla* (Kar. et Kir.) Bunge, *S. stellatiflora* G.L. Chu, *S. “orientalis*”. **2** - “maritima group”: diploids *S. crassifolia* Pall., *S. heteroptera* Kitag.; tetraploids (2n=4x=36) *S. salsa* Pall., *S. macrocarpa* Moq. **3** - “corniculata group”: diploid *S. tschujensis* Lomon. et Freitag, tetraploid *S. “grubovii*”; hexaploids (2n=6x=54) *S. corniculata* (C.A.Mey.)Bunge, *S. patagonica* Speg. Octoploids (2n(8x)=72) *S.”sibirica*”, *S. “ircutensis*” and decaploid cytotype (2n=10x=90) of *S. “sibirica*” hold a separate position which is in need of further consideration.

P1053. Inflorescence and flower development and taxonomy of the genus Salicornia (Chenopodiaceae) in European Russia

S. S. Beer[1], O. N. Demina[2], D. D. Sokoloff[1];
[1]Moscow State University, Moscow, Russian Federation, [2]Rostov Sate University, Rostov-on-Don, Russian Federation.

Main inflorescence of most Salicornia species is a spike of 3-flowered dichasia. Dichasia are situated in axils of reduced opposite leaves. Flowers have 3-4 almost completely united tepals, (1)2 stamens in median position, and a gynoecium with single ovule. In Salicornia heterantha Pankova & Demina, sp. nova, perianth tube of the central flower of dichasium is completely postgenitally fused to main axis of the spike. Perianth tubes of lateral flowers are free. In other Russian species all flowers are free. Early developmental stages are similar in all species studied. Central flower of dichasium is initiated first, followed by two lateral flowers. No lateral flower subtending bracts were found. Tepals are initiated almost simultaneously as separate primordial. They fuse congenitally later. Adaxial stamen is initiated before abaxial one. Gynoecium is initiated as a ring-primordium. Ovule occupies a central position in the flower; its primordium is well visible before gynoecium closure. Our data on reproductive morphology and development helps to clarify taxonomy of Russian Salicornia.

P1054. Combined analysis of the subfamily Gomphrenoideae (Amaranthaceae) using *rpl16* and *trnL-F* data

I. Sánchez-del Pino[1], T. Borsch[2], T. J. Motley[1];
[1]The New York Botanical Garden, Bronx, NY, United States, [2]Nees-Institut für Biodiversität der Pflanzen, Bonn, Germany.

The Amaranthaceae (70 genera and ~800 species) occurs in tropical and subtropical regions and it is commonly classified into two subfamilies. Subfamily Gomprenoideae has bisporangiate anthers, whereas anthers in Amaranthoideae are tetrasporangiate. The chiefly neotropical Gomphrenoideae contains 19 genera and 400 species."In order to test monophyly and generic relationships of the Gomphrenoideae, this study included a larger sampling of the subfamily and applied different molecular markers from previous studies. A combined analysis using *trnL-F* and *rpl16* indicated that Gomphrenoideae is monophyletic. There are three major clades and none of these support previous generic classifications. The first clade includes *Iresine*, *Irenella*, and *Woehleria ,* a relationship that is also supported by pollen data. A second clade contains *Pseudoplantago* (traditionally treated as the sole genus in the tribe Psuedoplantageae), *Gomphrena*, *Pfaffia*, *Hebanthe*, *Xerosiphon*, *Froelichia*, *Guilleminea*, *Gossypianthus*, and *Blutaparon*. The last clade includes *Tidestromia* as the sister group to a weakly supported *Pedersenia* and *Alternanthera* clade. These results indicate the need for a new tribal classification since currently accepted tribes and subtribes do not reflect natural groups.

P1055. C3 and C4 Chenopodiaceae species in the vegetation of the Urals: their comparative characteristics and distribution in relation to soil type and climate

M. V. Kapralov;
Institute of Plant and Animal Ecology, Ural Branch of Russian Academy of Science, Yekaterinburg, Russian Federation.

The Urals is situated on the Europe-Asia border and stretches from steppes to tundra that fits this region for comparative ecology investigations. The list of Chenopodiaceae species of the Ural flora is made using literature data and herbarium material and it currently contains 88 species from 24 genera. 21 listed species from 8 genera of subfamily Salsoloideae and 11 species from 4 genera of subfamily Chenopodioideae possess C_4 photosynthesis. Species riches decreases northwards from 81 species in the regions close to Russia-Kazakhstan border to 12 ones in the North Urals. The only C_4 species reaches the tundra zone - *Atriplex tatarica* L. - was collected there on railways. The most part of the C_4 Chenopodiaceae species (81%) is a component of the native vegetation of arid and salt areas of the South Urals, the part of native C_3 species is less (57%). Annuals dominate both among C_3 (91%) and C_4 (72%) species. Almost all C_4 chenopods are succulents, whereas only about 20% of the C_3 ones possess this trait. The distribution of taxonomical and physiological (C_3 and C_4) groups in relation to precipitation, temperature, aridity and soil type is discussed.

P1056. Phylogenetic relationships in *Blumea* (Asteraceae: Inuleae)

P. Pornpongrungrueng, M. H. G. Gustafsson;
Institute of Biological Science, University of Aarhus, Risskov, Denmark.

The genus *Blumea* (Asteraceae: Inuleae) comprises around 100 species distributed in tropical Asia, with some species in Australia and Africa. The delimitation of the genus has varied, and some species placed in *Blumea* have even been transferred to genera of the tribe Plucheeae. Analysis of sequences of the plastid trnL region and the nuclear rDNA Internal Transcribed Spacers (ITS) indicate that, apart from a few African species belonging in the genus *Laggera* of tribe Plucheeae, *Blumea* constitutes a monophyletic group with three well-supported branches: 1) the single species *B. balsamifera* (L.) DC., a shrub or small tree widespread in tropical Asia, 2) the Densiflora clade, a group of medium-sized perennial herbs and subshrubs, growing in the evergreen forests of tropical Asia and 3) the Lacera clade, a variable group of mostly weedy, often annual species, usually growing in open forests and fields in tropical Asia, Australia and Africa.

P1057. *Frolovia, Himalaiella* and *Lipschitziella*: Three small genera in *Cardueae* (*Compositae*) separated from *Saussurea*

E. Raab-Straube;
Botanischer Garten und Botanisches Museum Berlin-Dahlem, Freie Universität Berlin, Berlin, Germany.

Recent molecular as well as morphological studies suggest that the large genus *Saussurea,* consisting of approximately 350 species, is a paraphyletic assemblage. So far, three small genera *Frolovia* (5 species in Altai and Tian Shan), *Himalaiella* (11 species from Western to Eastern Himalaya and China) and *Lipschitziella* (2 species in Western Himalaya and Karakorum), have been recognized as distinct from *Saussurea*. In this study, DNA sequences from the nuclear ribosomal ETS, ITS and from the chloroplast *trn*L/*trn*F region of representative species of these genera, as well as from *Saussurea, Jurinea* and *Dolomiaea,* were analysed. The cladograms resulting from ETS and ITS sequence data confirm the paraphyly of the former *Saussurea* s.l. The *trn*L/*trn*F intergenic spacer shows very little variation in all examined species, however, a remarkable common 22bp insertion in *Dolomiaea, Jurinea, Frolovia, Lipschitziella* and *Himalaiella* suggests a monophyletic origin of these genera. Morphological data, especially from achenes and pappus, were used to characterize the three genera and are found to correspond well to the molecular results.

P1058. Genetic relationships among members of *Centaurea* sections *Acrolophus* and *Phalolepis* (Compositae) as inferred by RAPD markers

T. Touloumenidou[1], **T. Constantinidis**[2], A. Katsiotis[1];
[1]Laboratory of Plant Breeding and Biometry, Athens, Greece,
[2]Laboratory of Systematic Botany, Athens, Greece.

Shape of involucral bracts has traditionally been used as a discriminative character between *Centaurea* sects *Acrolophus* (Ac) and *Phalolepis* (Ph). However, morphological resemblance and adjacent distribution of critical species pairs (one in Ac, the other in Ph) question sectional distinction. We examined 18 members and 22 populations of the two sections by RAPD markers; among them critical groups as *C. attica* (Ac) - *C. subsericans* (Ac) - *C. pseucocadmea* (Ph), *C. cithaeronea* (Ph) - *C. musarum* (Ph), *C. incompleta* (Ac) - *C. litochorea* (Ph) and *C. niederi* (Ac) - C. *heldreichii* (Ph) - *C. leonidia* (Ph). Members of *C.* sects *Acrocentron, Microlophus* and also *Cyanus* and *Carthamus* were included for comparison. A total of 11 primers were used, out of 15 tested. UPGMA clustering failed to distinguish any deep dichotomy between the two sections, although comparison groups separated well. Interspecific genetic distance increased with geographic distance. Small groups of genetically close taxa such as *C. attica* (Ac) - *C. subsericans* (Ac) and *C. incompleta* (Ac) - *C. litochorea* (Ph) were formed. Our data do not support distinction between *Centaurea* sects *Acrolophus* and *Phalolepis*.

P1059. Molecular systematics of the *Rhaponticum* group (Compositae, Cardueae-Centaureinae): taxonomic, biogeographic and morphological implications.

O. Hidalgo, A. Susanna, N. Garcia-Jacas, T. Garnatje;
Botanical Institute of Barcelona, Barcelona, Spain.

The *Rhaponticum* group comprises about 8 genera and approximately 40 species. Besides the delineation of some genera (*Acroptilon*, *Leuzea*, *Rhaponticum*, *Oligochaeta* and *Ochrocephala*), the circumscription of the group is doubtful. The main point of disagreement is the position within the group of *Callicephalus*, *Karvandarina* and other basal genera from the Centaureinae with conflicting borders with the *Rhaponticum* group. Furthermore the phylogenetic relationships within the *Rhaponticum* group and within the genus *Rhaponticum* are largely unknown. To resolve relationships at the base of Centaureinae and within the *Rhaponticum* group, DNA sequences were generated from nuclear regions (ITS and ETS) as well as from cpDNA region (*trn*L-*trn*F). Our results suggest that *Rhaponticum* in its present circumscription is paraphyletic, which has deep nomenclatural and taxonomic implications. Phylogenetic reconstruction reveals a different delineation of the group, and points out that it is necessary to revise classification within the genus more in accordance with evolutive history.

P1060. Systematics and Biogeography of Klasea (Asteraceae: Cardueae-Centaureinae)

L. Martins;
Institute for Systematic Botany, Jena, Germany.

Klasea is a genus comprising ca. 45 species which is characterized by features mostly regarded as plesiomorphic within Centaureinae. It is traditionally included in Serratula, but it has been shown that such a treatment would make Serratula polyphyletic. Nearly all species of Klasea were investigated by means of nrDNA ITS and ETS sequences, morphology, and geographical distribution. Within the genus, three larger monophyletic groups (assigned to sections Klasea, Demetria, and Schumeria) and six additional clades comprising only one or two species each could be detected.

Centers of species richness are found in the mountains of Central Asia, in the Irano-Turanian region (eastern Anatolia to northeastern Iran), and in the Iberian peninsula. Whereas the Central Asian species all belong to sect. Klasea and the Iberian species to sect. Demetria (plus one species to sect. Klasea), representatives of all groups occur in the Irano-Turanian region. Thus it is very likely that the origin of Klasea and the first radiation within the genus occurred there.

P1061. Trichomes in the tribe Lactuceae (Asteraceae) - systematic implications

K. Krak[1,2], P. Mráz[2,3];
[1]Institute of Botany, Academy of Sciences of the Czech Republic, Pruhonice, Czech Republic, [2]Institute of Biology and Ecology, P. J. Šafárik University - Faculty of Science, Košice, Slovakia, [3]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia.

Although the infratribal classification of the Lactuceae has been the focus of several studies, relationships between the genera are not yet fully resolved. While trichome characters have been shown to be an important tool in taxa delimitation in many plant families, a detailed study on trichomes within the Lactuceae was still lacking. We assess here the contribution of trichomes to the clarification of their relationships. Trichome diversity was investigated on vegetative organs (stems and leaves) of 135 representatives of 53 genera by light and scanning electron microscopy. According to their morphology and anatomy, they were classified into 8 types and several subtypes. Presence or absence of particular trichome types was scored at genus level, phenetic analysis was performed, and the results were compared with other studies. The previously supposed monophyly of exclusively American genera and affinities between several other closely related genera were confirmed. A new circumscription of the subtribe Hieraciinae is proposed, which is in accordance with recent molecular data.

P1062. Molecular evidence for allopolyploid origins of *Carthamus creticus* and *C. turkestanicus* (Asteraceae, Cardueae)

R. Vilatersana[1,2], A. K. Brysting[2], C. Brochmann[2];
[1]Botanical Institute of Barcelona- CSIC, Barcelona, Spain, [2]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway.

The allopolyploids *Carthamus creticus* and *C. turkestanicus* are noxious weeds with wide Mediterranean distributions, and *C.*

creticus has also colonized all other Mediterranean climatic regions of the world (Argentina, Australia, California, Chile and South Africa). Previous morphological and caryological studies have suggested that the progenitor lineages of *C. creticus* ($2n = 64$) are represented by *C. lanatus* ($2n = 44$) and *C. leucocaulos* ($2n = 20$), and that those of *C. turkestanicus* ($2n = 64$) are represented by *C. lanatus* and *C. glaucus* ssp. *glaucus* ($2n = 20$), which also agree with their distribution areas. Here we address the origin of these two allopolyploids and their relationships with other species of the *Kentrophyllum* group using cloned fragments of two non-coding regions of the nuclear RNA polymerase genes (RPC2 and RPD2), one non-coding chloroplast DNA region (*trn*H-*psb*A) and DNA fingerprints (random amplified polymorphic DNAs, RAPDs). The results support the original hypotheses of allopolyploid origins, and both allopolyploids were genetically most similar to the progenitor lineage that contributed the highest number of chromosomes, *C. lanatus*.

P1063. Generic delimitations in Inuleae-Inulinae (Asteraceae)

M. Englund[1], A. A. Anderberg[2];
[1]Department of Botany, Stockholm University, Stockholm, Sweden,
[2]Department of Phanerogamic Botany, Swedish Museum of Natural History, Stockholm, Sweden.

The Inuleae subtribe Inulinae contains approximately 300 species in c. 30 genera distributed in the Old World. The phylogeny of the group has been studied on both morphological and molecular data, but many questions regarding the monophyly of the genera have not been adequately addressed, especially with respect to the large genera *Inula* (about 100 spp.) and *Pulicaria* (about 80 spp.). In the present study, a large number of species are included, representing almost all genera of the subtribe and most of the morphological variation within *Inula* and *Pulicaria*. In order to clarify the circumscription of the genera, DNA sequences from two cpDNA regions were analyzed. *Inula* was found to be paraphyletic including also genera such as *Telekia*, *Carpesium*, and *Pentanema*. *Pulicaria* and *Pentanema* were polyphyletic. The small genera *Jasonia* and *Dittrichia* were found to be ingroups in *Pulicaria* and the species of *Pulicaria* section *Francoeuria* belonged to another clade and is better recognized as a separate genus.

P1064. Sporoderm ultrastructure of different pollen types in Asterales

M. V. Tekleva[1], Y. V. Kosenko[2];
[1]PIN RAS, Moscow, Russian Federation, [2]MSU, Moscow, Russian Federation.

Pollen grains of some members of the Campanulaceae s.l. (Cyphoideae, Sphenocleoideae, and Campanuloideae) and Asteraceae (Asteroideae and Cichorioideae) were studied with SEM and TEM. The family Campanulaceae s.l. demonstrates pollen of different apertural types, from the polycolpate to polyporate. Each subfamily of the Campanulaceae is characterized by a certain palynotype. In the other family of this order, Asteraceae, only tricolporate pollen occurs. The Campanulaceae and Asteraceae which have tricolporate pollen differ by exine ultrastructure. In the Campanulaceae the spines of the investigated pollen are solid whereas in Asteraceae the spines can have 1 or 2 cavities in their bases. The architecture of the sporoderm ultrastructure on a familian level is well discerned. The subfamilies of both families have insignificant differences in ultrastructure of the pollen even between different apertural types in the Campanulaceae.

P1065. Leontodon tuberosus and Tragopogon floccosus - new species to the Bulgarian flora

D. Dimitrova, V. Vladimirov, S. Tzoneva;
Institute of Botany, Sofia, Bulgaria.

Currently, targeted research on Lactuceae has been undertaken in Bulgaria. Special attention has been given to poorly studied areas in the country. This has resulted in the discovery of several new species from the group.

So far the genus Leontodon comprised six species in Bulgaria - L. autumnalis, L. cichoraceus, L. crispus, L. hispidus, L. rilaensis and L. taraxacoides.

Leontodon tuberosus L. (Asteraceae: Lactuceae) is reported as new to the Bulgarian flora. This Mediterranean species was discovered in grasslands, in the southernmost part of the Black Sea floristic region, near the Turkish border. Although locally abundant the species is restricted to a relatively small area and is under serious threat by the increasing tourism development along the Black Sea coast.

The poster presents the distinguishing morphological characters from the other Bulgarian Leontodon species and the chromosome number and morphology. The national conservation status of the species is discussed.

P1066. Morphometric evaluation of infraspecific variability of *Picris hieracioides* (*Compositae*) in Europe

M. Slovák[1], K. Marhold[1,2];
[1]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia,
[2]Department of Botany, Charles University, Prague, Czech Republic.

Picris hieracioides is a morphologically very variable and taxonomically complicated species. Usually six subspecies have been accepted in recent European Floras (*P. hieracioides* subsp*. hieracioides*, subsp*. grandiflora*, subsp. *longifolia*, subsp*. rielii*, subsp*. spinulosa*, subsp*. villarsii*), but the taxonomic information is incomplete and often contradictory. Forty-seven population samples of *P. hieracioides* were collected from Central, Western and Mediterranean Europe, and analyzed morphometrically. Two main morphologically distinct groups of populations can be delimited: populations growing at lower altitudes in ruderal habitats, and those from more natural mountain habitats. Within the ruderal group, populations from Central Europe are differentiated from those from Sicily and Spain. The mountain group shows morphological differentiation into five groups, which occupy different European mountain ranges: (1) the Carpathians and E Alps, (2) the W Alps, (3+4) the Pyrenees, and (5) Sierra Nevada. These morphologically defined groups will be proved by cultivation experiments and molecular analyses, and related to the described subspecies.

P1067. Biogeographic patterns and affinities of the Pacific island genus Oparanthus (Coreopsideae: Asteraceae)

H. Dempewolf[1], T. J. Motley[1], D. H. Lorence[2], W. L. Wagner[3];
[1]The New York Botanical Garden, Bronx, NY, United States, [2]National Tropical Botanical Garden, Kalaheo, HI, United States, [3]Smithsonian Institution, Washington, DC, United States.

Oparanthus is a genus of four species endemic to French Polynesia. Two are endemic to Rapa iti in the Austral Archipelago and the other species are endemic to the islands of Nuku Hiva and Hiva Oa, respectively, in the Marquesan Archipelago. The genus has been variously circumscribed by earlier authors (e.g., in the genus *Bidens*). Recent phylogenetic studies of the Coreopsideae have shown that *Oparanthus* is not closely related to *Bidens*, but rather is sister to the Polynesian genus *Fitchia*. These studies also suggest that *Oparanthus* and *Fitchia* have close affinities with Caribbean genera. This study is a species-level phylogenetic analysis of *Oparanthus* using quickly evolving gene regions (ITS, ETS, and 5s-NTS) from the nuclear ribosomal genome. The goals of this study are to resolve the migration patterns of *Oparanthus* and *Fitchia* among islands of the southeastern Pacific and to further investigate the biogeographic affinities of this Pacific lineage to other members of the Coreopsideae.

P1068. Morphological, cytotaxonomical and embryological studies on the genus *Taraxacum* Weber (Asteraceae, Lactuceae) in Calabria (S Italy)

G. Aquaro, L. Peruzzi, G. Cesca;
Museo di Storia Naturale della Calabria ed Orto Botanico, Arcavacata di Rende (CS), Italy.

Due to the scarce knowledge of the genus *Taraxacum* Weber in Calabria (S Italy), we carried out morphological, cytotaxonomical and embryological studies on its representatives. Aim of this work, which is still in progress, is to contribute to the knowledge of this difficult genus with basic biosystematic data linked to well defined and localised populations. Our research is based on live plants collected during the year 2004 and on *exsiccata* from the herbarium of the University of Calabria (CLU) and from the Herbarium Centrale Italicum (FI). We have notice of the presence in Calabria of 6 *Taraxacum* sections: *Alpina*, *Erythrosperma*, *Obovata*, *Palustria*, *Scariosa*, *Taraxacum*. Eight populations were studied (coming from Pollino Massif, N Calabria; Catena Costiera and Sila Massif, C Calabria). Morphological data for each population are presented and discussed. The studied populations evidenced several ploidy levels, and often apomixy with *Taraxacum*-type embryo-sac development. It is of particular interest the presence in Calabria of a population (Sect. *Erythrosperma* Dahlst.) with $2n = 8$ chromosomes, a number never before quoted in literature for the whole genus.

P1069. Phylogenetic relationships among the genera of the subtribe Sonchinae (Asteraceae: Lactuceae) based on ITS and matK sequences

S. Kim[1], C. Lee[1], J. A. Mejías[2];
[1]University of California, Riverside, CA, United States, [2]Departamento de Biología Vegetal y Ecología, Sevilla, Spain.

The subtribe Sonchinae comprises of 13 genera and ca. 130 species and is the most widely distributed subtribe in Lactuceae, with a discontinuous, almost cosmopolitan, phytogeographically very peculiar distribution. Phylogenetic relationships among the genera have been poorly resolved in previous work. In this study, we sampled all representatives of the subtribe and sequenced nuclear ITS of nrDNA and chloroplast matK gene. Both sequences suggest that Reichardia and Launaea diverged first within the subtribe. The genus Sonchus is highly polyphyletic. Three monotypic genera in the Pacific, Embergeria and Kirkianella in New Zealand and Actites in Australia, evolved from some members of Sonchus sections Arvenses and Maritimi. The Juan Fernandez Island endemic Dendroseris, is deeply nested within the subtribe Sonchinae. The woody Sonchus alliance, consists of 6 genera and 31 species, in the Macaronesian Islands is monophyletic, but the closest continental relatives need to be determined. There are several major differences between nuclear ITS and chloroplast matK phylogenies. A phylogeny-based classification of the subtribe Sonchinae will be discussed.

P1070. A taxonomic study on the tribe of Astereae (Asteraceae) in east & northeast of Iran

K. Emadzade[1], A. Emami Nouri[2];
[1]Research Center for Plant Sciences-Ferdowsi University, Mashad, Islamic Republic of Iran, [2]University of Medical Sciences, Tehran, Islamic Republic of Iran.

Astereae is one of the tribes of Ateraceae. Its phylogenetic situation is between Calenduleae and Anthemideae. In “Flora Iranica” were recorded 14 genus and 33 species from Iran. This investigation is based on morphological study of specimens in east and northeast of Iran (Khorassan Province). *Psychrogeton cabulicus* BOISS. is reported as a new record to the flora of Iran which its distribution in region of Flora Iranica is in Turkmenistan and Afghanistan . 6 species including *Solidago virga-aurea* L., *Erigeron uniflorus* L., *Chameageron asterellus* (BORNM.) BOTSCH. , *Ch. oligocephalus* SCHRENK, *Conyzanthus squamatus* (SPRING.) TAMAMSCH and *Myriactis wallichii* DC. are recorded as new for the flora of east and northeast of Iran. *Psychrogeton andryaloides* (DC.) NOVOPOKR. ex KRASCH , *Psychrogeton persicus* BOISS. and *Lachnophyllum gossypinum* BUNGE are recognized as rare species. Distribution maps and identification key to the genera and species are provided.

P1071. Molecular phylogenetics of the Edelweiss (*Leontopodium*, Asteraceae)

C. M. Blöch[1], R. Samuel[1], B. Dickoré[2], T. F. Stuessy[1];
[1]Institute of Botany and the Botanical Garden Vienna, Vienna, Austria, [2]Departement of Systematic Botany, Albrecht-von-Haller Institute of Plant Sciences, University of Göttingen, Goettingen, Germany.

The main distribution of the genus *Leontopodium*, comprising c. 30-40 species, encompasses an extensive and largely contiguous area in Central and East Asia. Two taxa occur, widely disjunct, in the mountains of Central and South Europe (*L. alpinum*, *L. nivale*). The taxonomic status of the European representatives is questionable. Neither ITS nor AFLP data can apparently discriminate between them, although they may well comprise reproductively isolated strains. Sequence data of the ribosomal DNA (ITS and ETS) as well as the plastid *matK* and the *trnL*/*F* do support monophyly of the genus as well as the species concept. Having many representatives of Asiatic species of *Leontopodium*, as well as morphological, phytochemical and the geographical distribution pattern do support a division of the genus into two sections, Nobilia and Leontopodium, as suggested by Handel-Mazzetti (1927). Molecular data does not support the monotypic status of the genus *Sinoleontopodium* (Chen, 1985).

P1072. Evolution of non hermaphroditic breeding systems in Asteraceae

R. Torices, M. Méndez;
Universidad Rey Juan Carlos, Móstoles, Spain.

Although most flowering plants are hermaphroditic, other breeding systems (andromonoecy, gynomonoecy, monoecy, androdioecy, gynodioecy, dioecy) have evolved in numerous lineages. Dioecy is considered to have evolved mainly through monoecy or through gynodioecy as intermediate steps. In Asteraceae, hermaphroditism is the ancestral state and andromonoecy, gynomonoecy, monoecy, gynodioecy, and dioecy have evolved secondarily. No formal study has been carried out, however, on the number of independent evolutionary events involved in those changes of breeding system or the pathways followed from hermaphroditism to dioecy. Using a supertree of the family Asteraceae and the comparative method we aim to answer to the following questions: How many times have non-hermaphroditic breeding systems evolved in Asteraceae?, Is gynomonoecy an intermediate step in the evolution of monoecy in this family? Has dioecy evolved via monoecy or via gynodioecy in Asteraceae? Which are the ecological correlates of the evolution of dioecy in this family?

P1073. Botanical and ecological studies of the species of *Artemisia* L. genus in Azarbaijan-e-Gharbi, Iran

K. Saedi;
Tehran University, Karaj, Islamic Republic of Iran.

The largest formation in Irano Turanian zone as well as in Azarbaijan-e-Gharbi is *Artemisia-Astragalus*. Ecological and botanical attributes of habitats, cytogenetic, anatomy, morphology and essential oils were studied and separately discussed after One-way ANOVA in botanical, ecological and systematic aspects for eight populations (six species). Finally, all quantitative attributes were used for multivariable analyzing. Cytogenetically there was two different cytotypes for *A. spicigera* populations; these studies also determined the short arm of the chromosome as a useful trait for categorizing of the studied populations. Most species showed various xerophytic structures that are important in reclamation of similar ecological but disturbed habitats. Resulted cluster showed the dominancy of environmental conditions on systematic and taxonomy. Morphological, anatomical and karyotypical traits were used in PCA and cluster analysis to categorize population/species. Three main groups were categorized that it was in long with the last subgenus taxonomy except for *A. incana* population.

P1074. Comparative annual stem anatomy of East-European species of Artemisia L. (Asteraceae): taxonomic value.

A. Beer;
Moscow State University, Moscow, Russian Federation.

Anatomical features such as the depth of cork initiation, width of rays, presence of secretory canals and phloem fibres are most significant at sectional or subsectional level in genus Artemisia. Superficial cork is typically present in sect. Artemisia and Absinthium. Exceptions are A. vulgaris and A. hololeuca in which the cork is absent and A.latifolia in which the cork is initiated in depth cortex layers. The cork is never initiated in subepidermal layer in sect. Dracunculus. Species of sect. Seriphidium have both types of cork initiation. Wide rays are present in A tshernieviana and in other semi-shrubby species of sect Dracunculus. Secretory canals are always absent in sect. Seriphidium but present in the cortex in members of sections Artemisia, Absinthium and in some species of sect. Dracunculus (excepting A. vulgaris L., A. austriaca, A.pontica) and in secondary phloem in A tschernieviana and related species (sect. Dracunculus). These new data support the opinion about origin Artemisia from semi-shrubby forms and expand the conception of relationship within sect. Artemisia and Dracunculus in comparison with molecular data.

P1075. Leaf Epidermal Features In *Vernonia amygdalina* and *Vernonia cinerea*

A. O. Giwa;
National Centre for Genetic Resources and Biotechnolgy, Ibadan, Nigeria.

ABSTRACT

Leaf Epidermal Features In *Vernonia amygdalina* and *Vernonia cinerea*

Vernonia amygdalina Vernonia cinerea are tropical plant belonging to the family Compositae and is used widely as vegetable and medicinal plant.The periclinal surface of the epidermis or cuticle of the petiole, mid-rib and of subsidiary cells in *Vernonia amygdalina* is papillose, with papillose, with papillae appearing, in surface view, as striations. That of *Vernonia cinerea* is, however, non-papillose. Four types of trichomes are observable on the two species - regular and irregular T - shaped, uniseriate and sunken, bilobed trichomes. *Vernonia amygdalina* bears irregular T - shaped and bilobed trichomes while Vernonia cinerea has regular T - shaped, uniseriate and bilobed trichomes. All the trichomes except uniseriate type are glandular and more abundant on the abaxial surface than the adaxial surface of the leaf in both species. Stomata which are anomocytic and actinocytic also have similar distributional pattern.

P1076. Introduction of the genus Echinacea Moench species in Ukraine

V. Menshova;
Kyiv National University named by Taras Shevchenko, Kyiv, Ukraine.

In the O. V. Fomin Botanical Garden of the Taras Shevchenko Kyiv National University has been created the collection of the genus Echinacea Moench species: E. angustifolia DC., E. atrorubens Nutt., E. pallida (Nutt) Nutt., E. purpurea (L.) Moench, E. simulata Mc Gregor, E. tennessensis (Beadle) Small.

First the high introduction ability of the majority of the genus Echinacea Moench species has been substantiated. The comparative characteristics of peculiarities of development of investigated species have been carried out. The melliferous productivity of E. purpurea in its cultivation on the production plantations under the conditions of Ukraine has been substantiated. First the estimation of microelement contents of cultivated in Ukraine E. purpurea, E. pallida, E. angustifolia has been carried out. In extracts of E. purpurea the biologic-active substances of albumen - lectins - have been found. On base of integral estimation of the introduction peculiarities in culture of the inverstigated genus Echinacea Moench species has been established the possibility of their production cultivation in the majority of regions of Ukraine.

P1077. Reproductive biology of two closely related species of Leontodon L.(Asteraceae)

G. Cruz Mazo, M. J. Gallego;
Facultad de Farmacia, Sevilla, Spain.

We carried out a reproductive biology study of two closely related Leontodon (Asteraceae) species: L. salzmannii (Schultz.) Ball (endemic to the Morocco) and L. muelleri (Shultz. Bip) Fiori (occurring in Africa, Italy and SE of the Iberian Peninsula).Both species are annual and heterocarpic.

In order to gain insight into their breeding behaviour and to check on the possible sterility barriers, an artificial crossing program was prepared. It showed that self-incompatibility prevails in these species. Moreover cross-compatibility was found in most combinations within populations and between populations belonging to same taxon. Artificial hybridization showed that L. salzmannii and L. muelleri were cross-compatible. We studied seed-set and germination of seeds obtained after hybridization, as well as fertility, somatic chromosome number and meiosis in hybrid plants.

In the other hand, we observed that L. salzmannii and L. muelleri differ significantly in germination characteristics.

P1078. Cytogeography of *Pilosella officinarum* (Compositae, Lactuceae) in the Western Carpathians

P. Mráz[1,2], B. Šingliarová[1];
[1]Institute of Biology and Ecology, P.J. Šafárik University, Košice, Slovakia, [2]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia.

Pilosella officinarum is represented by 5 cytotypes (2x, 4x, 5x, 6x, 7x) throughout its distribution area. While the cytotype distribution is well documented for W and NW Europe, only scattered data were published from the rest of the area of this species. In total, 405 plants from the W Carpathians were analyzed by flow cytometry or classical counting within our study. Pentaploid level was found as the most frequent, following by hexaploid one. Mixed populations (5x + 6x) were represented in 8 % of cases. Contrary to the W Europe, tetraploids are very rare in the W Carpathians. The differences in altitudinal distribution were observed; 6x plants only rarely occur at high elevations in contrast to 5x plants, which are frequent there. Our W Carpathian data agree with the high proportion of 5x and 6x plants found in Scandinavia and in the Alps. Current cytotype distribution patterns probably reflect a postglacial colonization of the tetraploid cytotype from the pre-Alpic region, followed by the rise of ploidy level in the marginal areas in the north of Europe and in larger orophytic systems (Alps, Carpathians, ?Balkan).

Financial support: VEGA 1/1283/04, APVT-51-006002.

P1079. Chloroplast and low-copy nuclear region DNA evidence on phylogeny of Arnica (Asteraceae-Madieae): comparisons with nuclear ribosomal DNA data

C. Ekenäs[1], K. Andreasen[1], B. G. Baldwin[2];
[1]Department Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden, [2]University of California, Integrative Biology, University and Jepson Herbaria, Berkeley, CA, United States.

Arnica is a circumpolar genus of 29 spp restricted to the northern hemisphere. Previous taxonomic studies indicate high variability and a reticulate history of hybridization and polyploidy.

Chloroplast rpl16, rps16, trnT-L, and psbA-trnH spacer sequences were found to contain minimal sequence variation relative to variation in nuclear ribosomal transcribed spacers (ITS and ETS) for 26 Arnica species. The informative chloroplast DNA characters, however, confirm some of the clades in trees resulting from analysis of ITS and ETS variation. A phylogenetic hypothesis based on combined nuclear and chloroplast DNA data indicates that previous circumscriptions of subgenera in Arnica are problematic.

Sequencing of rapidly evolving, low-copy nuclear regions (Nitrate Reductase and RNA polymerase) is being pursued to obtain another line of evolutionary evidence, with the goal of generating a robust phylogeny of Arnica and for estimating proposed reticulate evolution of the genus.

P1080. Phylogenetic relationship of the intraspecific variation of Stevia origanoides (Eupatorieae; Asteraceae) based on AFLP.

M. Nakazawa[1], T. Kawahara[2], A. Soejima[3], K. Watanabe[4], T. Yahara[1];
[1]Kyushu University, Fukuoka, Japan, [2]FFPRI, Sapporo, Japan, [3]Osaka Prefecture University, Osaka, Japan, [4]Kobe University, Kobe, Japan.

Stevia (Eupatorieae; Asteraceae) is a large genus containing approximately 230 species, occurring in montane regions of southwestern USA through Central & South America. Mexico is a center of diversity with ca. 100 spp. diverged to annuals, perennials and shrubs. Forty-two species of them include agamospermous polyploids, most of which have wider distribution than sexual diploids. Our previous studies on Mexican Stevia using ITS data results in the following. Shrub and perennial-annual clades diverged at the base of phylogenetic tree. Agamospermous polyploids evolved independently in 15 perennial species, but did not evolve in annuals and shrubs. Stevia origanoides is one of the examples for sympatric speciation with both sexual and agamospermous form and has broad morphological variation in sexual diploids. We focused on the speciation among sexual diploids of S. origanoides. The various types of ecological and morphological lineages were analyzed based on AFLP analysis. We found that it includes more than 5 biological species. This finding suggests that S. origanoides is actively radiated to heterogeneous environments of slopes and cliffs in Mexico.

P1081. Origin and relationships of the austral genus *Abrotanella* (Asteraceae) inferred from DNA sequences

S. J. Wagstaff[1], I. Breitwieser[1], U. Swenson[2];
[1]Allan Herbarium, Landcare Research, Lincoln, New Zealand,
[2]Department of Phanerogamic Botany, Swedish Museum of Natural History, Stockholm, Sweden.

Relationships of the small austral genus *Abrotanella* are uncertain. It was previously included in the Anthemideae or more recently in the Senecioneae. We conducted a phylogenetic analysis of 39 accessions including most species of *Abrotanella* and putatative relatives including *Blennosperma, Crocidium* and *Ischnea*. These four genera have been considered to form subtribe Blennospermatinae. Our results suggest that the Blennospermatinae are polyphyletic. *Blennosperma, Crocidium* and *Ischnea* form a well-supported clade nested within the Senecioneae, while *Abrotanella* forms a another well-supported clade that is distinct from these genera. However, its sister is not resolved. Molecular dating of *Abrotanella* suggests that the lineage initially diverged during the early Miocene. Secondary species radiations in Australasia and in southern South America that occurred 3 million years ago undoubtedly reflect long-distance dispersal, colonization, and speciation. The divergence estimates are robust to the genes that were sequenced, to changes in the tree topology, and to the method used to estimate divergence times.

P1082. Systematics and Evolution of the Genus Formania

T. Gao;
Herbarium, Institute of Botany, the CAS, Beijing, China.

The systematic position of the monotypic shrubby genus Formania has been disputed for more than half a century. In this study, its position was assessed by using evidence from morphology and three DNA sequences. Results indicate that the apex of style branch of its disc floret is the “asteroid type”, not “styli trucati”. This evidence strongly supports the close affinity between Formania and the Astereae. Phylogenetic analyses of trnL /F spacer and the trnL intron also indicate that Formania has strong affinity with the tribe Astereae. Parsimony analyses of ITS sequences of the Astereae indicate that Formania is nested at the basal position of the clade comprising genera of subtribe Asterinae from Eurasia. This clade is only weakly supported. But the placement of Formania in the Euraisan Asterinae is justified by some morphological characters. Considering the woody habit and other primitive characters compared with the Eurasian Asterinae, Formania seems to represent part of the ancestral stock of subtribe Asterinae that found refuge in the Jinshajiang dry-warm valley after the radiation of the Asterinae in Eurasia.

P1083. Morphological analysis of *Euchiton argentifolius - Euchiton traversii* species complex (Gnaphalieae: Asteraceae)

C. M. Flann[1,2], P. Y. Ladiges[1], I. Breitwieser[3], N. G. Walsh[4], J. M. Ward[5];
[1]The University of Melbourne, Melbourne, Australia, [2]Nationaal Herbarium Nederland, Wageningen, The Netherlands, [3]Landcare Research, Lincoln, New Zealand, [4]National Herbarium of Victoria, Melbourne, Australia, [5]University of Canterbury, Christchurch, New Zealand.

Euchiton has an Australasian distribution with several species restricted to alpine regions in Australia and New Zealand. There is confusion as to the delimitation of species in the *E. argentifolius - E. traversii* complex. This paper resolves taxa by phenetic comparison of populations based on morphological characters, covering the geographic range of the complex. More than 140 specimens of six currently accepted taxa were included in this study. These encompass collections from seven herbaria and material collected in the field. Continuous measurements as well as binary characters and SEM were utilised. A generic split is confirmed within this group and several species are transferred. *Euchiton mackayi* is shown not only to be present in Australia, a significant range extension, previously being thought a New Zealand endemic, but it is also shown to have a strong affiliation with *E. argentifolius*. The outcome of this work is a clarification of the number of members in this alpine group, as well as revised distributions, resulting in a more workable taxonomy that will enable easier identification of these small but plentiful daisies.

P1084. Phylogenetic analysis of *Bulbostylis* Kunth (Cyperaceae) using plastid DNA sequence data.

A. P. Prata[1], D. Simpson[2], M. Chase[2], W. Thomas[3], M. G. L. Wanderley[1];
[1]Instituto de Botanica, Sao Paulo, Brazil, [2]Royal Botanic Gardens, Kew, Surrey, United Kingdom, [3]The New York Botanical Garden, New York, NY, United States.

Bulbostylis (ca.150 species) occurs primarily in tropical and subtropical regions. It is distinguished from other Cyperaceae genera by the presence of trichomes on the leaf sheath and a persistent style base on the achene apex. The genus belongs to the subfamily Cyperoideae, tribe Abildgaardieae which also includes *Abildgaardia*, *Fimbristylis* and *Nemum*. The relationships among and circumscriptions of these genera in Abildgaardieae have been controversial. *Bulbostylis* have been placed in different taxonomic positions. In order to elucidate species relationships, evaluate existing infrageneric classifications and test the circumscription of *Bulbostylis*, a phylogenetic analysis using cpDNA sequence data (*trnL* intron and *trnL-F* intergenic spacer) was carried out. 107 species of *Bulbostylis* were included, and *Fimbristylis* (7 species), *Nemum* (2), *Scleria* (2), *Becquerelia* (1) and *Lagenocarpus* (1) were used as outgroup.

P1085. Systematics of the genus Scleria Bergius

B. De Wilde;
University of Dublin, Trinity College, Dublin, Ireland.

Scleria Bergius is a large and important pantropical genus within the Cyperaceae comprising ca. 200 species. It is partly characterised by unisexual flowers in unisexual or bisexual spikelets and the presence of a hard, one-seeded nutlet.

Generic boundaries in this group are unclear, particularly the relationships between *Scleria*, *Acriulus*, *Diplacrum*, *Becquerelia*, *Bisboeckelerea* and *Calyptrocarya.* An absolutely essential part of the project therefore is to test the monophyly of the genus *Scleria* and clarify the relationships between *Scleria* and closely related genera.

An understanding of its phylogeny is crucial to the development of a phylogeny for the family as a whole. It will also help in understanding patterns of character evolution in the Cyperaceae and so contribute to an overall picture of evolution in the Monocotyledons.

Preliminary morphological and molecular analysis (trnL-F and ITS) have revealed new phylogenetically informative characters and allowed construction of a preliminary phlogenetic tree.

P1086. Systematics of Juncaceae

E. Jones;
Trinity College, Dublin, Ireland.

Phylogenetic relationships of Juncaceae and related families of Cyperales were investigated using DNA sequence data from the plastid rps16 intron, trnL intron and trnL-F intergenic spacer. Results using parsimony analysis of the aligned matrices find Juncaceae and Cyperaceae to be monophyletic families, which form a clade sister to a monophyletic Thurniaceae that includes Prionium (Prioniaceae), all three clades with 100% bootstrap support. Within Juncaceae the genus Luzula is monophyletic with 100% bootstrap support and sister to the rest of Juncaceae. Further groupings within the family indicate that the genus Juncus may be monophyletic only with the inclusion of the single-flowered genera of Juncaceae (Distichia, Oxychloe, Marsippospermum and Rostkovia; sequences of Patosia were not included). Major groupings within Juncus are supported by the morphological characters of septate or non-septate leaves and the presence or absence of bracts subtending the flowers, which have been used to define subgenera and sections within Juncus in classifications including Kirschner et al. 2002a, b, c. Reference to anatomy will also be made.

P1087. Cyperaceae C_3 and C_4: an overview on the Brazilian species.

M. Alves, S. Martins;
Universidade Federal de Pernambuco, Recife, Brazil.

Cyperaceae is one of the few families which both photosynthetic pathways (C_3 and C_4) are present. Cross sections of cataphylls, leaves, bracts, and steams were realized. Fresh and dried samples of 110 species from 24 genera occurring in different ecosystems mainly from NE Brazil were analyzed. Among the studied species, 40 have Kranz anatomy well characterized. Four subtypes were recognized - chlorocyperoid (*Ascolepis*, *Cyperus*, *Kyllinga*, *Lipocarpha*, *Pycreus*, *Remirea*), rhynchosporoid (*Rhynchospora*), eleocharoid (*Eleocharis*) and fimbristyloid (*Abildgaardia*, *Fimbristylis*, *Bulbostylis*). *Becquerelia*, *Calyptrocarya*, *Carex*, *Diplacrum*, *Fuirena*, *Hypolytrum*, *Lagenocarpus*, *Machaerina*, Mapania, *Oxycaryum*, *Pleurostachys*, *Scleria*, *Websteria* are exclusively C_3 genera. *Cyperus*, *Eleocharis*, *Fimbristylis*, *Rhynchospora* are genera with both pathways, however only one species is recognized as a C_3-C_4 taxon (*Rhynchospora globosa*). Species with an uncompleted third sheath and a subtype of Chlorocyperoid named Kranzkette were also recognized among the studied species. No geographical pattern of C_4 species or genera in Brazil is already recognized.

P1088. The genus *Bolboschoenus* in Central Europe: distribution and habitat differentiation

Z. Hroudová[1], P. Zákravský[1], K. Marhold[2,3], M. Duchácek[4];
[1]Institute of Botany, Academy of Sciences of the Czech Republic,

Pruhonice, Czech Republic, [2]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia, [3]Department of Botany, Charles University, Prague, Czech Republic, [4]National Museum, Department of Botany, Pruhonice, Czech Republic.

Formerly broadly conceived species *Bolboschoenus maritimus* (L.) Palla (= *Scirpus maritimus* L.) appeared to be a complex of taxa differing much more in ecology and their distribution areas than in morphological characters. The following species have been found to occur in Central Europe: *Bolboschoenus maritimus* (L.) Palla (saline habitats), *B. planiculmis* (F. Schmidt) T. V. Egorova (wet ditches, temporarily flooded field depressions), *B. yagara* (Ohwi) Y. C. Yang et M. Zhan (fishpond littorals, acid grounds), *B. laticarpus* Marhold, Hroudová, Zákravský & Duchácek (river shores and floodplains, temporarily flooded field depressions), *B. glaucus* (Lam.) S. G. Sm. (river floodplains, warmer regions). Their distribution in Central Europe was mapped based on revision of herbarium collections and authors' field investigations. The *Bolboschoenus* species, which differ in their distribution areas in Eurasia, meet in Central Europe; their areas of distribution within this region correspond to their habitat differentiation.

P1089. Chromosomal evolution of the genus *Eleocharis* (Cyperaceae), based on molecular phylogeny and karyomorphological observations

O. Yano, T. Hoshino;
Gra. Sch. Dep. Biosphere-Geosphere System Science, Fac. Informatics, Okayama Univ. Sci., Okayama, Japan.

The nrITS, nrETS 1f , and *trn*L intron sequence data were used to estimate the phylogeny of *Eleocharis* species, and karyomorphological observations were made on 20 species of this genus. Two major clades were identified in the Japanese *Eleocharis* molecular phylogenetic tree: (1) one including all species of section *Limnochloa*, and (2) the other species of the genus *Eleocharis*. Phylogenetic analysis including both Japanese and North American species also shows strong support for monophyly of the *Limnochloa* clade. The width of the spikelets in species of section *Limnochloa* is the same as that of the culms, and indicates that the relative widths of spikelets and culms are useful characters for classification. Two major clades were supported by karyomorphological data. All species of section *Limnochloa* had very small chromosomes, while sections *Pauciflorae* and *Eleocharis* had large chromosomes. The basic number of sections *Eleocharis* and *Pauciflorae* is thought to be x = 5. Chromosomal evolution in the genus *Eleocharis* with diffuse centromeric chromosomes, may be caused by both aneuploidy and polyploidy.

P1090. Taxonomical diversity of Cyperaceae Juss. in Ukraine

I. N. Danylyk;
Institute of Ecology of the Carpathians NAS of Ukraine, L'viv, Ukraine.

The Cyperaceae is one of the biggest families in Ukrainian flora. The systematic revision and chorological investigation of this family permitted to define taxonomic diversity and distribution within state borders. Carex demissa, C. loliacea, C. strigosa, C. bunnescens have been found as new species for Ukraine and proved the presence of Eleocharis mamillata. Availability of Cyperus badius, Eriophorum scheuchzeri, Schoenoplectus americanus, Rhynchospora fuscahave been revised as falsely mentioned for Ukrainian flora. Thus, Cyperaceae family is presented by 19 genus and 149 species. According to the species quantity genus are located in such order: Carex - 96 sp., Eleocharis - 13, Schoenoplectus - 7, Cyperus - 6, Bolboschoenus - 5, Eriophorum - 4, Scirpus, Isolepis, Juncellus, Cladium, Schoenus in twos, Scirpoides, Blysmus, Fimbristylis, Pycreus, Dichostylis, Mariscus, Torulinium, Rhynchospora - by 1 only. Intrageneric differentiation of the biggest genus is characterized by following data: subgenus Carex - 58 sp., Vignea - 26, Kreczetoviczia - 7, Psyllophora - 5 sp. 35 species of Cyperaceae in Ukrainian flora belong to the rare and threatened species.

P1091. A preliminary taxonomic subdivision of the Cyperaceae family in Venezuela

I. C. Fedon[1], R. M. Gonto[2];
[1]Fundacion Instituto Botanico de Venezuela, Caracas, Venezuela, [2]Universidad Central de Venezuela. Facultad de Ciencias, Caracas, Venezuela.

The Cyperaceae family in Venezuela occupies the seventh place in species diversity within the angiosperms. As part of the family revision a preliminary distribution of the species within their taxonomic level is presented, using specialized literature along with the creation of a database which includes the specimens deposited in Venezuelan herbaria (VEN, PORT, MY, MYF, CAR, CORO, MER, MERC, MERF, HERZU, GUY). The family is divided in: 4 subfamilies, 12 tribes, 36 genera, 425 species, 33 subspecies and 20 varieties. They occupy a variety of environments: from dry sea level, savannah, disturbed areas, forests, flooded areas as wetlands, to mountain “páramos” at 4200 m. The Cyperaceae includes 43 endemic species in Venezuela. Examples are: Carex roraimensis Steyerm.; Eleocharis ayacuchensis S. González & Reznicek; Eleocharis steyermarkii S. González & Reznicek; Everardia vareschii Maguire; Koyamaea neblinensis W.W. Thomas & Davidse; Lagenocarpus venezuelensis Davidse; Mapania aturensis D.A. Simpson; Rhynchospora agustiniana T. Koyama; Scleria camaratensis Core, among others.

P1092. Sedges may have edges - but what underlies them? Comparing the anatomy and morphology of sedges

K. L. Wilson[1], J. J. Bruhl[2];
[1]Royal Botanic Gardens, Sydney, Australia, [2]University of New England, Armidale, Australia.

Sedges, like many other monocots, have limited macro-morphological variation with organs (especially leaves and inflorescences) frequently reduced or cryptic in their external structure. This has led to difficulties in understanding relationships or even in distinguishing related species. The underlying anatomy helps us understand the morphology and evolution of sedges, especially in groups that are scleromorphic. Many Australasian /Gondwanic genera fall into this category. The usefulness of anatomical features has been well understood by cyperologists, as exemplified by the recognition of the correlation of vegetative anatomy with the different photosynthetic pathways found in the family. Examples will be drawn from published and unpublished studies on *Cyperus, Lepidosperma, Mesomelaena, Schoenus,* as well as *Juncus* in family Juncaceae, the putative sister to Cyperaceae, of the continuing value of anatomical characters in interpreting morphology, identifying species and understanding relationships within the sedges and the rushes.

P1093. *Pycreus* P. Beauv. in East Africa; genus or subgenus?

K. Hoenselaar[1], A. M. Muasya[2], D. A. Simpson[1];
[1]RBG Kew, Richmond, Surrey, United Kingdom, [2]Herbarium, National Museums of Kenya, Nairobi, Kenya.

Taxonomic progess in large genera such as *Cyperus* L s.l. (600 spp., Cyperaceae) is hampered by an iadequate infrageneric classification with no general agreement on its circumscription. When splitting *Cyperus* s.l. into several subgenera, *Pycreus* P. Beauv. (70 spp.) is one of the larger subgenera, with its highest concentration in Africa. It is treated by some as a separate genus or as part as *Cyperus* s.l. by others. *Pycreus* differs from *Cyperus* by having 2 (not 3) style-branches placed dorsally and ventrally in the flower, and by the lateral compression of the nutlet. Based on these characters *Pycreus* can be considered as a separate genus from *Cyperus* s.s. Discussion rises however whether *Pycreus* is a polyphyletic group, for reduction from 3 to 2 style-branches is common in Cyperaceae. Although molecular studies support the theory that *Pycreus* is indeed a polyphyletic group, it will be considered a valid genus based on its morphological differences, at least for the East Africa region. A synopsis of the East African species will be presented.

P1094. Inferring phylogenetic relationships in Carex subgenus Vignea (Cyperaceae): impact of nrDNA pseudogenes and paralogs.

M. King, E. H. Roalson;
Washington State University, Pullman, WA, United States.

Carex subgenus *Vignea* (Cyperaceae) includes approximately 320 species and is organized into approximately 25 sections. Recent molecular phylogenetic studies have suggested that subgenus *Vignea* forms a well-supported monophyletic group, but relationships within *Vignea* are more problematic. Past classifications of *Vignea* have loosely placed most of the species into sections based on discontinuities in complex morphological characters and recent phylogenetic analyses has suggested that limits of several of these sections do not follow evolutionary patterns. We explore the molecular evolutionary dynamics of nrDNA ITS and ETS to investigate what role ribosomal DNA paralogs and psuedogenes might play in confounding our assessment of the sectional limits of many androgynous *Vignea*. Additionally, nrDNA inferred polyphyly of several species has prompted investigation of the potential impact of hybridization and lineage sorting among supposedly distantly related taxa.

P1095. A taxanomic study on six sections *Ischnostachyae*, *Anomalae*, *Capitellatae*, *Debiles*, *Capillares* and *Molliculae* of *Carex* L. in Korea (Cyperaceae)

Y. C. Oh[1], C. S. Lee[2], J. Y. Yoon[1];
[1]Department of Biology, Sungshin Women's University, Seoul, Republic of Korea, [2]Department of Life Sicence, Ewha womans University, Seoul, Republic of Korea.

Morphological characters of 14 taxa in 6 sections *Ischnostachya* (one taxon)*, Anomalae* (one taxon), *Capitellatae* (five taxa), *Debiles* (one taxon), *Capillares* (one taxon) and *Molliculae* (five taxa) of genus *Carex* (Cyperaceae) were reexamined. The epidermal patterns of perigynium, achene and leaf were investigated by using a scanning eletron microscope (SEM) and a light microscope (LM). Morphological characters such as rhizome, spike, width of leaf, leaf sheath, involucre, involucre sheath, beak of perigynium, shape of perigynium shape, and leaf epidermal patterns were useful for the identification of observed fourteen taxa. The number of spike, arrangement of psitillate or staminate spike and presence of bract were very useful characters to divide the treated 14 taxa into two groups, which the first group belonged sect. *Capitellatae*, the second group belonged to sections *Ischnostachya, Anomalae*, *Debiles, Capillares* and *Molliculae* . A key based on data was presented here.

P1096. Ecological influences on *Carex* speciation.

C. H. Guibert, P. H. Linder;
Institute of Systematic Botany, Zurich, Switzerland.

With circa 2000 species widespread in the Northern hemisphere *Carex* contains half of the Cyperaceae species, consequently *Carex* is critical for understanding the evolution of Cyperaceae. In Europe some 200 species of *Carex* occur and these are found in almost every possible habitat. We investigate the habitats of *Carex* in Switzerland where 96 species occur; most of them are found in sunny, wet habitats in mid-altitude (500m-1000m), but there are species present at all altitudes, in wet or dry habitats, in full sun or deep forest shade. These habitat types can be described by physical factors such as pH, water supply, altitude, soil constitency, light availability. In order to establish how phylogenetically conservative these habitats are, we map them over the phylogeny derived from sequence variation in cpDNA (*trn*T-L-F and *mat*K). The generalist and specialized species are pointed out and the results are summed up on the poster.

P1097. The complex *Carex muricata* in Europe

A. Molina, C. Acedo, F. Llamas;
University of León, Ponferrada, Spain.

Carex, the fifth big plant genus, has a difficult taxonomy because of the closely related and similar species, among hybridization tends to obscure taxa delimitation. So, in Europe *muricata* group in sect. *Phastoglochin,* includes taxa with overlapped characters. Some works agree in the difficulty of taxa delimitation, and highlight its confuse nomenclature. Our research was based on herbarium material and, field collections mainly from the Alps, Cantabrian and Pyrenean Mountains. Some 1000 sheets were revised; but to perform statistical and numerical analysis, we selected 140 specimens covering the whole geographic range and morphological variation and, ten belonging to the similar *C. otrubae* that easily hybridize with them. We analyzed all relevant characters indicated in former studies, together with other that allow us to distinguish the taxa. The variability of 66 characters was estimated, but only 61 were selected to perform PCA and hierarchical clustering that corroborate five taxa at species level, *C. spicata*, *C. muricata*, *C. pairaei*, *C. divulsa*, and *C. guestphalica* and several subspecies, some of them new.

P1098. Reproductive ecology of *Carex typhina*, a rare sedge in Maine, USA

S. L. Cromley, C. S. Campbell, A. C. Dibble, C. R. Schwintzer;
University of Maine, Orono, ME, United States.

Carex typhina is considered rare, threatened, or a species of concern throughout much of its range in eastern North America. In Maine, the only known location of *C. typhina* is a floodplain forest that has undergone a recent, anthropogenic reduction in spring flooding. We studied 753 individuals at this population to identify potential adverse effects of the change in seasonal hydrology. In 2004 we determined reproductive mode, reproductive output, and germination requirements in different habitats. Although this species was capable of self-fertilization and out-crossing, it was primarily self-fertilized. Large numbers of viable seeds were produced (375 ± 343, n = 61). Average achene weight and percent of perigynia with ripe achenes did not differ significantly between habitats. In an *ex situ* study, seeds germinated readily in shallow water and on moist soil. Light was required for germination, but germination was reduced when light was filtered through leaves. The Maine population is currently vigorous, but the new flooding regime might increase competition from woody plants and thus inhibit *C. typhina* germination.

P1099. The sex of Carex secalina (Cyperaceae): from structure spikes to evolution

M. Lembicz, A. Bogdanowicz, A. Rogowski, W. ł ukowski;
Institute of Environmental Biology, Poznan, Poland.

In this study we have indicate the usefulness of the traits of life history in recognition of the species evolution. Carex secalina is one of three species representing the section Secalinae in the subgenus Carex. Over the whole range it is considered a rare species, growing in isolated localities in Europe and Asia. In the life history of a sedge Carex secalina we have found out that a sex of spikes ranges from mono-zone unisexual through two-zone bisexual - androgynous and gynaecandrous - to bisexual three and four - zone. Bisexual spikes have not been reported for this species and section. In all populations, individuals had generative shoots with bisexual spikes; yet most of the shoots with bisexual three-zone were recorded in a population within man-made habitats. We suggest that it is not the two-zone spikes but multi-zone spikes that are starting point for all spikes forms observed today; evolution to other forms would proceed through simple reduction of particulary zones of a complex onflorescence. In the discussion an attempt was made to modify the present model of sex evolution of spikes in genera from the subgenus Carex on the basis of ecological studies.

P1100. Studies in some European *Carex.* Taxonomic problems in typifying Hudson's *Carex* names

C. Acedo[1], A. Molina[1], C. Jarvis[2], F. Llamas[1];
[1]University of Leon, Leon, Spain, [2]Department of Botany, Natural History Museum, London, United Kingdom.

Carex is one of the biggest and taxonomically complex genus in the temperate and cold floras of the Northem hemisphere, increasing from 500 to 2.000 species in a century. Its difficult taxonomy, the morphologically similar species groups, and the common hybrids enlarge the problems. In addition, nomenclature is also confuse. In working with sect. *Phastoglochin* we found that Hudson's names have been applied in different senses. So, the aim of our work is to study this genus in his Flora and typify all new names to establish their correct application. A search for original material was made in the possible herbaria BM-SL (located for *C. divisa*), K, LINN, and, OXF and cited books (i.e. we select a Morison's plate for *C. recurva*). For names we were unable to locate original material we select a neotype. (i.e. *C. patula*). Furthermore, we typified other names (i.e. *C. canecens*) because Hudson's concept is not equivalent to the Linnaeus's one. Finally, taking into account the different concept of *C. inflata* in the second edition, we selected a different type for each case. In other cases we only made taxonomic considerations allowing to interpret Hudson's concept

P1101. Phylogenetic analysis of *Carex pisiformis* complex and allied species (Cyperaceae) based on nuclear DNA sequences

T. Masaki, N. Miyoshi, T. Hoshino;
Gra. Sch. Dep. Biosphere-Geosphere System Science, Fac. Informatics, Okayama Univ. Sci., Okayama Japan., Okayama, Japan.

Species of *Carex pisiformis* complex (sect. Praecoces) are distributed in eastern Asia, and this complex is one of the most taxonomically complicated groups of sedges in Japan. Different taxonomic systems were proposed. In this study, phylogenetic relationships of *C. pisiformis* complex and allied species were estimated from the internal transcribed spacer (ITS) and external transcribed spacer (ETS) regions of nuclear ribosomal DNA. Two major clades were identified by molecular data: (1) subsect. Pisiformes, and (2) subsect. Foliosissimae. *C. pisiformis* complex is belong to subsect. Pisiformes, which is considered closely related to subsect. Foliosissimae (Akiyama 1955). These two clades were supported by karyomorphological data. The species of former clades had 2n=56-80 and small chromosomes, while latter clades had 2n=30-44 and large chromosomes. Species of subsect. Pisiformes differed from subsect. Foliosissimae by long leaf blades and conspicuous discoid appendage at the apex of achenes. Based on the ITS and ETS data, phylogenetic relationships among species of *C. pisiformis* complex are also discussed.

P1102. Preliminary results concerning Ebenaceae phylogeny

A. Geeraerts, K. Geuten, E. Smets;
Laboratory of Plant Systematics, Institute of Botany and Microbiology, Leuven, Belgium.

Ebenaceae s.s. (without the subfamily Lissocarpoideae) is a family of trees and shrubs with characteristic unisexual flowers, a persistent calyx and tasty berries. Some representatives, such as *Diospyros ebenum*, *Diospyros celebica* and *Diospyros melanoxylon*, produce the well-known ebony, used for furniture, musical instruments, etc...(Wallnöfer 2001). Ebenaceae s.s. comprises two genera: the pantropical *Diospyros* and the smaller genus *Euclea*, limited in distribution to Africa, Arabia and Australia. The molecular study at hand is based on a sampling of 55 species using one nuclear (ITS region), the *rps*16 intron and three cpDNA spacers (*trn*L-*trn*F, *trn*H-*psb*A and *atp*B-*rbc*L). Preliminary results confirm the paraphyletic nature of *Diospyros* at generic level as two *Diospyros* sections (*Forsteria* and *Royena*) cluster together with representatives of genus *Euclea* in Parsimony and Bayesian analyses. Also, *Royena* seems to be paraphyletic: it forms a clade with section *Forsteria*.

P1103. Differentiation of seeds in the genus Erica

P. Szkudlarz[1], E. G. H. Oliver[2];
[1]A. Mickiewicz University, PoznaŒ, Poland, [2]National Biodiversity Institute, Claremont, South Africa.

Erica belongs to the most numerous species of the Ericaceae family. It counts almost 800 species. Most of them occur on the relatively small area in southern Africa. Despite a great interest of researchers in this species, many problems still remain unsolved. One of them is a limited knowledge of the structure of seeds.

The presented thesis contains the results of the preliminary stage of research of the seeds of this genus. It contains the description of the morphological and anatomical structure of seeds of 33 species from the Erica genus. The taxa chosen for the research originate from the Republic of South Africa, from the floristic center of genus diversity. The structure of seeds was prepared on the basis of observations using the light microscope and the scanning electron microscope. The analysis conducted on the basis of the isolated features shows clearly separate morphological groups, varying in the sculpture and thickness of the seed skin. The morphological diversity of this group of species does not agree with the currently adopted taxonomic division within the genus.

P1104. Phylogenetics of Balsaminaceae based on atpB-rbcL spacer sequences

S. B. Janssens[1], K. Geuten[1], Y. Yuan[2], Y. Song[2], P. Küpfer[2], E. Smets[1];
[1]Laboratory of Plant Systematics, B-3001 Leuven, Belgium, [2]Institut de Botanique, Neuchatel, Switzerland.

Balsaminaceae are a morphologically diverse family consisting of 1000 representatives that are mainly distributed in the Old World tropics and subtropics. In order to understand the evolution of this family, we obtained chloroplast *atp*B-*rbc*L sequences for 87 Balsaminaceae species and 5 outgroup species. Phylogenetic reconstructions using parsimony and Bayesian approaches provided a well-resolved phylogeny in which the sistergroup relationship between *Impatiens* and *Hydrocera* is confirmed. The overall topology of *Impatiens* is strongly supported and most of the delimited clades can easily be associated with a specific area of distribution. Based on our results, we assume that *Impatiens* has originated in South China from where it initially colonised the adjacent regions and afterwards dispersed into North America, Africa, India, Southeast Asia and the Himalaya. Despite the good resolution, it remains difficult to find morphological synapomorphies for the different clades that we find in the *atp*B-*rbc*L tree.

P1105. Molecular phylogenetics and patterns of seed evolution in *Lysimachia* (Myrsinaceae)

I. Oh[1,2], J. Schönenberger[3], M. Källersjö[1], A. Anderberg[1];
[1]Swedish Museum of Natural History, Stockholm, Sweden, [2]Uppsala University, Uppsala, Sweden, [3]Stockholm University, Stockholm, Sweden.

The genus *Lysimachia* (ca. 150 species) was recently transferred to the family Myrsinaceae based on molecular phylogenetic data. Phylogenetic analyses of ITS, *trnL-F*, and *ndhF* sequences have shown that *Lysimachia*, as understood in traditional classification systems, is likely to be paraphyletic. We have investigated seed morphological characters of 40 *Lysimachia* species from across the genus as well as of representatives of other genera that have been resolved close to or within *Lysimachia* in previous molecular studies. We used a molecular phylogenetic framework based on published (i.e., ITS and *trnL-F*) and unpublished (i.e., *ndhF*) sequence data for a comparison of seed morphology and phylogeny. Our main goal was to find out whether patterns of seed evolution are congruent with the recently found phylogenetic relationships. We also discuss the significance of single morphological character complexes to reveal additional phylogenetic relationships within the genus *Lysimachia* and related taxa.

P1106. Morphological and molecular support for the classification of *Gilia* (Polemoniaceae).

J. Porter;
Rancho Santa Ana Botanic Garden, Claremont, CA, United States.

Gilia Ruiz & Pav. (Polemoniaceae) has been and remains taxonomically controversial. Comparative DNA sequence data conflict with classifications of the family (and with circumscriptions of *Gilia*). Some authors suggest that *Gilia* is polyphyletic. V. E. Grant has suggested that non-molecular data available are sufficient erect a phenetic classification in Polemoniaceae and that based upon this evidence *Gilia* is monophyletic. Here I examine this morphological evidence, using phenetic (UPGMA, Neighbor joining) and parsimony. Molecular phylogenetic analyses of nrITS and cp*trnL-F* region DNA sequences are presented, with broader sampling of *Gilia*. Groups based on phenetic methods differ significantly from Grant's and the Porter and Johnson classifications, but the two later classifications fit the non-molecular data equally well. The Porter and Johnson classification is also supported by molecular data. Phenetic and phylogenetic analyses provide evidence that *Gilia* s.l. is not monophyletic.

P1107. Diversification of Erica L. (Ericaceae) in South Africa's Cape Province

T. M. Schuster, K. A. Kron, C. M. Bush;
Wake Forest University, USA, Winston Salem, NC, United States.

Extensive analyses of morphological characters of *Erica* L., the largest genus in Ericaceae and in the flora of Southern Africa, have been undertaken to date. The center of diversity of *Erica* L. lies in the southern Cape Province; only 76 of the 860 recognized species are found in the remainder of Africa, Europe, and the Middle East. Previous molecular studies indicate that the South African species are derived. In this study molecular analyses of data from the nuclear genome (*leafy* and *rpb*2) are employed to investigate monophyly and resolution of intrageneric relationships of this taxon. Parsimony analyses of sequence data from 69 species of *Erica* from the southern Cape differing in pollination syndrome, flower morphology, geographical distribution, and soil type preferences are carried out. Indehiscent and dehiscent fruit type is taken into account as this has been a factor for inclusion of the previous "minor" genera into *Erica* L. Species sampling for this study was done to represent the most recent classification including 41 sections. Results of our analyses indicate that indehiscence as well as bird pollination has likely arisen multiple times within the group.

P1108. Palynological variation of Marcgraviaceae

L. van Evelghem[1], F. Lens[1], **S. Dressler**[2], S. Vinckier[1], S. Janssens[1], S. Dessein[1], E. Smets[1];
[1]Laboratory of Plant Systematics, K. U., Leuven, Belgium, [2]Forschungsinstitut Senckenberg, Frankfurt/M., Germany.

A survey of the palynological variation of Marcgraviaceae is given based on LM, SEM and TEM observations from all seven currently accepted genera. Features of taxonomic importance within the family are pollen shape, sexine sculpturing, and ultrastructure of the pollen wall. The genus *Marcgravia* can be distinguished from all other genera by the presence of small grains (15-25 µm) with a high percentage of reticulate sexine patterns and a thin nexine, supporting the division of the family into two subfamilies. Furthermore, *Sarcopera* could be defined by the presence of an oblate spheroidal to even suboblate shape, while *Ruyschia* and *Souroubea* typically show prolate spheroidal to subprolate pollen grains. Another important character is the presence of a thick foot layer, which is characteristic of the genera *Norantea*, *Sarcopera* and *Schwartzia*. From a palynological point of view, Marcgraviaceae have many features in common with the related Tetrameristaceae/Pellicieraceae, but they clearly differ from Balsaminaceae, which are also close to Marcgraviaceae based on DNA sequence data.

P1109. Some aspects of reproductive biology of *Rhododendron schlippenbachii*

A. A. Babro;
Komarov Botanical Institute, St-Petersburg, Russian Federation.

Rhododendron schlippenbachii is a valuable ornamental shrub, which produces a lot of viable seeds under its natural conditions. Under introduction conditions in Saint-Petersburg its flowering and real seed productivity are poor. Embryology and reproductive biology of *R. schlippenbachii* are studied weakly. Data available on other species of this genus allow to suppose that one of the causes of low seed productivity of the plants in St-Petersburg is winter and spring frosts. However the disturbances in microspore development that occur right after the meiosis completion (long before the period of steady frosts) indicate the effect of other factors, in particular, the changes of air and soil humidity. Relatively high quality of mature pollen (fertility is up to 68%, viability - 31-55%) while there is a high amount of abnormal microspores allow to suppose that either some microspores degenerate during microsporogenesis or flower buds with high amount of abnormalities stop their development.

Supported by grant “Leading Scientific Schools of Russia” (2148.2003.4).

P1110. Special traits in the inflorescences of Marcgraviaceae - taxonomy and pollination patterns in the neotropical family

S. Dressler[1], M. Tschapka[2];
[1]Forschungsinstitut Senckenberg, Frankfurt/M., Germany, [2]Biologie III, Universität, Ulm, Germany.

A characteristic synapomorphy of the neotropical Marcgraviaceae are extrafloral nectary cups of various shapes and arrangements within the inflorescence. The evolution of these unique structures implies close interactions with the respective pollinators. Unfortunately knowledge on pollination ecology is rather scarce: very few taxa are intensively studied in their natural habitats. However, inflorescence geometry, colour patterns, and time of anthesis give hints towards the predominant pollinators that may include insects, birds, bats and arboreal mammals. In contrast, there are observations of autogamy, yet cleistogamy in *Marcgravia*. Therefore, generalisations are not expedient and thorough field studies are necessary to reveal the pollination systems which may differ within genera and are instrumental in understanding the evolution of this group.

Based on monographic studies the delimitation of the seven genera and selected characters are discussed in light of the different pollination syndromes exemplified by this family.

P1111. Peculiarities of mucilage-producing cells distribution in some Ericaceae

O. V. Yakovleva, **A. Y. Yakovlev**;
Komarov Botanical Institute RAS, St.-Petersburg, Russian Federation.

Mucilage producing cells (MPC) are wide spread in plants. A general tendency can be traced in MPC distribution within tissues and organs of higher plants. In primitive Dycots MPC occur in leaf epidermis and in developed ones in seed epidermis. The difference in MPC distribution can be trased within one family. In Ericaceae, in Rhododendroideae and Ericoideae MPC were found in leaf epidermis, in Vaccinioideae in exotesta. The species, investigated with TEM Loiseleuria, Erica, Calluna, Arbutus, Vaccinium, Oxycoccus differed in mucilage structure. In investigated Ericaceae a relation is found between MPC location and presence of protein containing plastids (PCP). Such relation we also found in other families. In Ericaceae species with MPC in leaf epidermis PCP were found in parenchyma cells of xylem group in petiole. In species with MPC in exotesta PCP were found in parenchyma cells of phloem group in fruit stalk. The investigated species did not in protein inclusion ultrastructure in plastids. Investigation granted by RSCI (project N 04-04-49417).

P1112. Phylogenetic relationships among Sapotaceae (Ericales) in Australia and Oceania: molecular evidence for generic polyphyly and repeated dispersal

I. V. Bartish[1], U. Swenson[1], J. Munzinger[2];
[1]Swedish Museum of Natural History, Stockholm, Sweden, [2]Centre IRD de Noumea, Noumea, New Caledonia.

The phylogeny of a representative group of genera and species from the Sapotaceae tribe Chrysophylleae, mainly from Australia and New Caledonia, was studied by jackknife analyses of sequences of nuclear ribosomal DNA. The phylogeny conflicts with current opinions on generic delimitation in Sapotaceae. Pouteria and Niemeyera, as presently circumscribed, are both shown to be nonmonophyletic. Earlier classifications in which more genera are recognized may better reflect relationships among Australian and New Caledonian taxa. Hence, there is need for a revision of generic boundaries in Chrysophylleae. Section Oligotheca have been recognized as the separate genus Planchonella, a monophyletic group that needs to be resurrected. Four clades with moderate to strong support in our jackknife analysis have a group of Australian species that is sister/basal to a relatively large monophyletic group of New Caledonian endemics, suggesting multiple dispersal events between this small and isolated tropical island and Australia. We also found an interesting case of a relatively recent and rapid radiation of several lineages of Sapotaceae within New Caledonia.

P1113. Evolutionary aspects of morphological characters of some European species of *Erica* L. (Ericaceae)

J. Fagúndez, J. Izco;
University of Santiago de Compostela, Santiago de Compostela, Spain.

A set of selected morphological characters with evolutionary information is used for the stablishment of a phylogenetic approach to the species of five sections of European species of genus *Erica* that are treated as a monophyletic group including the following species: *E. ciliaris*, *E. cinerea*, *E. maderensis*, *E. terminalis* and the *E. tetralix* group (*E. andevalensis*, *E. mackaiana* and *E. tetralix*). Character selection and stablishment of primitive state were determined using the following criteria: 1. Character evolution in the family extracted from different studies. 2. Evolutionary suggestions mainly on bract and bracteoles position given by E.G.H. Oliver in African species of *Erica*. 3. The principles of vestigial functional organs as the functionality of bracts or sepals in primitive species. Cladogram resulting from this study shows *E. ciliaris* as a primitive species of the group and *E. cinerea* as the most evolutionated species. From these results, evolutionary considerations are made in terms of ecological requirements and geographic distribution. Infrageneric systematics are discussed.

P1114. Pollen morphology of *Enkianthus* Lour. (Ericaceae) and its taxonomic significance

A. G. Sarwar[1,2], H. Takahashi[1];
[1]Laboratory of Systematic Botany, The Hokkaido University Museum, Hokkaido University, Sapporo, Japan, [2]Department of Crop Botany, Bangladesh Agricultural University, Mymensingh, Bangladesh.

Pollen morphology of 13 taxa and 10 species from about 12 species of *Enkianthus* were examined by light and scanning electron microscopy. Anderberg’s infrageneric classification of *Enkianthus* (1994) was reexamined. The pollen grains are monad, oblate spheriodal to prolate or circular in shape, and 3- to 5-colpor(oid)ate. Exine sculpture varies from granulate to coarsely rugulate-psilate. Infraspecific geographical difference in palynological characters is found in *E. deflexus.* The sections are clearly differentiated into two distinct groups, *Enkiantella* - *Meisteria* and *Andromedina* - *Enkianthus*; however, it seems to be difficult to differentiate within these sections on the basis of palynological characters only. The members of *Enkiantella* - *Meisteria* group with 3-colporate pollen grains are the primitive species in this genus. The major evolutionary trend in exine sculpture from finely verrucate-rugulate to coarsely rugulate-psilate, is suggested within *Enkianthus*. Anderberg’s infrageneric classification comparatively best suits the present result with some exceptions.

P1115. The analysis of transition between two *Primula vulgaris* subspecies

Y. V. Kosenko[1], P. A. Volkova[1], A. B. Shipunov[2];
[1]Moscow State University, Moscow, Russian Federation, [2]Institute of Information Technologies, Moscow, Russian Federation.

The common primrose (*Primula vulgaris*, Primulaceae) consists of several subspecies, two of them (subsp. *vulgaris* and subsp. *sibthorpii*) form a transitional zone in the Russian Black Sea coast, near Tuapse and Sochi. These two subspecies are growing together and even sometimes produce mixed populations, but generally subsp. *sibthorpii* (with violet or pink flowers) grows in lower altitudes than subsp. *vulgaris* (with yellow or white flowers). To test the hypotheses about geographical and spatial distribution, the morphometric material (more than 2310 plants were measured) is collected. We found that there is significant trend to increase the proportion of violet and pink-flowered plants in the populations from north-east to south-west. It is possible to divide populations on "north" and "south" forms. The length of transitional zone is about 30 km along coastal line. However, there is no significant morphological differences between colour forms. There is also the weak correlation between flower color and altitude.

P1116. Marcgraviaceae: resolution of interspecific and intergeneric differences in unresolved molecular polytomies using flavonoid distributions

D. E. Giannasi[1], **N. M. Ward**[2];
[1]University of Georgia, Athens, GA, United States, [2]California Native Plant Society, Sacramento, CA, United States.

Marcgraviaceae is a distinctive neotropical family in the Ericales with approximately 130 species distributed from the Caribbean and southern Mexico to northern Bolivia. Previous *ndhF, trnL-F,* and *rbcL* sequence comparisons resolved two major lineages within Marcgraviaceae corresponding to subfamilies Marcgravioideae and Noranteoideae. The monogeneric Marcgravioideae is united by both morphological synapomorphies and molecular data. In contrast, subfamily Noranteoideae appears to be delimited by plesiomorphic morphological characters but is supported as monophyletic by molecular data. Despite considerable morphological differences among taxa of Noranteoideae, cpDNA sequence data do not resolve some currently recognized genera as monophyletic groups. This study examines flavonoid distributions in an attempt to resolve molecular polytomies in the family. Preliminary data reveal flavonoid patterns that provide some resolution of intergeneric and interspecific relationships.

P1117. Establishing *Eschscholzia californica* as a model plant for basal eudicots

A. Scholz, B. Melzer, S. Gleissberg;
Institut für Spezielle Botanik, Mainz, Germany.

Studies in model plants show considerable variation of developmental mechanisms that are attributable to evolutionary changes. In our attempts to elucidate development and evolutionary patterns of dissected leaves, we are establishing *Eschscholzia californica* as a model organism for basal eudicots, in order to help bridging the gap between well investigated monocots such as *Zea* and *Oryza*, and core eudicot model plants. Our previous *in situ* expression studies in *Eschscholzia* indicated that leaf dissection may be under redundant control of *FLORICAULA* and *KNOX* genes in basal eudicots, and that redundancy may have been reduced in specific core eudicot lineages. To further explore *Eschscholzia* leaf development, we attempt to modulate gene expression through *Agrobacterium*-mediated transformation and through Virus-induced gene silencing (VIGS). Furthermore, we are investigating the role of hormones in leaf development of *Eschscholzia* since auxins and gibberellins are known to interact with both *FLORICAULA* and *KNOX* genes in core eudicots.

P1118. Phylogenetic Study of Menispermaceae

F. M. B. Jacques;
Muséum National d'Histoire Naturelle, Paris, France.

The family Menispermaceae, a major group of basal Eudicot, is mostly represented by tropical climbers belonging to about 500 species. Its phylogeny is very badly understood since there is no recent revision of the group. We therfore provide here the first results of o morphological study tending to fill this lack. Characters of leaves, inflorescences, flowers, fruits and pollen were used. A special attention was given to the endocarp, that are traditionally used as a discriminating character of the diffenrent tribes. We described the endocarp structure trough morphometrics and questioned homologies such as the condyle (a cavity of endocarp). We also begun a large-scale study of Menispermaceae wood anatomy on specimens from all around the world. The large fossil record of this family, quite rich in the Early Tertiary of northern hemisphere temperate regions, brings palaeobotanical information in this study. A parsimony analysis allows us to process the whole dtaset. It appears that some reassessments have to be made; The new phylogeny permits study of character evolution and biogeographical considerations.

P1119. Patterns and Rates of Nucleotide Substitution in Angiosperms

M. E. Sparks, J. A. Udall, V. Brendel, J. F. Wendel;
Iowa State University, Ames, IA, United States.

We have reliably aligned reciprocally closest homolog pairs for two eudicots (*Gossypium, Arabidopsis*) and two members of the Poaceae (*Oryza*, *Zea*). Using reciprocal outgroups to polarize molecular evolutionary events, we demonstrate that patterns of nucleotide substitution differ between eudicots and the Poaceae at fourfold degenerate codon sites (FDCS's). While base composition of FDCS's in *Gossypium* and *Arabidopsis* closely parallels that of introns from the same genes, *Zea* and *Oryza* exhibit FDCS composition distinct from that of introns, suggesting operation of a cryptic mode of selection. Our analysis provides the first robust estimates of neutral rates of transition and transversion substitutions in angiosperms, as well as variance in rates among a large set of genes. These data permit us to address the divergence of the Poaceae from eudicots as well as other divergence events.

P1120. Monophyletic origin and Adaptive Radiation in Hawaiian Chamaesyce (Euphorbiaceae) based on ITS and 5S-NTS sequence variation

C. W. Morden[1], T. J. Motley[2];
[1]University of Hawaii, Honolulu, HI, United States, [2]New York Botanical Garden, New York, NY, United States.

Chamaesyce is a cosmopolitan genus of ca. 250 species. The Hawaiian complex constitutes 16 endemic species that have radiated from a herbaceous weedy colonist into a spectacular assemblage of small shrubs to trees. Habitats include coastal strand, dry shrubland and forests, and rainforests up to 2000 m elevation. All species manifest the C_4 photosynthetic pathway, and are the only such plants to occur in tree form or in wet, understory habitats. Phylogenetic analysis indicates species from Kauai (the oldest island at 5.5 my) are basal and that taxa have followed the stepping stone model of dispersal across the younger islands. Clades include species from all islands suggesting back dispersal or later speciation events. The eight varieties of *C. celastroides*, the most variable species, is paraphyletic and in need of taxonomic revision. Intrapopulation variation of some species has been also been examined and with variation that exceeds that found in any other Hawaiian radiation.

P1121. Pollen morphological trends in Euphorbiaceae

C. Khunwasi[1], K. Pyramarn[1], K. Kasetsinsombat[2];
[1]Chulalongkorn University, Bangkok, Thailand, [2]Mahidol University, Bangkok, Thailand.

Pollen materials obtained from fresh and herbarium specimens of 68 genera and 216 euphorbiaceaous species found in Thailand were acetolysed. Measurement and morphological observations were made under a Nikon AFX 35, using a x10 eyepieces and x100 immersion objective. All measurement was based on at least 10 pollen grains. External ultrastructures of pollen grains were observed by scanning electron microscope. The SEM micrographs were taken using a JEOL JSM 5410 LV. The permanent slides of the pollens were kept in Kasin Suvatabhandhu Herbarium, Department of Botany, Chulalongkorn University. A conspicuous morphological diversity of euphorbiaceous pollen was evident from 61 pollen types constructed in the present study. They were mainly based on the various types of apertural system and ornamentation. Based on these diversed pollen types, nineteen morphological trends were purposed.

P1122. Phylogenetic Relationships within the Subtribe Euphorbiinae (Euphorbiaceae) Based on Nuclear Ribosomal ITS and Chloroplast *ndhF* Sequence Data

K. Park[1], R. K. Jansen[2];
[1]Kyung-Nam University, Masan, Republic of Korea, [2]University of Texas at Austin, Austin, TX, United States.

Phylogenetic relationships within Euphorbiinae were inferred from analyses of the nuclear ribosomal ITS and the chloroplast gene *ndhF*. Relationships inferred from two data sets are mostly congruent and support for the monophyly of subgs. *Esula*, *Chamaesyce*, *Euphorbia* and *Lacanthis, while* subg. *Agaloma* and subg. *Eremophyton* are polyphyletic. African succulent Euphorbiinae are mostly divided into two independent groups: spiny group I, forming a strongly supported clade with three subclades (subg.*Euphorbia*, subg. *Lacanthis* and *Monadenium*+*Synadenium*); and non-spiny group II, containing sects. *Meleuphorbia*, *Medusae*, *Treisia* and *Pseudacalypha.* In the ITS tree, the non-spiny clade is sister to the rest of the Euphorbiinae, whereas the basal position is displaced by subg. *Esula* in *ndhF* trees. The South American *Agaloma* sect. *Stachydium* was not nested within the major *Agaloma* clade, but it formed a sister group to *Pedilanthus*. In both analyses, subg. *Poinsettia* is nested within the core *Agaloma* clade, while subg. *Chamaesyce* forms a sister group to core *Agaloma* group. Eurasian subg. *Esula* forms two subclades, corresponding to sect. *Esula* and sect. *Tithymalus.*

P1123. Taxonomic revision of *Croton* sect. *Lamprocroton* (Müll. Arg.) Pax. (Euphorbiaceae)

L. R. Lima[1], J. R. Pirani[2];
[1]IBt-SMA/SP & IB-USP, São Paulo, Brazil, [2]IB-USP, São Paulo, Brazil.

Croton (Euphorbiaceae) is a pantropical genus with more than 800 species in 40 sections. *Croton* sect. *Lamprocroton* is a section whose the boundaries between species are controversial. The main goal of this work is to achieve a revaluation of the circumscription of the group, through a phylogenetic analysis and taxonomic study of its species, presenting identification key, descriptions, illustrations, comments and geographical distribution. Field work and analysis of collections from the main herbaria housing neotropical specimens have been carried out. Morphologically, the members of *Lamprocroton* are characterized as monoecious or dioecious shrubs, with a lepidote indumentum, entire leaves with no glands, terminal inflorescences that lack bisexual cymules, staminate flowers with 10-15 stamens and pistillate flowers without petals or with reduced petals. 25 species, 3 of them new, are here recognized in the group. Most of the section is South-American, with 2 species in Mexico. The phylogenetic analysis, based on morphological and molecular data, support the monophyly of the section, and allow some hypothesis on evolution of characters in the group.

P1124. Evolution of the *Andrachne* clade (Phyllanthaceae or Euphorbiaceae s.l.)

M. Vorontsova, P. Hoffmann, M. Chase;
Royal Botanic Gardens, Kew, Surrey, United Kingdom.

The *Andrachne* clade is a novel association comprising eight genera previously classified in five tribes and subtribes. *Actephila*, *Andrachne*, *Leptopus*, *Meineckia*, *Poranthera*, *Oreoporanthera*, *Zimmermannia* and *Zimmermanniopsis* contain 129 species of diverse life forms adapted to habitats ranging from tropical rainforest to desert margins and ericoid alpine meadows. Distributions of three genera are geographically disjunct between the Old and the New World. The preliminary results of our phylogenetic study using ITS and *matK* sequence data of 19 taxa are largely congruent. *Zimmermannia* and *Zimmermanniopsis* are embedded in the *Meineckia* clade. *Andrachne* and *Leptopus* are separate lineages, but *Andrache cuneifolia* and *Andrachne ovalis* are distinct from both. Dating the nodes of the phylogenetic tree and performing a biogeographical analysis will contribute to a greater understanding of the evolution of these taxa in space and time, particularly their adaptation to specialised ecological niches.

P1125. Multiple colonization events for the Madagascan species of the genus *Euphorbia* L. (Euphorbiaceae)

T. Haevermans;
Muséum national d'Histoire naturelle, Paris, France.

The subcosmopolitan genus *Euphorbia* L. is one of the largest plant genera on earth. Despite numerous studies, its taxonomy is still obscure, it certainly contains at least 2000 species but a lot of novelties are waiting to be described. The Madagascan flora alone comprises nearly 8% of the world's *Euphorbia* species, with ca. 170 known species and varieties, almost all of them restricted to the island. This work aims to define the main Malagasy species groups, placed in a global context to clarify the taxonomy of the group while defining affinities of the Madagascan flora. This is a first step towards a better understanding of the infrageneric classification. This poster is based on a paper in prep (Thomas Haevermans, Victor Steinmann, Vincent Savolainen, Petra Hoffmann, Emile Randrianjohany and Jean-Noël Labat). In this paper, both maximum parsimony and Bayesian analyses of ITS regions are compared, and the evolution of some morphological characters is discussed.

P1126. Molecular Phylogeny of *Euphorbia* subgenus *Esula* (Euphorbiaceae) based on nrDNA ITS region and plastid DNA *mat*K gene sequences

J. Tho[1], D. Kim[1], J. Lee[2], B. Oh[3], **J. Kim**[1];
[1]Dept. Biology, Daejeon University, Daejeon, Republic of Korea, [2]Korea Research Institute of Bioscience and Biotechnology, Daejeon, Republic of Korea, [3]School of Life Science, Chungbuk Nat'l University, Cheongju, Republic of Korea.

NrDNA ITS region and plastid DNA *mat*K gene were sequenced to assess the monophyly and phylogenetic relationships of twenty eight taxa of *Euphorbia* subgenus *Esula* species. Three species of *Euphorbia* subgenus *Chamaesyce* were applied as the outgroups. NrDNA ITS region(ca. 0.6-0.7kb) were sequenced with two primers(ITS5 and ITS4). And plastid *mat*K gene(ca. 1.7-1.9kb) were fully sequenced with previously reported seven primers<from M. Lavin>, and another newly designed five internal primers to adjust the clonal sequences. Phylogenetic analyses were carried out with 220 phylogenetic infomative sites. Also, MP tree(CI=0.812, RI=0.883) was produced and 1,000 replicate Bootstrap analysis were performed to confirm the tree strength on each node. Based on the nrDNA ITS region and plastid *mat*K gene sequences results, Sect. *Helioscopiae* was the sistergroup of subsect. *Galarrhoei* and subsect. *Verticillatae*. And the taxa of subsect. *Esula* represent a monophyletic group. Even though the heterogeneous clades combination was found among sect. *Tithymalus,* This result demonstrate the monophyly of subgenus *Esula* and strongly support previous RAPDs data.

P1127. Systematics and Phylogeny of North-Asian spurges (Euphorbia L.)

K. S. Baikov;
Central Siberian Botanical Garden, Siberian Branch of Russian Academy of Sciences, Novosibirsk, Russian Federation.

Investigation of spurges (Euphorbia L.) from Northern Asia using evolutionary morphology, ecological geography and phylogenetic analysis is completed. The comparative analysis of the various approaches to construction of general system of genus Euphorbia is carried out. Conceptions of subgenus, section and subsection in this genus are elaborated, sets of the most important diagnostic features are described for each taxonomic level. A new variant of division of subgenus Esula on sections and subsections is proposed. Method SYNAP was improved: new procedure of polymorphic characters is developed, reversion scale was increased. Modeling phylogenetic relations between 29 species of genus Euphorbia from section Esula, 14 species from section Tulocarpa and six species of section Holophyllum were executed by method SYNAP using different sets of elementary evolutionary vectors. Than phylogenetic relationship between sections and subgenera was performed. The received phylogenetic scheme was compared with ecological and geographical features of species. It was useful for description of series as a low-level species groups. Works is supported by RFBR.

P1128. Histological studies on cyathia of some *Euphorbia* species

N. Papp, L. G. Szabó;
University of Pécs, Pécs, Hungary.

Euphorbia species have a special inflorescence namely cyathia: it contains a central female flower surrounded by 5 male flowers, 4-5 nectaries and bractea. We studied the histology of the cyathia, with special emphasis on the nectaries in some *Euphorbia* species.

Nectaries have cuticle, epiderm, glandular tissue and parenchyma in all species. The xylem vessels have spiral secondary cell wall thickenings. The nectary cuticle of *E. amygdaloides* and *E. palustris* is thin, that of *E. cyparissias*, *E. esula*, *E. myrisnites* and *E. virgata* living at xeroterm area is thicker. Nectary of *E. palustris* has the highest epidermal cells and the largest number of cell rows of glandular tissue (6-7) which varied from 1 to 4 in the other plants. Cells of glandular tissue are isodiametric in all species except of *E. cyparissias*. Biggest cells of glandular tissue were detected in the nectary of *E. virgata*. The histological structure of the nectary was specific for the studied plant species.

P1129. Taxonomic studies of the two Nigerian varieties of Ricinus communis

K. B. A. Akeem[1], T. O. B. Omobola[2];
[1]University of Lagos, Lagos, Nigeria, [2]University of Agriculture, Abeokuta, Nigeria.

Ricinus L.(Euphorbiaceae)is a monotypic genus represented by R. communis in Nigeria. It comprises two distinct varieties which may grow either in gregarious or solitary formations. The distinguishing features of the species are colour of vein, petiole and stem which may be green or brown, number of fruit prickles as well as shape of midrib and types of stomata, pollen grains and crystals which may occur either as raphides or localized crystals of calcium oxalate in the epidermal cell lumen. Epidermal wall pattern is usually curved or undulate while cell shape varies from polygonal to irregular. Stomata number per millimetre square ranges from 5-8 on both surfaces and stomata types are anisocytic, anomocytic and paracytic. In the two varieties, polymerase chain reaction (PCR) amplications with random amplified polymorphic DNA (RAPD) primers indicated similarities and differences at 0.59 and 0.41 coefficient levels respectively. Ricinus communis has both commercial and medicinal uses.

P1130. Distribution patterns of *Croton* (Euphorbiaceae) in Brazil

M. B. R. Caruzo, **I. Cordeiro**;
Instituto de Botânica, São Paulo, Brazil.

Croton L. is the second largest genus of Euphorbiaceae, with over 1200 species, mostly found in tropical regions. Its main centres of diversity are in the Neotropics, with c. 300 species recorded for Brazil. To identify distribution patterns of the genus in Brazil, we analysed c. 2130 herbaria collections from the total range of 33 species that occur in the State of São Paulo. Natural populations of many species were also visited in order to better understand their lifeforms, habitats and morphological variability. The few endemic species found are trees from the southeastern Atlantic rainforest, one of them restrict to a small area in São Paulo. The other species were classified as mesothermic or megathermic. The latter show preference for tropical areas: among them are those widespread in the neotropics, those found all over South America, and those from central or northeastern Brazil, with their southern limits in São Paulo. The group of mesothermic species includes exclusively grassland herbs, with almost all populations below the Tropic of Capricorn, and northern limit in São Paulo State. The bearing of these data on neotropical biogeography is stressed.

P1131. A taxonomic revision on the genus of Euphorbia (Euphorbiaceae) in Iran

Y. Nasseh, M. R. Joharchi;
Rasearch Center for Plant Science, Mashad, Islamic Republic of Iran.

Euphorbiaceae is the fifth great family of flowering plants and *Euphorbia* is one of the largest genus of flowering plants that based on Flora Iranica consists of over 100 species in Iranica region and more than 60 species in different parts of Iran. In this work plants belong to this genus were studied and in this order to all of the herbarium materials preserved in a few herbaria collected from different parts of Iran and specimens in the feild were studied and determinated and the following results are presented:
- There are 65 species of *Euphorbia* in different parts of Iran.
- The species *E. rosularis* A.THEOD. and *E. maculata* L. are recorded for the first time from Iranica area and the flora of Iran. These species in the flora of USSR. have been formerly known as an endemic of Turkmenistan and caucasus respectively.
- The species *E. franchetii* B.FEDTSCH., *E. grossheimii* PROKH., *E. consanguinea* SCHRENK and *E. kopetdaghi* PROKH. are reported for the first time for the Flora of Iran
- *E. cheirolepioides* RECH.f. is synonym with *E. grossheimii.*
-The species *E. aellenii* RECH.f. according to this study is synonym with *E. kopetdaghi* PROKH..

P1132. Character evolution of Alnus (Betulaceae) and fossil leaves and cones from the Tertiary of Northern Thailand

P. J. Grote;
Suranaree University of Technology, Nakhon Ratchasima, Thailand.

Alnus Mill. (Betulaceae) today comprises approximately 35 species and is widespread in the temperate Northern Hemisphere, extending to Southeastern Asia and to the Andes. Tertiary macrofossils are widely distributed in North America, Europe, and Asia, usually as isolated leaves and infructescences. Recent leaves were surveyed to search for taxonomically important characters to allow placement of fossil leaves within subgenera or smaller subtaxa of *Alnus*. Semicraspedodromy was observed in some species of the subgenera *Alnus* and *Clethropsis*, but not in *Alnobetula*. Character evolution analysis using parsimony suggested that craspedodromy was plesiomorphic in the genus with independent evolution of semicraspedodromy in three subclades. Veins reaching the sinus before branching to the teeth is a derived character having evolved one or more times. Fossil leaves and seed cones were found in lacustrine deposits in early Miocene or late Oligocene basins in Northern Thailand. The venation pattern and teeth of the leaves are most similar to those of Recent *Alnus fernandi-coburgii* and *A. cremastogyne* (both subgenus *Alnus*) from China.

P1133. Cuticle micromorphology and anatomical structures of leaves of *Fagus* L.(Fagaceae) and its taxonomic implication

S. H. Cho[1], K. J. Kim[2], J. H. Pak[1];
[1]Kyungpook National University, Daegu, Republic of Korea, [2]Graduate School of Biotechnology, Seoul, Republic of Korea.

The genus *Fagus* is distributed over the Eastern Asia, U.S.A. and Ukraine in the northern hemisphere. Many kinds of taxonomic system have been controversial. Cuticle micromorphology and anatomical structure of all 8 species of *Fagus* and outgroup were examined. 23 cuticle morphology have been described. The subsidiary cell shape, size of stomata, and so on, are considered important characters for the infrageneric classification. In the anatomical structure studies, 13 characters of anatomical features have been described. Shape of epidermal cells, papillae and shape of vascular bundle are considered important. A parsimony analysis of 26 characters resulted in a single most parsimonious tree with consistency indices of 0.73 and retention indices of 0.73 and tree lengths of 48 steps. The topology obtained from the analysis showed two major clade. The first clade was supported bootstrap value 80%, and the second clade bootstrap value 87%. Based on the cuticle morphology, the taxanomic system of Shen(1992) was generally supported except *F. longipetiolata*. .

P1134. Alders (*Alnus* Mill., Betulaceae) in the European Russia

V. V. Ilinsky[1], A. B. Shipunov[2];
[1]Moscow South-west high school 1543, Moscow, Russian Federation,
[2]Institute of Information Technologies, Moscow, Russian Federation.

Alders (*Alnus* Mill.) are the common trees in Europe and Asia, and there are some taxonomically interesting forms on the border of the area. The examples of those forms are *A. kolaensis* Orlova (from Kola Peninsula and nearby North Karelia) and *A. barbata* C.A. Mey. (from Caucasus). Some researchers consider these forms as separate species, but others -- as subspecies of *A. incana* or *A. glutinosa* (respectively), or even as hybrids between these two species. We have checked mentioned hypotheses using multivariate methods based on classic morphometrics data and two variants of geometric morphometrics of alder leaf. We found that *A. "kolaensis"* is most probably the varieties or even the ecological form of *A. incana*. On the contrary, *A. barbata* must be considered as separate species. Our data show that the results of geometric morphometrics and classic morphometrics could be significantly different. The most productive way of placing the landmarks on the leaf is (in our case) to mark the end-points of the secondary veins.

P1135. Cuticle micromorphology of leaves of *Quercus* L. (Fagaceae) and its taxonomic implication

J. H. Pak[1], S. H. Cho[1], K. J. Kim[2];
[1]Kyungpook National University, Daegu, Republic of Korea, [2]Graduate School of Biotechnology, Seoul, Republic of Korea.

.

The genus *Quercus* is widespread in the Northern hemisphere in habitats ranging from temperate and tropical forests to dry thorn scrub and semi-desert. Camus recognized 2 subgenera and 6 sections. However, some taxonomic system are still different from each other. Cuticle micromorphology of 22 species of *Quercus* and outgroup were examined by the SEM. 22 species selected each two or more species in all section of genus *Quercus*. Outgroup selected the genus *Trigonobalanus* and *Alnus*(Betulaceae). 10 characters of the inner surface and 8 characters of the outer surface of the cuticle have been described. The present of papillae, arrangement of subsidiary cell, shape of anticlinal cell wall are considered important character for infrageneric classification. A parsimony analysis of 18 characters resulted in 72 most parsimonious tree with tree length of 66 steps. The topology obtained from the analysis showed 2 major clade. Based on the cuticle morphology, the two subgenus delimitation of Camus was supported. However, sect. *Erythrobalanus* and sect. *Cerris* formed one group, and sect. *Lepidobalans* formed polytomy.

P1137. Inflorescence and floral development in *Streptocarpus* and *Saintpaulia* (Gesneriaceae)

E. M. Haston, L. P. Ronse De Craene;
The Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

Floral development and inflorescence structure within *Streptocarpus* and *Saintpaulia* were investigated using Scanning Electron Microscopy (SEM). We discuss the structure of the pair-flowered cyme and the floral ontogeny found in the Gesneriaceae in a phylogenetic context with particular reference to an East African clade of *Streptocarpus* and *Saintpaulia*. Current phylogenetic hypotheses divide the caulescent East African *Streptocarpus* species into two distinct clades, one of which (*Str. caulescens*, *Str. glandulosissimus*, *Str. holstii* and *Str. buchananii*) is sister to a monophyletic *Saintpaulia* clade. In both clades of caulescent East African *Streptocarpus*, helical sepal initiation was observed, as opposed to the apparently more general adaxial to abaxial unidirectional pattern in *Streptocarpus*. In the *Str. caulescens* clade bracteoles were absent or present on only one lateral axis, with a monochasial branching pattern in which the lateral cyme unit develops on the ebracteolate axis. The impact of bracteole loss on the developmental stages of the inflorescence was evaluated.

P1138. Molecular identification of *Aeschynanthus* (Gesneriaceae) leading to a discovery of an undescribed species

J. Denduangboripant[1], P. Jaidee[2], W. Chulalaksananukul[2], S. Panha[1];
[1]Department of Biology, Faculty of Science, Chulalongkorn University, Bangkok, Thailand, [2]Department of Botany, Faculty of Science, Chulalongkorn University, Bangkok, Thailand.

Aeschynanthus is an epiphyte genus widespreading in SE Asia. Species identification of the genus relies heavily on their flower and seed morphology. This usually causes a great difficulty when the reproductive parts are unavailable. We therefore performed molecular identification using our previously-prepared *Aeschynanthus* phylogeny based on internal transcribed spacer (ITS) sequences. Several cultivated plants were bought and their ITS sequences were obtained. One plant was suggested to be *Columnea* sp., misunderstood by a plant seller to be *Aeschynanthus*. Others were proposed to be *A. radicans*. We also collected some wild *Aeschynanthus* seedlings which then were genetically suggested to be *A. hildebrandii*. Interestingly, one plant sample with very unusual pinkish flowers showed unique ITS sequence characteristics and may putatively be an undescribed species. This molecular identification study of cultivated and wild *Aeschynanthus* therefore showed a great advantage of using molecular techniques to identify any problematic taxon, especially when it is difficult to investigate taxonomically significant organs.

P1139. Reproductive biology of African violet (*Saintpaulia*): evolutionary and conservation consequences

J. K. Kolehmainen[1], P. Mutikainen[2];
[1]University of Helsinki, Helsinki, Finland, [2]University of Oulu, Oulu, Finland.

To find out the reproductive potential and evolutionary mechanisms affecting species integrity and population viability of the endangered genus *Saintpaulia*, flower and seed biology, flowering phenology and pollination of three *Saintpaulia* species were studied in the East Usambara Mts., Tanzania. The synchrony observed in flowering in *S. confusa* and *S. difficilis* may enable hybridization between these two species, but partial phenological separation may contribute to the integrity of *S. grotei*. Although the level of flower abortion is high in *S. confusa*, each pollinated flower yields about 1000 seeds, a large proportion of which is probably deposited in the seed bank. Seed germination level is also high. *S. confusa* produces fruits following both self and cross pollination whereas spontaneous self pollination seems not to occur. Thus, seed production depends on sufficient pollinator service. Floral heteromorphy (i.e. enantiostyly) likely further enhances cross pollination, suggesting that the genus predominantly outcrosses. Thus, *Saintpaulia* populations are likely to suffer from negative effects of inbreeding if they become small and isolated.

P1140. Molecular origin of floral symmetry and inflorescence morphology in Gesneriaceae

C. Wang[1,2], M. Möller[3], Q. C. B. Cronk[2];
[1]Institute of Ecology and Evolution, Taipei, Taiwan Republic of China, [2]Botanical Garden and Centre for Plant Research, University of British Columbia, Vancouver, BC, Canada, [3]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

The *GCYC* genes are involved in the development of zygomorphy in flowers. We have compared *GCYC* expression between wild type and the peloric form (actinomorphy) of African violet. Both *GCYC* homologues (*SaGCYC 1A* & *SaGCYC 1B*) of the wild type *Saintpaulia* are expressed only in the adaxial (dorsal) petals and sepal, and *1B* is more strongly expressed than *1A*. Surprisingly, *SaGCYC 1A* & *1B* are also expressed only dorsally in the flower of the peloric form, with an even higher expression level. The increased *1A* & *1B* transcript level implies that the peloric mutation is in a gene downstream of *GCYC*, involved in regulatory feedback of *GCYC.* The ventral identity gene *DIV* is a possible candidate. We also isolated the inflorescence identity gene *GFLO* from *Titanotrichum* to study its effect on the development of the inflorescence. The *GFLO* expression pattern indicates that it is required for inflorescence initiation and flower induction. However, the *GFLO* transcript is reduced when bulbiliferous shoots start to initiate. The *GFLO* down-regulation appears to correlate with the loss of floral determinacy in the raceme inflorescence, and therefore with the generation of side branches.

P1141. Phytogeographic notes of Gesneriaceae in the Ryukyus, Japan

G. Kokubugata[1], M. Yokota[2], S. Kobayashi[3], C. Peng[4];
[1]National Science Museum, Tokyo, Tsukuba, Ibaraki, Japan, [2]University of the Ryukyus, Nishihara, Okinawa, Japan, [3]Makino Botanical Garden, Kochi, Japan, [4]Academia Sinica, Taipei, Nankang, Taipei, Taiwan Republic of China.

The family Gesneriaceae consists of ca. 3,700 species in 147 genera that are distributed mainly in the tropics with some members extending into temperate zones. Seven species are known from the Ryukyus islands that are situated between Kyushu (Japan) and Taiwan. *Aeschynanthus acuminatus*, a widely distributed species in Asia, and has been previously documented only once from Iriomote island of the Ryukyus (in 1973). We (SK) reconfirmed the presence of this locally rare species on this island in 2004. *Conandron ramondioides* occurs in China, Taiwan and Japan (including Iriomote). Taxonomic treatments for this widespread but scattered species have been varied. Based mainly on corolla morphology, we concluded that plants from the Iriomote and Taiwan were distinguishable from those of mainland Japan. *Titanotrichum oldhamii* is distributed in China, the Ryukyus and Taiwan. In the Ryukyus, this species are known from Ishigaki and Iriomote islands. However, little has been known of this species in Ishigaki. We (MY) documented a new habitat of *T. oldhamii* on this island in 2004.

P1142. The developmental analyses of the unique leaf morphogenesis in rosulate *Streptocarpus*

K. Nishii, T. Nagata;
The university of Tokyo, Tokyo, Japan.

In common dicots, leaves are formed from shoot apical meristem (SAM) mostly of a tunica-corpus structure. However, acaulescent species of *Streptocarpus* form leaves without SAM. We are interested in elucidating this unique leaf formation process, and have performed developmental analyses. When we followed the leaf formation pattern, we found 1st leaf was always observed at the axil of macrocotyledon where caulescent species retain SAM. As it was revealed that 1st leaf was formed consistently at this place, we could follow this process in detail. When leaf promordium bulged, the tunica-corpus-like structure that was previously identified as groove meristem (GM) was observed, and differentiated to leaf. Although it was said by previous other studies that cells in the GM divide to form a leaf by themselves, it was revealed that tissues of inner parenchyma and procambium in the petiolode tissue adjacent to the GM divided to the formation of 1st leaf actively as well as the GM did. Thus it is inferred that the GM would have a role in forming leaves as a kind of leaf organization center. These outcomes are discussed in reference to internal factors that affected these processes.

P1143. Developmental and genetic aspects of the actinomorphic flowers of *Bournea* (Gesneriaceae)

Y. Z. Wang, X. R. Zhou;
Laboratory of Systematic and Evolutionary Botany, Institute of Botany, Chinese Academy of Sciences, Beijing, China.

Bournea Oliv. is one of the few genera of Gesneriaceae having actinomorphic flowers. Regarding its two species, *B. leiophylla* has pentamerous flowers, while those of *B. sinensis* are tetramerous. Floral development of *B. leiophylla* shows that even though five stamens are basically equal in length in the mature flower, the adaxial and lateral stamens are remarkably smaller than the two abaxial stamens during early developmental stages. Four developmental genes associated with floral symmetry have been isolated from the floral tissues in *B. leiophylla* and *B. sinensis*. The four genes include G*DIV1* and G*DIV2*, two homologues of the *DIVARICATA gene* (*DIV*) in the model plant *Antirrhinum majus*, and two *CYCLOIDEA*-like genes (*CYC*), G*CYC1c* and G*CYC1d*. Remarkable are 40-80bp insertions both in G*CYC1c* and G*CYC1d* of *B. sinensis*. Perhaps they are possibly responsible for the fusion of the two adaxial petals of *B. leiophylla* into a single adaxial petal in *B. sinensis*. Comparison of expression of the four developmental genes suggest a network in function and regulation of these genes associated with the origin and developmental evolution of the actinomorphic flowers in *Bournea*.

P1144. Molecular phylogenetic studies and character evolution of *Didymocarpus* Wall. from Thailand

P. Palee[1], M. Möller[2], J. Denduangboripant[3], V. Anusarnsunthorn[1];
[1]CMU Herbarium, Department of Biology, Faculty of Science, Chiang Mai University, Chiang Mai, 50200, Thailand, [2]Royal Botanic Garden Edinburgh, 20A Inverleith Row, Edinburgh EH3 5LR, Scotland, United Kingdom, [3]Department of Biology, Faculty of Science, Chulalongkorn University, Phyathai Road, Bangkok, 10330, Thailand.

Molecular phylogenies have been generated to investigate relationships among species of *Didymocarpus* Wall. in Thailand. Fifteen Thai species have been included in a parsimony analysis using the internal transcribed spacer (ITS) of ribosomal DNA (rDNA). To test the relationships among the Thai species, additionally, four species from China, three species from Malaysia and one species from Bhutan were also included, as well as five outgroup taxa, three *Chirita* spp, *Briggsia muscicola* and *Oreocharis auricula*. The trees were rooted on the latter. The analysis show that the *Didymocarpus* species included formed a strongly supported monophyletic clade. The genus included two strongly supported clades. The results further suggest that the origin of *Didymocarpus* is the Malay Peninsula with whitish to yellow corolla, followed by species from southern and eastern Thailand, China and Bhutan with a corolla shape reduced to a narrow tube of purple to violet. To fully understand the evolution in this genus inclusion of further material is required.

P1145. Gentianaceae in the flora of Ukraine

N. Shiyan;
M. G. Kholodny Institute of Botany of NAS, Kiev, Ukraine.

As a result of our taxonomical revision of Gentianaceae family in the flora of Ukraine, the systematical structure was specified. In the Ukrainian flora this family is represented by *Blackstonia* (*B. acuminata* (W.D.J.Koch & Ziz) Domin, *B. perfoliata* (L.) Huds.), *Centaurium* (*C. erythraea* Rafn, *C. littorale* (D.Turner) Gilmour, *C. pulchellum* (Sw.) Druce and 2 subspecies, *C. spicatum* (L.) Fritsch, *C. uliginosum* (Waldst. & Kit.) G.Beck ex Ronniger), *Gentiana* (*G. acaulis* L., *G. asclepiadea* L., *G. cruciata* L., *G. laciniata* Kit. ex Kanitz, *G. lutea* L., *G. nivalis* L., *G. pneumonanthe* L., *G. punctata* L., *G. utriculosa* L., *G. verna* L.), *Gentianella* (*G. amarella* (L.) Bɞrner and 2 subspecies, *G. lutescens* (Velen.) Holub and 2 subspecies), *Gentianopsis* (*G. ciliata* (L.) Ma Yu-Chuan) and *Swertia* (*S. alpestris* Baumg., *S. perennis* L., *S. punctata* Baumg.). Occurrence of *Gentiana frigida* Haenke and *G. tenella* L. was not confirmed in the Ukrainian flora. Meanwhile, we propose to include *Gentiana acaulis*, *G. laciniata*, *G. lutea*, *G. nivalis, G. punctata*, *G. utriculosa, G. verna*, *Swertia alpestris* and *S. perennis* into the new version of “The Red Book of the Ukraine”.

P1146. Problems with Gentianaceae in regional floras in Brazil

I. Cordeiro;
Instituto de Botânica, São Paulo, Brazil.

Gentianaceae are represented in Brazil by c. 28 genera and 90 species, belonging to three of the five tribes of the family: Saccifolieae (*Curtia*, *Hockinia*, *Saccifolium*, *Tapeinostemon* and *Voyriella*), Chironieae (*Centaurium*, *Coutoubea*, *Deianira*, *Schultesia*, *Symphyllophyton* and *Zygostigma*), Helieae (*Adenolisianthus*, *Aripuana*, *Calolisianthus*, *Celiantha*, *Chelonanthus*, and *Helia*) and *Voyria*, a genus still *incertae sedis*. The only flora dealing with the family as a whole is the Flora brasilensis in the 19th century. More recently appeared the floras of Rio de Janeiro (1966) and States of Santa Catarina (1971) and São Paulo (2005). In the mountains of central Brazil, the Floras of the Serra do Cipó (1987) and Grão Mogol (2004) both in the State of Minas Gerais and the Pico das Almas in the State of Bahia (1995) were produced. In the north, the family was treated in the Floras of Guayana Highland (1978) and of the Reserva Ducke (1999) in the State of Amazonas.

Since only few revisions are published and many of the species are narrow endemics and poorly known, there are problems on species circumscriptions. Generic limits are likewise controversial, mainly in tribe Helieae.

P1147. Phylogeny of *Gentiana Sect. Calathianae* based on chloroplast PCR-RFLP

M. Haemmerli;
Université de Neuchâtel, Neuchâtel, Switzerland.

Gentiana Sect. Calathianae is distributed in Europe, Asia, North America and North Africa, primarily occupying mountainous to alpine habitats. A phylogeny based on chloroplast PCR-RFLP is presented, including 18 taxa with 250 accessions, using 8 different non-coding regions, each digested with 4 enzymes covering about 15% of the plastid genome. Different monophyletic lineages can be recognised, such as the two annuals *G. nivalis*. and *G. utriculosa* and the eastern Alpine *G. pumila* s.str. that is separate from *G. pumila subsp. delphinensis*. The taxa of *G. verna* s.l. are divided into an Alpine/Pyrenean clade and another covering the southeastern European mountains. *G. brachyphylla* s.str. from Alpine populations is placed in a separate lineage where it groups neither with *G. brachyphylla subsp. favratii* nor with plants from southern Spain. *G. bavarica* and *G. rostani* represent two distinct monophyletic species placed in different subclades.

P1148. Seed and pollen morphology of the Neotropical moon-gentians (Macrocarpaea: Gentianaceae)

J. R. Grant;
Université de Neuchâtel, Neuchâtel, Switzerland.

There are many taxonomically useful seed morphological characters in Macrocarpaea. Therefore, seeds of 81 species (out of 106 in the genus) were studied by SEM. Mature seeds are miniscule in size, 0.2-2.2 x 0.2-1.0(-2.2) mm, yet display a wide range of diversity. Four broad morphological seed types are identified, conforming to the four sections of the genus: “Flattened type seeds” for sect. Tabacifoliae (southeastern Brazil), “Perimetrically winged type seeds” for sect. Choriophylla (central Andes, especially the Huancabamba region), “Rimmed type seeds” for sect. Macrocarpaea (northern Andes, southern Mesoamerica, Greater Antilles, and Guayana Shield), and “Winged type seeds" for sect. Magnolifoliae (central Andes). Additionally, SEM studies of pollen exine in 88 species confirm the presence of two morphological types. The Glabra-type (3-colporate, spheroidal with reticulate exine) is present in most species of the genus, while the Corymbosa-type (formerly Rusbyanthus-type) (3-colporate, spheroidal, with warty exine) occurs in 13 species of sect. Magnolifoliae providing an additional unique character to define the section.

P1149. SEM observations of seeds of gen. *Gentiana* L. and their systematic significance

N. Davitashvili, G. Karrer;
University for Natural resources and Applied Life Sciences, Vienna, Austria.

The genus *Gentiana* includes about 360 species distributed in temperate, arctic and alpine parts of the northern hemisphere mainly. Seeds of gentians show high diversity in size, shape and surface pattern, and furthermore have been reported to be of systematic importance in this genus. Unfortunately, until now, seeds of only a limited number of taxa have been studied in detail. As part of a taxonomic study of the genus *Gentiana* we investigated seed morphology in order to evaluate its taxonomic significance.

Seeds of taxa from 7 sections (*Pneumonanthe, Cruciata, Frigida, Isomera, Microsperma*, *Kudoa*, *Monopodiae*) were examined with the scanning electron microscope. Qualitative characters of seed shape and testa ornamentation were selected and cluster analysis (UPGMA) was performed on the base of presence and absence of coded characters.

Based on seed shape, testa cell shape, and surface ornamentation, eight morphological types are recognized. The results of cluster analysis revealed that seed micromorphology follows the sectional classification, thus providing a useful tool for studies on evolution and systematics of gentians.

P1150. The Indo-Chinese Gentianaceae

S. Hul;
Muséum national d'Histoire naturelle, Paris, France.

Introduced in 1789 by Jussieu, the Gentianaceae gathered about 10 genera. Later, other scientists attached to this family a great deal of species and genera, spread in various tribes.

Presently the Gentianaceae accounts ca. 76 genera and 100 species. Cosmopolitan, it mostly spreads upon temperate areas in either high or low altitude; in tropical Asia it is encountered in wet district of mountains, sometime in savannah or in clear deciduous woods with Dipterocarpaceae. Dop & Gagnepain mentionned 19 genera and 22 species in Cambodia, Laos and Vietnam. Following our study 10 genera and 27 species were listed to the Flora of Cambodia, Laos and Vietnam.

While revising Gentianaceae for this Flgra, the study of material from Asia, mostly the Indo-Chinese Peninsula drove us to identify 40 species. Amofg these species, 11 new species and 1 new subspecies are recorded.

P1151. Conflicting genetic and morphological patterns in European *Gentianella* sect. *Gentianella*

J. Greimler[1], C. G. Jang[2], B. Hermanowski[3], A. N. Müllner[4];
[1]Institut of Botany, Vienna, Austria, [2]Chungbuk National University, Cheongju Chungbuk, Republic of Korea, [3]Universität für Bodenkultur, Vienna, Austria, [4]RBG Kew, Richmond, Surrey, United Kingdom.

The low divergence in ITS nrDNA and *trn*L-F cpDNA sequences indicates a very young diversification within European *Gentianella* Moench sect. *Gentianella*. AFLP data, however, revealed strong differentiation on the geographical scale despite low morphological differences. In contrast high genetic similarities were found among taxa of the Alps, that are morphologically very distinct. In a morphological analysis we found only few morphological characters of taxonomic significance. In one of these characters: papillae on the calyx lobes, we demonstrated by Scanning Electronic Microscopy (SEM) that there are three different types that were not distinguished hitherto. A strong response to the environmental variable altitude was found in nearly all morphometric traits. Altogether genetics and morphology show different patterns in the sect. *Gentianella* which raises questions on morphological homoplasy and reticulate evolution.

P1152. Testing the monophyly of selected infrageneric taxa within the genus *Mimosa* (Leguminosae, Mimosoideae)

R. Grether[1], G. P. Lewis[2], M. Luckow[3];
[1]Depto. Biología, División CBS, Universidad Autónoma Metropolitana-Iztapalapa, 09340 México, D.F., Mexico, [2]Royal Botanic Gardens, Kew, Richmond, Surrey TW9 3AE, United Kingdom, [3]L. H. Bailey Hortorium, 462 Mann Library, Cornell University, Ithaca, 14853, NY, United States.

Mimosa is the largest genus in tribe *Mimoseae* (510 species) occurring mainly in America. The aims of this study are: 1) to test the monophyly of sections of *Mimosa*; 2) to test the monophyly of three series of sect. *Batocaulon*; 3) to assess the phylogenetic relationship among the New World species and allied Old World ones, and 4) to test the sister group relationship between *Piptadenia* and *Mimosa*. This phylogenetic analysis, based on morphological, palynological, and anatomical data, was carried out using PAUP and Winclada; species of *Mimosa* (twenty-seven), *Piptadenia* (four), and one species each of *Pithecellobium*, *Enterolobium*, and *Acacia*, were studied. Fifty-five unordered characters were scored, with equal weighting. Our conclusions are: 1) Monophyly of *Mimosa* is confirmed. Section *Calothamnos* is monophyletic, whereas *Mimadenia*, *Batocaulon*, *Habbasia*, and *Mimosa* are not; 2) Series *Leucaenoideae* and *Rubicaules* are not monophyletic; ser. *Bahamenses* groups with Mexican and Madagascan species; 3) *Piptadenia* is not monophyletic and, in part, is sister to *Mimosa*; 4) Our results are the basis to carry out a collaborative, molecular phylogenetic study of *Mimosa*.

P1153. Taxonomy of *Astragalus* Subgenus *Cercidothrix* (Fabaceae) in Iran: Complex *Dissitiflori*

F. Ghahremaninejad;
Teacher Training University of Tehran (University of Tarbiat-Moaallem), Tehran, Islamic Republic of Iran.

Astragalus is the biggest genus of flowering plants with nearly 2500 species.

This paper is about a part of bifurcating hairy *Astragalus* sections. Bifurcating hairy *Astragalus* are involved in the *Astragalus* subgenus *Cercidothrix* Bunge, which is charachterised by the presence of bifurcate hairs. This subgenus has nearly 850 species in the Old World, nearly 200 of which occure in Iran. Iranian species occure in less than 20 sections.

The subject of this paper is taxonomy of six related and nearly homogenus sections in these subgenus. Four sections are more herbal: Sect. *Craccina* (Steven) Bunge (24 species), Sect. *Hololeuce* Bunge (36 species), Sect. *Onobrychoidei* DC. (83 species), and Sect. *Ornithopodium* Bunge (17 species). Two othere sections are more woody sections: Sect. *Erioceras* Bunge (37 species), and Sect. *Dissitiflori* DC (187 species).

Here these sections are studied morphologically and anatomically. Based on these study the most important characteristics for the separation of the sections, relationships between the sections and identification key for them are presented.

Here it is revealed these are natural groups.

P1154. Remarks on *Medicago* sect. *Dendrotelis* (Fabaceae) based on morphological and molecular data (ITS and *trnL-F*)

A. Juan[1], **M. B. Crespo**[1], M. Lledó[2], S. Ríos[1], M. F. Fay[2];
[1]Instituto Universitario de Investigación-CIBIO, Alicante, Spain, [2]Royal Botanic Gardens, Kew, United Kingdom.

Medicago sect. *Dendrotelis* includes shrubby perennial plants with stipitate pods with 1-3 coils, flowers with the keel equaling or slightly longer than the standard, and embryos with the radicle about half as long as seed. Three Mediterranean taxa native to littoral areas and islands are included: *M. citrina*, *M. arborea* and *M. strasseri*. The taxonomic status of *M. citrina* varies depending on different criteria. To clarify this point, macromorphological (leaves, petals, pollen, pod, etc.) and micromorphological data (pollen, leaf, etc.), together with sequences of two DNA regions (nuclear ITS, internal transcribed region; and the plastid *trnL-F* region (the *trnL* intron and the *trnL-trnF* intergenic spacer) were studied. The combined data showed sect. *Dendrotelis* as a monophyletic group, related to sect. *Medicago*. Within this clade, the western Mediterranean *M. citrina* appears as the sister group of the eastern taxa (*M. arborea* and *M. strasseri*).

P1155. Comparative anatomy of seed coats with some characteristic patterns on their surface in subfamily Caesalpinioideae (Leguminosae)

T. Nemoto[1], H. Aida[1], G. Lewis[2], H. Murata[3], S. Katsuki[4];
[1]Ishinomaki Senshu University, Ishinomaki, Japan, [2]Royal Botanic Gardens, Kew, United Kingdom, [3]Setsunan University, Hirakata, Japan, [4]National Institute of Health Sciences, Tanegashima, Japan.

Seed surface patterns such as pleurogram-areole and pitted ones were anatomically investigated and compared in the subfamily Caesalpinioideae. The seed coat is generally composed of cuticle, epidermal palisade cells, hypodermal hour-grass cells, and parenchyma cells. The epidermal palisade cells are separated into two layers by a light line running across each cell periclinally, and the relative height of the two layers varies among species and also partly within a seed. In the latter cases the conspicuous variation in the relative height is found between the inside and outside of pleurogram. Based on variation in the relative height the pleurograms are distinguished into two types in the Caesalpinioideae, one of which is similar to those found in the subfamily Mimosoideae. This type occurs in genera of Dimorphandra group of the tribe Caesalpinieae, which is located on the closest position to the Mimosoideae. In *Senna*, moreover, the areole was anatomically shown to be similar to that of the whole seed of the species without pleurogram-areole pattern. Although *Chamaecrista* has the peculiar pitted pattern, the seed coats are similar to those of the areole of *Senna*.

P1156. Understanding diversification of Neotropical *Acacia* (Leguminosae: Mimosoideae) and estimating endemism indices.

M. D. L. Rico-Arce;
Royal Botanic Gardens, Kew, Richmond, Surrey, United Kingdom.

Acacia, the second largest genus in the family Leguminosae, is currently a pantropical genus with 1 350 species placed into three subgenera. Most species are native to Australia where subgenus *Phyllodineae* is predominant. Maslin (2003) presented a comprehensive historical review of the generic status.

American *Acacia* comprises c 158 species with c. 49 infraspecific taxa. Subgenus Aculeiferum section Filicinae (c 20 taxa) is excluded from *Acacia* and placed in *Acaciella* Britton & Rose. In the neotropics subgenus *Aculeiferum* comprises 98 species, 34 vars. and subgenus *Acacia* 60 species, 17 vars. Ecologically, *Acacia* is mainly associated with drylands and secondary growth, but numerous species are elements of tropical wet forest.

A component analysis of the species was undertaken using c 50 different geographical regions to estimate endemism indices. Analysis of morphological patterns was based mainly on inflorescence, fruit and seed structure. These analyses show that the most specialised group (myrmecophyllous species) is concentrated in the Mesoamerican region. A table of species habitats and conservation status is presented.

P1157. Molecular phylogeny of *Andira* Lam. nom.cons. (Leguminosae, Papilionoideae): A case study of neotropical speciation

C. K. Skema[1], R. T. Pennington[2];
[1]Cornell University, Ithaca, NY, United States, [2]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

The nuclear ribosomal internal transcribed spacer region (ITS) was sequenced for 42 accessions representing 25 of the 29 species of *Andira* (Leguminosae, Papilionoideae). Maximum parsimony, maximum likelihood and Bayesian analyses produced similar tree topologies, demonstrating the monophyly of *Andira* and resolving two major clades. Relationships among five, small lineages remain largely unresolved and poorly supported. Molecular rates analysis suggests multiple Amazonian rain forest lineages, two Guayanan rain forest lineages, and a Brazilian Atlantic coastal forest lineage diverged in the Miocene. Movement out of the rain forest habitat into new biomes (seasonally dry tropical forest, cerrado, montane forest, restinga) accompanied bursts of speciation across the genus in the Plio-Pleistocene with as many as twelve *Andira* species originating since that time. *Andira* demonstrates an evolutionary history of both ancient and recent speciation.

P1158. Evolutionary history of the highly diverse Genistoid core (Leguminosae) inferred from phylogenetic analyses of nuclear ribosomal (ITS and ETS) and plastid (*trn*L-*trn*F IGS) DNA sequences

P. Cubas[1], C. Pardo[1], A. Aïnouche[2], M. T. Misset[2];
[1]Departamento de Biología Vegetal II, Facultad de Farmacia, Universidad Complutense, Madrid, Spain, [2]Laboratoire de Botanique, UMR CNRS 6553 Ecobio, Université de Rennes-1, Rennes, France.

Phylogenetic analysis of the Genisteae s.l. recognises a well-supported genistoid core, comprising *Cytisus*- and *Genista*-related genera (the ‘Cytisus group’ and ‘Genista group’), and several other taxa whose relationships are not yet well established (*Lupinus*, *Argyrolobium*, *Adenocarpus*). We present phylogenetic trees based on ITS and ETS regions (nrDNA), and *trn*L-*trn*F IGS (cpDNA) of the genistoid core. The nrDNA regions provide more parsimony informative characters than the cpDNA, the latter shows indels and rearrangements that yields relevant phylogenetic information. A comparison of the topologies provided by the different markers shows incongruence/instability in the position of key taxa (e.g. *Argyrocytisus*, *Erinacea*, *Gonocytisus*, *Petteria Retama*, *Spartium*) that is suggestive of reticulate evolution. We also discuss the evolutionary pattern differences of the *Cytisus* group vs the *Genista* group, and the position of small segregate genera (e.g. *Podocytisus*, *Lembotropis*, *Pterospartum*).

P1159. Critical taxonomical revision of Fabaceae in Ukraine flora.

A. A. Kagalo;
Institute of Ecology of the Carpathians of N.A.S. of Ukraine, Lviv, Ukraine.

Behind the different data the family Fabaceae of Ukraine flora totals from 300 up to 500 species. Such significant distinction among indicated species is caused various by treatments taxonomical volume of some taxa of a species rank and genera. It causes significant different interpretations in comparison with floras of neighbouring states and territories.

The critical taxonomical revision of the family will be spent with the purpose of the coordination of nomenclature and taxonomical disagreements in frameworks of Central European flora.

The plenty of species rank taxa was described earlier wrongly in genera Astragalus, Medicago, Lotus, Genista etc.

The critical analysis of the chorological information on presence of those or other species in territory of Ukraine is necessary, as many species were specified for territory wrongly. The important meaning for this purpose there is a critical processing of herbarium materials, which were a little involved in time of taxonomical processings of the family in last 40 years.

On tentative estimations the aggregate number of species of the family will make about 400 taxa of a species rank.

P1160. Phylogenetic analyses of subtribe Trigonellinae: Medicago, Melilotus, and Trigonella (Leguminoseae) using nucleotide sequence data from two nuclear protein-coding genes, Le and pgiC, and plastid gene matK

K. P. Steele[1], S. Zarre[2], M. F. Wojciechowski[3];
[1]Arizona State University East, Mesa, AZ, United States, [2]Tehran University, Tehran, Islamic Republic of Iran, [3]Arizona State University, Tempe, AZ, United States.

Phylogenetic relationships of species in subtribe Trigonellinae (*Medicago* and *Trigonella*) were examined based on analyses of nucleotide sequences of the plastid gene *mat*K and two nuclear genes, Mendel’s stem length gene, *Le*, and the gene encoding cytosolic phosphoglucose isomerase, *pgi*C. Perennial species of *Trigonella* section Ellipticae that had not been included in previous molecular analyses were also sampled. Relationships of species of *Medicago* previously included within *Trigonella* and species of section Medicago (including *Medicago sativa*) were of particular interest. Results of the analyses were used to evaluate characteristics of the legume that have been considered important in past generic delimitation, but are subject to some obvious as well as more subtle convergent evolution. Species in subtribe Trigonellinae include a geocarpic annual, annual and perennial herbs, and shrubby species; this variation in habit is also considered in a phylogenetic context.

P1161. Molecular phylogenetics of *Amorpha* L. (Fabaceae) based on evidence from chloroplast and nuclear markers

S. C. K. Straub, J. J. Doyle;
Cornell University, Ithaca, NY, United States.

Amorpha L. is a genus of about 15 species belonging to the tribe Amorpheae within the papilionoid subfamily of legumes. The taxonomy of this group is complex and perplexing due to the high degree of environmental plasticity exhibited within species and gradation of character variation between species. This genus has not previously been the subject of phylogenetic analysis based on either morphological or molecular characters. The complicated taxonomic history of *Amorpha* makes the use of molecular phylogenetic analyses an appropriate measure to resolve relationships. Ascertaining the origin of the constituent genomes of *Amorpha fruticosa*, a tetraploid, is one goal of this study. A number of chloroplast haplotypes based on spacer region sequences have been observed within and between species. In addition, many low copy nuclear candidate genes containing introns have been identified through comparison of *Medicago* and *Arabidopsis* sequences. These include *ARG1* and *sterol 24-C-methyltransferase*, which show intron variation between taxa. Phylogenies of these and other unlinked markers will allow analysis of sources of incongruence among *Amorpha* species.

P1162. Phylogenetic relationships among species of Mimosa (Legumminosae) based on cpDNA.

C. F. Bessega[1], H. E. Hopp[2], R. H. Fortunato[3,4];
[1]Departamento de Ecología, Genética y Evolución, Buenos Aires, Argentina, [2]Instituto de Biotecnología, INTA, Castelar., Buenos Aires, Argentina, [3]Instituto de Recursos Biologicos CIRN, INTA, Castelar., Buenos Aires, Argentina, [4]Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Buenos Aires, Argentina.

Phylogenetic relationships among 26 southamerican species of genus Mimosa were analysed on the basis of both the intron and the intergenic spacer TrnL-TrnF in order to clarify taxonomic assignments based on morphological characters. Seven species representing related genera were also sequenced and analyzed. The basic data matrix included 1137 characters. A total of 144 equally parsimonious trees were retrieved (633 steps, IC=0.66 and IR=0.59). The consense tree showed that Mimosa might be a monophyletic group sister to genus Piptadenia. These preliminary results indicate that two groups can be distinguished within Mimosa: one of them includes species of the section Baulocaulon DC. and the other one species of the sections Habbasia DC., Mimosa and Caulothanmus Barneby. The latter might be sister to Scrankia, now recognized in the synonymy of Mimosa. Finally, the species of the section Caulothanmus studied here did not group within the same clade suggesting that this section in not a natural group.

P1163. Is there congruency between traditional classification and molecular relationships in the genus *Cicer* L.? Insights from nuclear and chloroplast sequence data

F. Javadi, H. Yamaguchi;
Osaka Prefecture University, Sakai, Osaka, Japan.

Cicer L. is a genus composed of ca. 43 species with distribution in Central and Western Asia, Europe and Africa. Four sections have traditionally been defined based on morphological characters and geographical distribution: *Cicer*, *Chamaecicer*, *Polycicer* and *Acanthocicer*. As a part of comprehensive systematic study of the genus *Cicer*, nuclear ITS and chloroplast *trnK*/*matK* sequence data were determined to elucidate the congruence between traditional classification and molecular relationships in the genus. Twenty-eight species belong to four sections and five outgroup taxa from Vicieae, Trifolieae, and Galegeae were analyzed in this study. The maximum parsimony analyses of nrDNA and cpDNA data indicate three major clades and non-monophyly of the annual species in the genus *Cicer*. Molecular data suggest that traditionally defining features are actually phylogenetically homoplastic, leaving present infrageneic boundaries in doubt and a taxonomic realignment of infrageneric delimitation and composition should be considered. The character evolution of life cycle, pollen morphology, and canavanine content will be discussed in the phylogenetic tree.

P1164. Floral organogenesis in tropical legume genera (*Adesmia* and *Aeschynomene*) and its systematic implications.

J. E. A. Mariath[1,2], M. C. Moço[3], D. S. Sampaio[4];
[1]UFRGS, Porto Alegre, Brazil, [2]CNPq Researcher, Brasilia, Brazil, [3]UFPR, Curitiba, Brazil, [4]UFRGS - PPGBot, Porto Alegre, Brazil.

Floral organogenesis of Aeschynomene (A. falcata and A. sensitiva) and Adesmia species (A. securigerifolia, A. riograndensis, A. punctata var. hilariana, A. latifolia, A. ciliata, A. tristis and A. muricata) were studied using scanning electron microscopy. The aims were to identify ontogenetic characters and discuss its systematic value. In Aeschynomene species the five isolated sepals primordia are initiated in unidirectional order from abaxial side. Otherwise, in A. sensitiva these primordia were grouped in two poles forming a two-lobed calyx and petals initiate asymmetrically. This and others ontogenetic differences corroborates with the separation of section Ochopodium from Aeschynomeninae subtribe. The Adesmia species share the initiation of sepal whorl in unidirectional order from adaxial side, except in Adesmia latifolia, that initiates in simultaneous way. This ontogenetic character was considered genera diagnostic because is completely different from other papilionoids. Others ontogenetic differences between Adesmia species were described, and infrageneric taxa reorganization was suggested.

P1165. Phylogeny and systematics of the genus *Lathyrus* L. (Fabaceae): evidence from nuclear ITS sequences

S. S. Neves[1], G. J. Kenicer[2], P. Fevereiro[1,3], M. C. Vaz Patto[1];
[1]Instituto de Tecnologia Química e Biológica, Universidade Nova de Lisboa, Oeiras, Portugal, [2]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom, [3]Departamento de Biologia Vegetal, Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal.

The genus *Lathyrus* (Fabaceae) comprises c. 160 species of annual and perennial herbs, morphologically and ecologically diverse, with a worldwide distribution. Due to their resistance to drought and flooding, some *Lathyrus* species (e.g. *L. sativus* - grass pea - and *L. cicera* - chickling vetch) have great agronomic potential as supplementary sources of calories and protein for human populations and as forage crops in the poorest regions in the World. The systematics and phylogeny of the genus have been investigated using both morphology and molecular data, mostly plastid DNA. We used the nrDNA ITS region to investigate the relationships in the genus, including a representative sampling of its sections and main clades, as well as species from other genera in the tribe Vicieae. *Lathyrus* and *Pisum* are shown as a strongly supported monophyletic group. Phylogenetic resolution within *Lathyrus* is still low, but it might be improved with the increasing sampling. Nevertheless, various groups are recognized, some confirming previously suggested assotiations, such as the affinity of Sect. *Aphaca* to Sect. *Pratensis*, and the close relationship of *L. clymenum* and *L. ochrus*.

P1166. Phylogenetic Relationships in Iranian *Medicago* Species Using RAPD Markers

F. Ghanavati, J. Mozafari;
SPII (Seed and Plant Improvement Institute), Karaj, Islamic Republic of Iran.

Genetic diversity of 54 populations from 22 species of *Medicago* collected from Iranian natural habitat was studied. DNA was extracted from bulked leaf samples of each population and used for RAPD. RAPD markers produced by 11 UBC primers was analyzed according to Maximum Parsimony method. Using PAUP software, a phylogenetic tree with 5 main clusters was generated. Populations of *M. aculeala, M.constricta, M.rigiduloidos* and *M. rigidula* with hard pod walls and spongy texture were classified in one cluster. Populations of *M. sauvagei*, *M. laciniata* and *M. polymorpha* with soft and flexible pod walls were classified in a separate cluster. Populations of each species were classified in subclusters, indicating that RAPD was capable of identifying genetic diversity at the species level. Populations of one species grown under similar climatic conditions were grouped together under the cluster of that species. This indicates that genetic diversity correlates with geographical distribution of wide spread annual medic species in Iran. Results showed RAPD is applicable as a complementary tool in taxonomic identification of *Medicago* at both species and population levels.

P1167. Morphological and molecular variation in *Desmodium sumichrastii* (Fabaceae) a potentially useful species in ecological restoration.

B. Y. Bedolla-García, S. I. Lara-Cabrera, **R. A. Lindig-Cisneros**;
Facultad de Biología. Universidad Michoacana de San Nicolás de Hidalgo, Morelia. Michoacan, Mexico.

In many ecological restorations is essential to introduce many of the native species that have been extirpated through the degradation process and are not longer present on or near the site. For successful reintroduction use of the appropriate ecotypes and knowledge of genetic variation of the species is necessary. For temperate forests in Mexico and Central America there is no information regarding phenotypic and genetic variation of native shrub species. One such species is *Desmodium sumichrastii* (Fabaceae) a nitrogen fixing species with potential for restoration of temperate forests. Morphological variation in 80 herbarium specimens (70 characters were considered) and RAPD primer analysis of four populations was carried out. Results showed high variation among populations that increases with geographic distance. Due to the high morphological and genetic variation, for choosing collecting sites for ecological restoration, closest populations to the restoration site are recommended.

P1168. A phylogenetic analysis for 44 species of Old World *Trifolium* as well as 4 species from New World

M. Vatanparast, S. Kazempour Osaloo;
Department of Plant Biology, Tarbiat Modarres University, Tehran, Islamic Republic of Iran.

A phylogenetic analysis for 44 species of Old World *Trifolium* as well as 4 species from New World of all 8 sections and for two outgroup taxa (*Trigonella foenum graecum and T. stellata*) using 50 morphological characters were conducted. The results strongly supported monophyly of the genus. Species of section *lotoidea* are sisters to the remainder species of the genus. Sections *Vesicaria* and *Chronosemium* form monophyletic groups, separately, with high bootstrap value. The two largest cosmopolitan sections, *Lotoidea* and *Trifolium* are not, however, monophyletic. The New World species (*T. nanum*, *T. longipes*, *T. pinetorum* and *T. depauperatum*) are nested clearly within the old world ones and form a paraphyletic group in spite to previous treatments. The two species (*T. nanum*, *T. longipes*) of section *lotoidea* are basal within the genus that supporting the hypothesis of New World origin for the genus.

P1169. A Morphological Evaluation of *Medicago* Pollens

F. Ghanavati, J. Mozafari;
SPII (Seed and Plant Improvement Institute), Karaj, Islamic Republic of Iran.

Having more than 23 species of *Medicago,* Iran is one of the origins and centers of diversity of this genus. Because of close similarity in sexual organs and pod-characteristics, taxonomical classification of these species based on morphological characteristics is difficult. Scanning Electron Microscopy (SEM) was used to study the major characteristics of pollen among Iranian *Medicago* species. Pollens were mostly tricolpate, but quadricolpate or hexacolpate pollens were also seen in one species. The equatorial view was ovalish rectangular or spherical shapes and the polar view was obtuse-triangular, truncate-triangular or square tips. Majority of species showed reticulate (perforate, faveolate, regulate and scrobiculate) and verrucate exine surface. *M. rigiduloides* with quadric or hexic colpate pollen was barely distinguishable from *M. rigidula* with tricolpate pollen exine surface. On the other hand, *M. tornata* with its spherical pollen and verrucate exin surface was obviously different from *M. polymorpha* with rectangular pollen and reticulate exine surface. This is the first report of *M. rigiduloides* and *M .tornata* from Iran.

P1170. Cladistic and phenetic analysis of the relationships in *Vicia* subgenus *Cracca* (Fabaceae) based on morphological data

M. Leht;
Estonian Agricultural University, Institute of Agricultural and Environmental Sciences, Tartu, Estonia.

The variation of 89 multistate morphological characters of 44 species from *Vicia* subgenus *Cracca* Peterm. was investigated with cladistic and phenetic methods using *Lathyrus sylvestris* L. and *Pisum elatius* M. B. as outgroups. The subgenus appears monophyletic, the *Ervum* group is supported as a section. The sections *Vicilla* (Schur) Aschers. & Graebner and *Cassubicae* Radzhi appear monophyletic when *V. amoena* Fischer is moved to the section *Cassubicae*. Placement of *V. biennis* L. in a separate section is supported, while the sections *Variegatae* Radzhi and *Panduratae* Kupicha are nested in the section *Cracca* Dumort and section *Pedunculatae* Rouy is not supported as monophyletic. Use of different outgroups results in slightly different substructures for sect. *Cracca*. Differences in the placement of some species (*V. onobrychioides* L., *V. megalotropis* Ledeb. and *V. biennis*) as well as in the structure of the subclades of the section *Cracca*, depending on the outgroup choice, clearly reveal the level of steadiness or instability of some groupings formed in the analysis of the morphological characters.

P1171. Molecular phylogeny of *Acacia* subgenus *Phyllodineae* (Leguminosae: Mimosoideae) based on nuclear DNA sequences

D. J. Murphy[1], G. K. Brown[2], J. T. Miller[3], P. Y. Ladiges[2];
[1]Royal Botanic Gardens Melbourne, Melbourne, Australia, [2]School of Botany, The University of Melbourne, Melbourne, Australia,
[3]Department of Biological Science, University of Iowa, Iowa City, IA, United States.

Acacia subgenus *Phyllodineae* is a diverse assemblage including over 950 species, most of which occur in Australia. Chloroplast DNA evidence supports the monophyly of subg. *Phyllodineae,* with its probable sister taxon in the tribe Ingeae. Within *Phyllodineae* relationships of taxa have remained largely unresolved. In this study sequences of the ETS and ITS were used to test the monophyly of the seven currently defined sections. It is now clear that most of these sections are not monophyletic; instead the taxa are resolved into three main clades.

Previous studies assumed a natural division between taxa with uni-nerved phyllodes (section *Phyllodineae*) and those with pluri-nerved phyllodes (*Juliflorae* and *Plurinerves*). However, this division is not supported by sequence data of nDNA. Section *Phyllodineae* is polyphyletic, indicating that phyllode nerve-number is homoplasious. Also at least two separate reversals to the plesiomorphic state of bi-pinnate foliage have occurred. There is support for a modified version of Vassal's section *Pulchelloideae*, bringing together disparate taxa from sections *Alatae*, *Pulchellae*, *Phyllodineae* and *Lycopodiifoliae.*

P1172. Molecular Phylogeny of the Old World *Astragalus* L. (Fabaceae) as Inferred from nrDNA ITS Sequence Data

S. Kazempour Osaloo;
Tarbiat Modarres University, Tehran, Islamic Republic of Iran.

Phylogenetic relationships among 230 species of the Old World *Astragalus* and 2 of the New World one were inferred from analyses of nuclear rDNA ITS sequences. The results of phylogenetic analyses suggest that all *Astragalus* species sampled, except taxonomic outliers including three annual species, *A. epiglottis*, *A. annularis* and *A. vogelii* (newly established as *Podlechiella vogelii*) and six perennials (from sect. *Phyllolobium*), are united in a single clade, so-called *Astragalus* s. str. Our results show that *P. vogelii* is allied with an assemblage of *Colutea persica* and a clade of six species of sect. *Phyllolobium* at the base of the trees. The three monotypic annual segregate genera *Thlaspidium* (= *A. thlaspi*), *Barnebyella* (= *A. migpo*), and *Ophiocarpus* (= *A. ophiocarpus*) are clearly nested within *Astragalus* s. str. Among sections analyzed, only sects. *Acanthophace*, *Ammodendron*, *Bucerates* (including monotypic *Cyamodes*), *Cenanthrum*, *Caraganella*, *Chronopus, Eremophysa*, *Incani, Laxiflori* and *Lotidium* appear to be monophyletic.

Key words: *Astragalus*, Fabaceae, nrDNA ITS, Phylogeny

P1173. *Vicia cracca* and *V. tenuifolia* in Eastern Europe

M. V. Skotnikova, A. G. Elenevskij;
Moscow Pedagogical State University, Moscow, Russian Federation.

Vicia cracca and V. tenuifolia are two closely related species of Fabaceae widely distributed in Europe and Mid-Russian Valley. V. cracca usually inhabits forest and forest-steppe zones. V. tenuifolia is primarily a steppe species but it can be found much further north. Russian scientists traditionally delimit these species as in natural habitats they can be distinguished by general appearance. But the exact defining characters are uncertain. That’s why V. tenuifolia is treated as a subspecies of V. cracca by many European authors (Hegi, 1924; Guinea, 1953; Davis, 1978). On

the other hand, overlapping habitats of these taxons require them to be regarded as species.
With the purpose of settling this question we've analyzed 10 defining characteristics of the vetches from Mid-Russian forest-steppe where habitat overlapping is great. These included length and width of the leaflets and their ratio, leaf and raceme lengths and ratio, leaf and stem pubescence, corolla and limb length and their ratio, raceme length and density. Raceme and flower characteristics define V. tenuifolia as a separate species. Further research on legume characteristics is being conducted.

P1174. Systematics of the Legume Fossils from the Miocene Shanwang Flora of Shandong Province, Eastern China

Q. Wang[1], D. Dilcher[2];
[1]Institute of Botany, Beijing, China, [2]Florida Museum of Natural History, Florida, FL, United States.

The Miocene Shanwang flora from Shandong Province, eastern China has provided beautifully preserved legume fossils since the 1930's. To date, 9 legume genera have been reported, including *Albizia*, *Cercis*, *Gleditsia*, *Gymnocladus*, *Indigofera*, *Podogonium* (or *Podocarpium*), *Pueraria*, *Sophora*, and *Wisteria*. However, the systematics of many of these legume fossils are uncertain and in need of further study. Attention needs to be given to a detailed reinvestigation of their biological characters such as leaflet architecture and associated reproductive organs. Also, their phylogenetic and biogeographic significance needs to be assessed. These legume fossils are usually preserved in the diatomaceous shales, so their leaflet architecture and associated fruit characters are often exquisitly preserved in great detail so that careful comparisons can be made between the characters of the fossils and those of extant species. Based upon this potential to understand, the systematics and their biogeographic significance of these legume genera from the Shanwang flora should be reappraised in the future research.

P1175. Morphology, Diversity and Phylogeny of *Paloue*, *Elizabetha*, *Heterostemon* and Related Caesalpinoid Legumes from Northeastern South America

K. M. Redden, P. S. Herendeen;
The George Washington University, Washington, DC, United States.

Most phylogenetic analyses of species level relationships in the Leguminosae have focused on the subfamilies Mimosoideae and Papilionoideae and only recently have efforts been directed at groups within the subfamily Caesalpinioideae. Most phylogenetic work within the subfamily concentrates on higher level relationships among the tribes, subtribes, and genus groups. Over half of the genera of Caesalpinioideae are grouped in the large Detarieae s.l. clade. Within his clade, *Heterostemon* (7 spp.), *Elizabetha* (10 spp.), *Paloue* (4 spp.) and *Paloveopsis* (1 sp.) are endemic to northeastern South America and are thought to be closely related. This study uses morphological, anatomical and molecular characters to explore generic limits and relationships among these genera. Preliminary results support the monophyly of *Heterostemon*, *Elizabetha*, and *Paloue*, and also support the recognition of *Paloveopsis* as a distinct monospecific genus. Patterns of floral evolution implied in these results will be discussed in a phylogenetic context.

P1176. Pollen morphology in Iranian species of *Trifolium* sect. *vesicaria* using pollen morphology

F. Salimpour;
Azad university ,Tehran north branch, Tehran, Islamic Republic of Iran.

The species of Vesicaria section and T. spumosum of sect. Mistyllus collected from various locations in Iran, were used in this study. Pollen grain characteristics of species were evaluated by Scaning Electron Microscopy(S.E.M.). Characteristics of pollens such as polar length(P), equatorial length(E), P/E ratio, furrow length and ornamentation of exine surface were studied. The largest pollen belonged to T. fragiferum and smallest one to T. clusii. The pollen grains were oblong, trizoncolporate and triangular-obtuse in polar view and exine surface were regular or irregular reticulate. A cluster analysis divided the examined species into five groups. T. fragiferum and T. clusii were allocated in two different groups. T. physodes joined to T. spumosum of section Mystillus in another group. T. tumens was seperated in a different group and three annual species, T. resupinatum, T. tomentosum, T. bullatum were classified in another group. The relatedness of T. spumosum to sect. Vesicaria is very high, which can be classified in the same section. A Factor Analysis indicated that characteristics were the most sources of variation compared to other grains. .

P1177. Phylogeny and taxonomy of the genus Lotus (Leguminosae): evidence from nrITS sequences and morphology

G. V. Degtjareva, **T. E. Kramina**, D. D. Sokoloff, T. H. Samigullin, C. M. Valliejo-Roman;
Moscow State University, Moscow, Russian Federation.

Lotus is the largest genus of the tribe Loteae. It includes important crop plants and a model legume, Lotus japonicus. Taxonomy of Lotus is complicated, and a comprehensive taxonomic revision of the genus is needed. We have conducted phylogenetic analyses of Lotus based on nrITS data and morphological characters. We have included a lot of species not used in previous molecular (Allan et al. 2003, 2004) and morphological (Arambarri 2000) phylogenetic studies. Most important conclusions are: (1) previous findings that Dorycnium and Tetragonolobus cannot be separated from Lotus at the generic level are well supported; (2) L. creticus should be placed into section Pedrosia rather than into section Lotea; (3) wide treatment of section Ononidium is unnatural; (4) section Lotus, in its traditional circumscription, is not monophyletic; (5) L. aegaeus is closest to L. gebelia; (6) segregation of L. shimperi and allies into section Chamaelotus (Kramina & Sokoloff 2003) is well supported.

P1178. Evolution in the tribe *Hedysareae*

M. Ranjbar, R. Karamian;
University of Bu-Ali Sina, Hamadan, Islamic Republic of Iran.

5 genera of Iranian Hedysareae tribe (Fabaceae) have been studied. *Taverniera* (3 spp.), *Alhaji* (1 spp.), *Eversmannia* (1 spp.), *Hedysarum* (16 spp.), *Onobrychis* (64 spp.). The systematic position of these genera in Hedysareae was studied using testa micro- and macromorphology. Structure, distribution and taxonomic importance of foliar stomata in specimens of these taxa have been studied. In the specimens belong to the genus *Taverniera* (primitive genus) and *Eversmannia* (advanced genus), four stomatal types, anisocytic, staurocytic, brachyparacytic and anomotetracytic have been recognized. Apomorphic and plesiomorphic states are suggested for seed testa, phytodermological and morphological characters. Shrubby habit with long internodes simple leaves, short and few flower, reticulate sculpturing on seed coat, and dominance stomatal types anisocytic and staurocytic are the most important plesiomorphies, often observed in primitive genus tribe as *Taverniera.* Woodiness represents an advanced state in *Eversmannia.* Woodyfication along with simple leaves and reticulate pattern is a primitive state in tribe Hedysareae*.*

P1179. Taxonomy of *Heteropterys* subsection *Stenophyllarion* (Malpighiaceae) in Brazil

R. Sebastiani, **M. C. Mamede**;
Instituto de Botânica, São Paulo, SP, Brazil.

Heteropterys is the second largest genus of Malpighiaceae, showing as autapomorphy the schizocarpic fruit, with each mericarp with a large dorsal wing with inferior margin thickened. *Heteropterys* comprises two subgenus, four sections and six subsections. Recent studies pointed out the monophyletism of subsect. *Stenophyllarion*. The species of this group occur as vines from Southeasteam states of Brazil to Argentina, mostly in the Atlantic coastal forests, and are characterized by the petiole glandular at the base, the leaves glabrous or glabrate and the umbells with small short-peduncled flowers. Field work, anatomical studies and analysis of herbarium collections (including types) allow us to accept eight species: *H. crenulata*, *H. fluminensis*, *H. intermedia*, *H. leschenaultiana*, *H. pauciflora*, *H. microcarpa*, *H. wiedeana* and one new species. Many new synonyms were proposed and lectotypes designated, specially when original collections were based on syntypes.

P1180. A systematic analysis of *Heteropterys* (Malpighiaceae) based on molecular data

A. M. Amorim[1,2], C. C. Davis[3], W. R. Anderson[3];
[1]Universidade Estadual de Santa Cruz, Ilhéus, Brazil, [2]Herbarium

CEPEC, Ilhéus, Brazil, [3]University of Michigan Herbarium, Ann Arbor, MI, United States.

Heteropterys is the largest genus of Malpighiaceae with ca. 140 species. All species are found in the Neotropics except *H. leona,* which occurs in both the Caribbean and coastal West Africa. The genus is characterized by a noteworthy synapomorphy: the dorsal wing of the samara is elongated and thickened along the abaxial edge, and the lateral wings are strongly reduced or absent. A molecular phylogenetic analysis was performed on the genus using plastid (matK, nadhF, rbcL, trnL-F) and nuclear (nrITS, PHYC) sequence data. Independent and combined analyses show similar results: the genus is monophyletic, and subgenus *Parabanisteria*, subsections *Aptychia* and *Stenophyllarion* (subg. *Heteropterys*), and series *Metallophyllis* (subg. *Heteropterys*) all form well-supported clades. The series *Madarophyllis* are included with *Metallophyllis* clade and the subgenus *Heteropterys* and series *Xanthopetalis* not reveal a monophyletic group. However, future rearrangements will be necessary to improve the infrageneric taxonomy of the genus. This study provides comments on representative taxa, geographical distribution, habitat, and pollen morphology.

P1181. Phylogenetic relationships of Quiinaceae (Malpighiales): insights from trnL-trnF sequence data

J. V. Schneider[1], U. Swenson[2], G. Zizka[3];
[1]Spezielle Botanik, Universität Leipzig, Leipzig, Germany, [2]Dept. of Phanerogamic Botany, Swedish Museum of Natural History, Stockholm, Sweden, [3]Botanik und Molekulare Evolutionsforschung, Forschungsinstitut Senckenberg & J. W. Goethe-Universität Frankfurt, Frankfurt / Main, Germany.

The small neotropical family Quiinaceae, together with Ochnaceae and Medusagynaceae, forms a well-supported clade within Malpighiales. Phylogenetic analyses using molecular data (rbcL, ndhF, 18S) have resulted in unclear relationships and/or delimitation of these three families, the reason why they recently were merged into Ochnaceae sensu lato. In order to provide further insights into their relationships, we analysed DNA sequences of the trnL-trnF region of the plastid genome in combination with morphology. Quiinaceae were recovered as a well-supported monophyletic group with Medusagynaceae as the closest sister taxon. Both lineages form the sister group to Ochnaceae. Reconstruction of the breeding system modes showed that perfect flowers (*Froesia*) are the ancestral state in Quiinaceae, while dioecy (*Lacunaria*) and androdioecy (*Quiina*, *Touroulia*) are derived.

P1182. Leaf morphology, anatomy and ultrastructure in four European Salix species

M. Guzicka, D. Tomaszewski;
Institute of Dendrology, Kórnik, Poland.

Four European *Salix* species were analyzed: *S. alba*, *S. triandra*, *S. viminalis* and *S. purpurea*. The taxa belong to two subgenera and different sections. Preliminary observations showed a marked interspecific variation in leaf morphology, mainly concerning formation of the wax layer. A detailed analysis using SEM revealed that the layer varies from an amorphous film (*S. viminalis*) to large crystalloid structures (*S. alba*). Additional anatomical and ultrastructural investigations with LM and TEM provided valuable information, which supplements the scarce published data. Anatomical investigations involved traits like: leaf blade thickness, stomata density, epidermis and hypodermis thickness, number of cell layers in palisade and spongy mesophyll. Interspecific variation was proved also by ultrastructural analysis. The study revealed substantial differences between the four taxa, which could be important for taxonomic research on the genus *Salix*.

P1183. Biosystematics and chorology of the genus Nymphaea L. (Nymphaeaceae) in Sardinia (Italy).

M. Urbani, G. Becca, M. Schintu;
Dipartimento di Botanica ed Ecologia vegetale, Sassari, Italy.

Nymphaea L. is a cosmopolitan genus composed of ca. 50 species divided into five subgenera. Among them the subgenus *Nymphaea* Planchon [=subgen. *Castalia* (Salisb.) DC.], characterized by diurnal anthesis, is present in the Mediterranean region, Sardinia and Sicily islands included, with one species *N. alba* L. Recently, the presence of this taxon in Sardinia and Sicily was given as "probably extinct" or "perhaps extint". In this note the results of one-year-long observations on five natural populations, selected and sampled mainly in the N-NW Sardinia, are reported and the presence of *Nymphaea* in the island is obviously confirmed. Through the study of flower, fruit and seed morphology, rhizome and leaf morphology and anatomy and from first observations on phenology and reproductive biology, the attribution of the Sardinian "morphotypes" to the taxon *N. alba* is discussed. A citotaxonomic study, based on chromosome counts from germinating seeds is also presented.

P1184. Diversity of putative nymphaealean waterplants in the Lower Cretaceous of the Araripe Basin, Brazil

B. A. R. Mohr[1], M. E. C. Bernardes-de-Oliveira[2,3], C. M. Castro-Fernandes[3];
[1]Museum of Natural History, Institute of Palaeontology, 10 115 Berlin, Germany, [2]Laboratory of Geosciences, University Guarulhos, Guarulhos (SP) 07023-070, Brazil, [3]Institute of Geosciences, University of Sao Paulo, Sao Paulo (SP) 05508-080, Brazil.

The Aptian Crato Formation (Sergipea variverrucata palynozone) of NE Brazil contain angiosperm remains, mostly magnoliids. These include three taxa of water plants with nymphaealean features, such as creeping rhizomes and peltate leaves. The first taxon bears thin ovate petiolate peltate small leaves with actinodromous venation. Solitary flowering structures on peduncles also derive from the rhizome. The flowers contain up to 12 apocarpous free carpels, including small seeds with hilum, that are spirally attached to the flat receptacle. Carpel arrangement and seeds are similar to the Cabombaceae. The second taxon has petiolate, nearly orbicular, crenate, actinodromous leaves. Floral features are missing, but its general habit is close to that of members of extant Nymphaeaceae. The third taxon, also characterized by a horizontal rhizome with roots, bears relatively large petiolate peltate leaves with an entire to slightly sinuate margin and an actinodromous venation. One solitary multipartite flower sits on a thick peduncle of which the anatomical features are preserved. This plant might belong to the Nymphaeales or alternatively to the Nelumbonaceae.

P1185. White water-lily flowers behavior (*Nymphaea candida* J. et C. Presl.) in different photoperiods

E. Y. Peskova[1], P. A. Volkova[1], S. I. Sonina[2], A. B. Shipunov[3];
[1]Moscow State University, Moscow, Russian Federation, [2]Moscow State Social University, Moscow, Russian Federation, [3]Institute of Information Technologies, Moscow, Russian Federation.

Water lily (*Nymphaea*, Nymphaeaceae) flowers are established as a good example of "plant clock". Our aim is to find the main factors that cause the behavior of *Nymphaea candida* flowers in natural habitat during different photoperiods.

Continuous observations were held during three field seasons on 41 flowers in Northern Russia population for six 24-hours days in Arctic day photoperiod; and 91 flowers in Middle Russia for 15 days in natural conditions, plus also in experiments without light and with single flash illumination in the mid-night. We estimated the degree of openness and degree of submergence of each flower.

Common tendencies for the change of flower openness look like circadian cycles. The degree of flower submergence changes with hardly seen periodicity, which usually expressed in weak nonlinear trend. Therewith, we observed coordinated changes of flower openness and flower submergence in one lake of Northern Russia and did not observe them in the other lake.

We propose that flower openness and flower submergence change independently of each other and their changes are synchronized by the changing of dark and light day-periods.

P1186. Host specialization in *Orobanche foetida*

M. M. Rojas[1], D. Rubiales[2], J. I. Cubero[2], J. C. Sillero[1];
[1]IFAPA-CIFA, Cordoba, Spain, [2]IAS-CSIC, Cordoba, Spain.

Orobanche foetida is widely distributed in Mediterranean area on wild legume plants, but has not been reported on cultivated legume species, except on faba bean in Tunisia.

A population of *O. foetida* collected on *Astragalus lusitanicus* in Spain and another population collected on faba bean in Tunisia were studied to compare the pathogenicity on faba bean. The Spanish population was no infective on faba bean and seeds were poorly stimulated by all faba bean accessions. However, a substantial proportion of geminated seeds were able to contact and start attachment of faba bean roots, although failed to get established due to a frequent hypersensitive like host root cells reaction. On the contrary, the Tunisian population was very infective on faba bean and seeds germinated profusely in all faba bean accessions, with a higher success in attachment to faba bean roots and almost null hypersensitive like reaction, resulting in a high establishment. Some genotypic variation in resistance was observed in faba bean germplasm. Resistance against *O. crenata* was not operative against *O. foetida*, with the exception of cv. Baraca, the most resistant to both species.

P1187. Evolution of phytochromes in parasitic Orobanchaceae

J. R. Bennett[1], S. Mathews[2];
[1]Natural History Museum, London, United Kingdom, [2]Arnold Arboretum of Harvard University, Cambridge, MA, United States.

The evolution of heterotrophy in plants may involve the evolution of new morphological features such as haustoria, but there may also be reduced selective pressure for the maintenance of features associated with photosynthesis. Some developmental processes mediated by phytochrome photoreceptors, such as leaf and chloroplast development and the expression of photosynthetic genes are altered in parasitic plants. Orobanchaceae contains both holoparasitic and hemiparasitic species and so offers a system in which to investigate how the functions of phytochromes might be altered in parasitic plants. We have used DNA sequences of *PHYA*, the gene encoding phytochrome A, to infer a phylogeny for the family. The well-supported gene phylogeny suggests that at least some hemiparasites and holoparasites have two copies of *PHYA* and that some *PHYA* genes harbor novel introns. There is also evidence that *PHYA* sequences are evolving under relaxed constraints and we are investigating patterns of molecular evolution in more detail to determine whether selective pressures change along branches to major clades or whether they might be closely correlated with shifts in habit.

P1188. Genetic diversity in two variants of *Orobanche gracilis* Sm. [var. *gracilis* and var. *deludens* (Beck) A. Pujadas] from different regions of Spain

B. Roman[1], R. Hernandez[2], A. Pujadas[2], J. Cubero[2], D. Rubiales[3], Z. Satovic[4];
[1]IFAPA - CIFA, Cordoba, Spain, [2]ETSIAM - UCO, Cordoba, Spain, [3]IAS - CSIC, Cordoba, Spain, [4]Faculty of Agriculture, Zagreb, Croatia.

The pattern of genetic variation among populations of two taxa of *Orobanche gracilis* Sm. [var. *gracilis* and var. *deludens* (Beck) A. Pujadas] from Northern and Southern Spain growing on different hosts was analysed using RAPD markers. The Dice's distance matrix was analyzed by UPGMA method and the resultant dendrogram clearly divided populations by region and botanical variety with the Southern populations being more differentiated among them in both cases (var. *gracilis* and var. *deludens*). Concerning *O. gracilis* var. *deludens*, the dendrogram has also shown host differentiation between populations growing on two different species, *Ulex baeticus* and *Ulex parviflorus*. A complementary analysis of principal coordinates (PCoA) confirmed these results. The analysis of molecular variance (AMOVA) indicated that the lowest level of differentiation was found among the Northern *O. gracilis* var. *gracilis* populations whereas in the case of *O. gracilis* var. *deludens* from the South most of the genetic diversity was attributable to differences among populations.

P1189. Hemiparasitism: a way station to holoparasitism or an evolutionary stable strategy?

J. E. Armstrong;
Illinois State University, Normal, IL, United States.

Is hemiparasitism an evolutionary stable strategy (ESS) or just a way station on the road from autotrophy to holoparasitism? Studies on the obligate hemiparasite *Pedicularis canadensis* (Rhinanthaceae) suggest that in prairie communities where nutrients or water are very limiting factors, parasitism is an adaptation both for enhancing acquisition of nutrients, particularly nitrogen, and/or water and for enhancing photosynthesis, thus maintaining both systems. The presence of the hemiparasite even enhances species diversity by extracting a higher cost upon dominate species, like grasses, in comparison to ephemerals like shooting star, *Dodecatheon meadia*. This lousewort species also inhabits forest communities in eastern North America where the prairie model predicts increased gain via parasitism without enhancing photosynthesis. If so, the lousewort's photosynthetic potential should decline in forest communities shifting the balance toward holoparasitism.

P1190. Anatomical features of the stem structure in the *Orobanchaceae*

E. O. Korol`kova;
Moscow State Open Pedagogical University, Moscow, Russian Federation.

All the of *Orobanchaceae* are parasitic plants without chlorophyll. This family consists of nearly 225 species belonging to 16 genera. The anatomical structure of the stem sin 87 species of 13 genera has been studied.
In connection with parasitic way of life this plants have very simple morphological structure. Their anatomical structure become more develop, especially their excretory system. There are two excretory mechanisms (by the glandular hairs in *Orobanche*, and by the epidermal cells in *Cistanche*) were found.
As the anatomical data on stem structure shown, the *Orobanchaceae* is a natural taxon that should not be regarded as subfamily *Orobanchoideae* of the family *Scrophulariaceae*. The taxonomic position of the genus *Lathraea* in *Scrophulariaceae* is confirmed, however, by its stem anatomy. The diagnostic value of some stem features of *Orobanchaceae* has been established. The sections of genera *Orobanche* and *Cistanche* are well distinguished by features of stem anatomical structure.

P1191. The Figwort Family (Scrophulariaceae Juss.) in Belarussian Flora

M. A. Jus;
Belarussian State University, Minsk, Belarus.

Scrophulariaceae is one of the largest family of Angiosperm in the temperate areas of the North hemisphere. The objects of our investigation include aboriginal and synantropical components of Scrophulariaceae (incl. Orobanchaceae Vent.) in Belarus. The work comprises critical taxonomic revision of complex groups, nomenclatural, caryological, ecological and phytocoenological information about all species of Figwort family in this region, with an issue of 8 years work of the author, with field experiences and revision of more than 7 000 specimens of the herbaria KRAM, KW, LE, LECB, LW, LWS, MHA, MSK, MSKU, MW, WIR etc. The phytogeography of the Scrophulariaceae in this region is compared to the flora in other neighbour areas (Poland, Baltic countries, adjacent regions of the Ukraine and Russia). Among the main contributions in our work are also presented an analytical key for the identification of the taxa, dot maps of the distribution of the endangered, rare and critical species, as well as information about protection and sustainable use of representatives of the Figwort family in Belarus.

P1192. Phenetic analyses of morphological traits in the Alectra sessiliflora complex (Orobanchaceae)

J. J. Morawetz, A. D. Wolfe;
The Ohio State University, Columbus, OH, United States.

Alectra (Orobanchaceae) is a genus of primarily hemiparasitic herbs. *Alectra sessiliflora* var. *sessiliflora*, var. *senegalensis* and var. *monticola* form a morphologically cohesive group with overlapping distributions throughout sub-Saharan Africa, and are characterized by sessile yellow flowers and a branching habit. Traditional characters used to distinguish varieties were stamen filament pubescence or calyx pubescence. These characters are degenerate, preventing confident placement of a single specimen within one variety. This difficulty suggests that the taxonomic delimitations may not be meaningful. A phenetic study was undertaken to determine if this complex is best treated as a single large polymorphic taxon, or as a series of similar yet discrete taxa. Seventeen morphological characters were examined on 134 operational taxonomic units (OTUs), and the data were analyzed using UPGMA, PCA and discriminant analyses. Discrete clusters were not identified by the analyses.

P1193. Distribution patterns of the genus Piper (Piperaceae) in a South-Ecuadorian montane rain forest

B. Hell;
Faculty of Biology, Bielefeld, Germany.

The studies were conducted in the area of the Estacion Cientifica San Francisco which is situated on the eastern slope of the

Cordillera El Consuelo in Southern Ecuador. The data were obtained from 15 permanent plots in ravines and ridges along an altitudinal gradient between 1850 and 2450 masl. All (morpho-) species of the genus Piper were registered with height and diameter. 701 individuals belonging to 21 species were counted and identified. Data on abiotic factors obtained by former investigations were used to explain observed distribution patterns. The results indicate no significant impact by the altitudinal gradient on the number of species per plot. There are significant differences in species composition and distribution between ridge and ravine forests. The overall species richness is higher in the ravine forests plots. About half of the species identified are exclusively abundant in the ravines whereas the other half are common in both, ravines and ridges. Ridge forests comprise only a small amount of unique species. The average number of individuals and species of Piper per plot are significantly larger in the ravine forests.

P1194. Heterotopic expression of petal identity gene homologs in petaloid-bracts of *Houttuynia cordata*.

K. Hosokawa[1], M. Imafuku[1], Y. Tanabe[1], S. Aoki[1], K. Uehara[2], M. Hasebe[3], M. Ito[1];
[1]Grad. Schl. Arts and Sci., Univ. Tokyo, Tokyo, Japan, [2]Fac. Hort., Chiba Univ., Matsudo, Japan, [3]Natl. Inst. Basic Biol., Okazaki, Japan.

Heterotopy has been thought to be involved in the evolution of some novel structures in plants as well as animals. Petaloid-bracts are often associated with the evolution of pseudanthia and are reported from many angiosperm taxa. However, genetic mechanisms underlying their evolution are largely unknown. Recent molecular genetics studies showed that MADS-box genes play a key role in determining floral organ identity in flowering plants. One of the possible mechanisms responsible for the evolution of petaloid-bracts is heterotopic expression of petal identity genes in their development. To test this hypothesis, we cloned MADS-box genes from *Houttuynia cordata* (Saururaceae), which forms pseudanthia with white petaloid-bracts. Expression analyses of these genes by RT-PCR and *in situ* hybridization revealed that putative orthologs of the genes necessary and sufficient to determine petal identity in *Arabidopsis* are expressed in petaloid-bracts of *H. cordata.* Based on these results, we will discuss genetic control of petaloid-bract development and its evolution in *H. cordata.*

P1195. Phylogeny of the western Mediterranean species of the genus Aristolochia (Aristolochiaceae)

S. Wanke, K. Petzold, S. Prieskorn, R. Kaden, C. Neinhuis;
Institut für Botanik, Dresden, Germany.

Molecular results inferred the Mediterranean species as the most derived Aristolochiaceae, being part of an extended genus Aristolochia. An Asian origin of the paleotropical and mediterranean representatives has been considered in previous analyses. So far, the relationships and taxonomy within this clade are not yet specified and are discussed controversially. Current understanding of relationships is based only on morphological characters.

A phylogeny, based on coding and non-coding chloroplast sequences of the Mediterranean Aristolochia species is presented with insights into evolution, radiation and phylogeography. All clades gain maximum support. Aristolochia in the Mediterranean in total is monophyletic with the two Mediterranean lianas forming a monophyletic clade as well. Relationships previously proposed within the tuber-forming taxa, could not be confirmed. The multiple independent evolution of the geophytes is interpreted as an adaptation to different habitats.

P1196. Molecular phylogeny and revision of Aristolochia sensu lato (Aristolochiaceae), as inferred from rbcL, matK, and PHYA genes

T. Ohi-Toma[1], T. Sugawara[2], H. Murata[3], S. Wanke[4], C. Neinhuis[4], J. Murata[1];
[1]Botanical Gardens, The University of Tokyo, Tokyo, Japan, [2]Makino Herbarium, Tokyo Metropolitan University, Tokyo, Japan, [3]Faculty of Pharmaceutical, Setsunan University, Osaka, Japan, [4]Technical University Dresden, Dresden, Germany.

Taxonomic treatments of the genus Aristolochia sensu lato (400 spp.) have been ambiguous and controversial, especially on the generic status. In a recent cladistic analysis by morphological characters, it was proposed that it should be divided into four genera of two subtribes. To elucidate the phylogenetic relationships within the genus Aristolochia sensu lato, this study reconstructed the phylogeny on the basis of nucleotide sequences in chloroplast rbcL gene and the nuclear encoded phytochrome A (PHYA) gene for representative speceies, and those of matK gene for ca. 90 spp. All phylogenetic trees by three genes indicated that Aristolochia sensu lato consisted of two major lineages. The only matK phylogeny showed that each of two lineages included two sublineages, respectively. The chromosome numbers were also congruent the phylogeny. Considering the phylogeny, morphology, and chromosome numbers, we propose a revised system that classified Aristolochia sensu lato into two genera and four subgenera; Aristolochia subgenera Aristolochia and Pararistolochia, and Isotrema subgenera Isotrema and Endodeca.

P1197. Chloroplast DNA variation and geographic structure of the Aristolochia kaempferi group

K. Watanabe[1], T. Kajita[2], J. Murata[1];
[1]Botanical Gardens, Graduate School of Science, The University of Tokyo, Tokyo, Japan, [2]Department of Biology, Faculty of Science, Chiba University, Chiba, Japan.

The present study documents cpDNA variation in the Aristolochia kaempferi group (Aristolochiaceae), which consists of one Chinese and all Japanese and Taiwanese species of subgenus Siphisia, i.e. A. kaempferi, A. liukiuensis, A. shimadai, A. cucurbitifolia, and A. mollissima. Phylogenetic analysis based on the nucleotide sequences of matK gene, atpB-rbcL and trnS-trnG intergenic spacers of 138 individuals from 95 populations over their entire distribution range in Japan and Taiwan were carried out. A total of 38 haplotypes recognized in the analysis formed distinct six clades, that were not consistent with previous taxonomic classifications. However, the clades had significant association with geographic distribution of haplotypes, that was tested by the nested clade analysis (NCA). Phylogeographic processes inferred by NCA were consisted with hypothesis of range expansion from some refugia after the last glacial maximum. The cpDNA phylogenies being better correlated with geographical distribution than with taxonomic boundaries in the A. kaempferi group may suggest the possibility of hybridization and introgression, and / or parallel evolution.

P1198. Phylogeny and biogeography of Piper sect. Macrostachys (Piperaceae)

E. J. Tepe, M. A. Vincent, L. E. Watson;
Miami University-Department of Botany, Oxford, OH, United States.

Phylogenetic and biogeographic patterns were examined in the Neotropical *Piper* sect. *Macrostachys* (Piperaceae) using ITS sequence data. *Piper* sect. *Macrostachys* is composed of 35-50 species with centers of diversity in Ecuador and southern Colombia, and southern Central America. Low levels of molecular divergence suggest that this section has undergone rapid and recent diversification and this hypothesis was tested with a molecular clock. Although analyses produced only partially resolved trees, our results strongly support a monophyletic sect. *Macrostachys* and several well supported internal clades that largely correspond to morphological groupings and geographic areas. Because of the low resolution in the phylogeny and the finding that the basal most species of the section are widespread, the geographic origin of the section remains unclear. Our results do suggest, however, that diversification in *Piper* sect. *Macrostachys* did not occur over a long time in a stable tropical climate, but rather was linked with geologic and climatologic events associated with the uplift of the Andes and the Isthmus of Panama over the past 2-5 million years.

P1199. The Phylogeny and Taxonomy of Magnoliaceae

D. L. Fu;
Nontimber Forestry Research and Development Center, Chinese Academy of Forestry, Zhengzhou 450003, China.

The family Magnoliaceae is one of the most primitive groups of angiosperms and has played an important role in the research of the origin, evolution and systematics of flower plants. In this paper author has reviewed the history and new progress of taxonomic and phylogenetic research, especially the controversial views and insufficiencies of current systems such as Y. H. Law's (1998) and R. B. Figlar & H. P. Nooteboom's (2004). Some important species with special taxonomic meanings are discussed and some new taxa are described. Moreover the new phylogenic viewpoints, new cladogram and new system of the family are put forward. The system includes 3 subfamilies: Michelioideae (Law) D. L. Fu, subfam. comb. nov., *Magnolioideae* and Liriodendroideae (Bark.) Law, 5 tribes: Michelieae Law, Yulanieae D. L. Fu, trib. nov., Alcimandrieae (Law) D. L. Fu, trib. comb. nov., Magnolieae and Kmerieae D. L. Fu, trib. nov., 10 genera: *Michelia* L., *Paramichelia* Hu, *Yulania* Spach, *Alcimandra* Dandy, *Gynopodium* (Dandy) D. L. Fu, gen. comb. nov., *Magnolia* L., *Talauma* Juss., *Pachylarnax* Dandy, *Kmeria* (Pierre) Dandy and *Liriodendron* L..

P1200. Evolutionary patterns in Afro-Malagasy *Monodora* and *Isolona* (Annonaceae)

T. L. P. Couvreur[1], T. D. Deroin[2], M. Sosef[1], J. E. Richardson[1];
[1]Nationaal Herbarium Nerderlands, Wageningen, The Netherlands,
[2]Museum National d'Histoire Naturelle, Paris, France.

A systematic and anatomical study of the genera *Monodora* (c. 14 spp.) and *Isolona* (c. 19 spp.) is being undertaken as part of a revision of all African Annonaceae. Both genera have a tropical African distribution, with *Isolona* also present in Madagascar. They have paracarpic gynoecia, which are unique within the family, but they differ in the number and arrangement of the carpels. A molecular phylogeny of Annonaceae using plastid DNA sequences confirmed the monophyly of these two genera. However, *Monodora* and *Isolona* are distinct in their perianth morphology (weak gamopetaly, foliaceous and differentiated petals in two whorls *vs.* advanced gamopetaly, thick and equal sized petals in one whorl) and palynology (tetrads *vs.* monads) suggesting divergent pollination syndromes. A taxonomic revision is underway with a few newly identified species particularly from Tanzania. Generation of a phylogeny of both genera and their putative sister taxa using plastid and nuclear genes as well as morpho-anatomical characters, will be used to determine evolutionary patterns and to reconstruct the biogeographical history in the context of other tropical African taxa.

P1201. Factors limiting fruit production in Aristolochia paucinervis Pomel

R. Berjano, M. Arista, P. L. Ortiz, S. Talavera;
Departamento de Biología Vegetal y Ecología. Universidad de Sevilla, Sevilla, Spain.

Factors determining the fruit set of Aristolochia paucinervis Pomel (Aristolochiaceae) were studied in two different populations located in SW Spain during two consecutive years. This species is a Mediterranean tuberous perennial herb with protogynous trap flowers. To perform this study, flower production, fruit initiation, fruit abortion, fruit predation and fruit production were quantified. Aristolochia paucinervis showed a low fruit set in both populations during these two years. Low fruit initiation was the main factor limiting fruit production. Analysis of pollen tubes in stigmas suggested that the low fruit initiation was a consequence of deficient pollination. On the other hand, about 50% of the flowering plants did not initiate any fruit . The correlations found between the tuber weight and the number of flowers and fruits could indicate a gender diphasy situation, i. e. smaller plants only contribute to male function as pollen donors while bigger plants are hermaphodites. Thus, gender diphasy and deficient pollination explain the low fruit set found in Aristolochia paucinervis.

P1202. Contributions to karyosystematic of *Veronica* L. (*Scrophulariaceae*)

J. A. Sánchez Agudo, M. Martínez-Ortega, F. Gallego Martín, J. Sánchez Sánchez, E. Rico Hernández;
University of Salamanca, Salamanca, Spain.

The genus *Veronica* is characterized by a great karyologycal variability. Only in the annual taxa, more of six basic numbers have been found: 6, 7, 8, 9, 13 and 15. Anfiploidy and poliploidy together with other somatic processes have originated a lot of chromosome numbers and several ploidy levels.

This work is focused on the karyosystematic of some of the annual *Veronica* species present at the Iberian Peninsula and belonging to subgenus Cochlidiosperma (*V. panormitana*, *V. trichadena*, *V. cymbalaria*, *V. sibthorpioides*, *V. triloba*, *V. hederifolia*), Pellidosperma (*V. praecox*, *V. triphyllos*), Triangulicapsula (*V. chamaepithyoides*), Pocilla (*V. polita*, *V. agrestis*, *V. persica*, *V. filiformis*) and Chamaedrys (*V. verna*, *V. dillenii*). Some extraiberical taxa have also been considered in order to check the validity of some hypothesis about phylogeny and some correlations between ploidy level and other taxonomical characters, such pollen size or seed coat-type.

P1203. Diversity of seed funicles in Scrophulariaceae s.l. and related families of the Lamiales

C. A. Rebernig, A. Weber;
Centre of Botany, Vienna, Austria.

The delimitation and taxonomy of Scrophulariaceae is still under debate. Among morphological characters, seed morphology is of great importance. However, little attention has been paid to the fact how the seeds are attached to the placenta and if the seed funicle provides systematically valueable characters. 26 genera/39 spp. of Scrophulariaceae s.l. were investigated by means of SEM. The study enabled recognition of 6 types, which partly correlate well with subgroups of Scrophulariaceae. The *Digitalis*-type, for example, is characteristic of the tribes Verbasceae, Digitalieae and Veroniceae (sensu Fischer, 2004); the *Manulea*-type is concentrated in tribes Alonsoeae, Aptosimeae and Manuleae, all centred in South Africa. Study of development and abortive ovules showed that the seed funicle is rather part of the placenta than part of the ovule. Random tests in other families of Lamiales showed that there are no seed funcles comparable to those of Scrophulariaceae.

P1204. Pollen morphology of some species of the the genus *Veronica* in Iran

S. Saeidi-Mehrvarz[1], M. Zarrei[2];
[1]Faculty of Science,Guilan University, Rasht, Islamic Republic of Iran,
[2]Faculty of Science,Tehran University, Tehran, Islamic Republic of Iran.

Iran is an important centre of diversity of this genus, with 56 species, among them 18 endemics (Saeidi, 2000). Pollen morphology of 17 species as representatives of five sections within *Veronica* distributed in Iran were examined by LM and SEM. Detailed pollen morphological characteristics are given for these species. Of these, 6 were not studied so far. Pollen samples were acetolyzed. Length of equatorial and polar axis were measured with aid of a ×100 eyepiece. Measurement of grains was based on 30 grains per sample. Pollen grains are shed as monads. They are tricolpate (with three, equidistant, furrow-like apertures that are perpendicular to the equator which are meridional), or tetracolpate, isopolar and boat-shaped-oblong to spherical in equatorial view. They are also euprolate, radio-symmetric. Exine is tectate-columellate. The type of rugulate-perforate is more frequent between species examined and occurs in 14 species. Types of microreticulate and scabrate also observed in *V. beccabunga* and *V. hederifolia,* respectively.

Our results confirm the eurypalynous character of the genus suggested by Hong (1984) and Fernandez et al.(1997).

P1205. Anatomical studies in relation taxonomy of Persian Plantago species

F. Sharifnia;
Islamic Azad university north Tehran branch, Tehran, Islamic Republic of Iran.

Abstract: The present survey was performed on sixtheen Persian *Plantago* species,and some of stractural differences between the sections of the 16 species were evident.Thus we could see the contrast between the stractural stem.This structures are follows:circular structure with scattered hairs in Sect.Coronopus,stellate stracture in Sect.Arnoglossum,circulare and undulate in Sect.Plantago and AA.

Stems have a range from no hair to a very hairy state,also in species which have hairy stems a ligneous cell is visible in the base of hair.

There is a layer of sclerenchyma fibres after the different layers of the cortex.This layer is placed similar to stem plan.The primitive specis that is belong to Psyllium subgenus have more wooden parts than the advanced species that is belong to Plantago subgenus.In comparison between two subgenus,the species Psyllium subgenus have a thicker fibrous layer than the species Plantago subgenus.It seems as if the vascular boundles are inside this fibrous layer.

P1207. Study of micromorphology *Linaria Sec. Linaria* (*Scrophulariaceae*)in Iran.

M. Hamdi[1], M. Assadi[2];
[1]Islamic Azad of University, Garmsar, Garmsar, Islamic Republic of Iran, [2]Research Institute of Forest & Ranglands P. O. Box: 13185 - 116, Tehran, Islamic Republic of Iran.

The genus of *Linaria* (Scrophulariaceae) contain 150 species in the world. From these species 32 occur in Iran. The genus has been divided in 7 section on the base of shape and ornamentation of seed. Sec. *Linaria* have disc form winged seed. This section are variation species that almost distribution in extent of Iran. this section contain 50 species in world that 20 species occur in Iran. In this investigation to use of shape and ornamentation of testa cell seed and capsule, pollen, anatomy of stem and leaf that determined 5 new species from *Sec. Linaria* are for flora of the worldS. this investigation on morphological, pollenology, testa cell ornamentation, shape and surface seed and capsule to used SEM and anatomy stem and leaf. The specimens were collected from different regions in Iran and after recognition. Were studied for Numerical taxonomic studies, 70 qualitative and quantitative characters of morphological, pollen, seed, capsule and anatomy were selected for each specimen and finally species.

P1208. Wulfeniaceae Lakusic - New Family in Order Scrophulariales

R. D. Lakusic;
Faculty of Science and Mathematics, Banja Luka, Bosnia and Herzegovina.

There is new family described in the order Scrophulariales. It is named Wulfeniaceae and it includes following genuses: *Wulfenia* Jacq., *Wulfeniella* Lakusic, *Synthyris* Benth. and *Lagotis* Gaertn.
Genus *Wulfenia* Jacq. includes 5 species: *W. carinthiaca* Jacq. Carinthiacs Alps, *W. blecicii* Lakusic on North-East limestone Prokletije mountains, *W. rohlenae* Lakusic on vulkanic Prokletije mountains, *W. orientalis* Boiss. on East Turkey and West Syria mountains, and *W. amherstiana* Benth. on Himalaya mountains. All species have
2n = 18.
Genus *Wulfeniella* Lakusic includes 2 species with 2n = 16: *W. himalayca* (Hook) Lakusic on Himalaya mountains and *W. baldaccii* (Deg.) Lakusic on South-West Prokletija mountains.
Genus *Synthyrys* Benth. with 2n = 24, lives on N. Amerika mountains and includes 5 species: *S. missurica* (Bafin) Penn*, S. pinnatifida* Wats., S. *platycarpa* Gail & Penn., *S. reniformis* (Dougl.) Bentham and *S. stellata* Penn.
Genus *Lagotis* Geartn, which lives in Asia & N. Amerika mountains has 6 species*: L. uralensis* Schischkin, *L. cachmirian, L. glauca* Gaertn., *L. minor* (Willd.) Standl*. & L. tacedana* Miyabe & Tatewaki, with 2n = 22 & *L. missurica* (Rafin) Penn. with
2n = 44*.*

P1209. Taxonomic problems within genera *Callitrichae* in Poland

M. Drapikowska[1], A. BŃczkiewicz[2], K. Buczkowska[2], K. Szoszkiewicz[1];
[1]Depatment of Ecology and Environmental Protection, PoznaŒ, Poland,
[2]Depatment of Genetics, PoznaŒ, Poland.

The genera Callitrichae (water starwort) cover six species in the flora of Poland: C. hermaphroditica, C. hamulata, C. polymorpha , C. palustris (= C. verna), C. stagnalis, and C. platycarpa. These plants are considered to be stenobionts in relation to different enviromental factors, including the level of phosphorous and are used as bioindicators of water eutrophication. An accurate identification of species within Callitriche genera is difficult without developed fruits.
Preliminary studies of genetic variation of *Callitrichae* species were carried out in Poland on the basis of enzymatic protein analysis. The analyzed systems were GOT, ADH and MDH. The number of chromosomes was determined in each sample. Two groups of plants have been separated: with 2n = 10, (C. polymorpha and C. stagnalis - the both popular in Poland and difficult to differentiate), and a group with 2n = 20 (C. platycarpa and C. palustris).
Large morphological variation within the species results from a significant plasticity of individuals adaptable to changing conditions of the environment or from their genetic variation.

P1210. The origin and development of floral shoot and pre-anthesis cleistogamy in *Hydrobryopsis sessilis* (Podostemaceae)

M. Sethi;
Dept of Botany, Miranda House, Delhi, India.

Hydrobryopsis sessilis is a highly reduced, crustose and endemic member of subfamily Podostemoideae that grows attached to rocks in river waters. The dorsiventral plant body (interpreted as a stem) bears floral dwarf shoots all along the dorsal margin. This poster describes the reproductive biology of *Hydrobryopsis sessilis* with special reference to ontogeny of dwarf floral shoots, spatio-temporal relationship of the floral parts, pollination and breeding system. Tracheids differentiate with the onset of flowering. Each floral shoot meristem is deep-seated, tiny, concave, and arises endogenously as a result of lysigeny. The *ab initio* dorsiventrality of the carpels has been seen. A novel feature of the ovules is the occurrence of endothelium. *H. sessilis* is unique as it shows pre-anthesis, complete, constitutional cleistogamy under submerged conditions. A significant finding is the presence of several pollen tubes in the filaments of stamens indicating a trend towards cryptic self-fertilization.

P1211. Studies in Mexican Podostemaceae: physiology in *Marathrum*

M. Collazo-Ortega, K. Jiménez-Durán, D. Guzmán-Merodio, R. Luna-Ramos, A. Novelo-Retana, J. Márquez-Guzmán;
Universidad Nacional Autónoma de México, México, D. F., Mexico.

The study was carried out in the Horcones and Las Juntas Rivers at south of Puerto Vallarta, Mexico. Field studies of leaves photosynthetic rate (ppm CO_2 cm^{-2} min^{-1}), leaves chlorophylls *a* (Chl *a*), *b* (Chl *b*) and carotenoids concentration (mg mL^{-1}), foliar area (cm^2) and biomass in plants of *Marathrum rubrum* and *M. schiedeanum* were conducted during March, June, September and December 2004. In reproductive phase photosynthetic rate was about 0.04051 (*M. rubrum*) and 0.6239 (*M. schiedeanum*); in vegetative phase values was about 1.0466 (*M. rubrum*) and 16.1183 (*M. schiedeanum*). In *M. rubrum* Chl *a* varied from 5.3092 to 8.4519, Chl *b* from 9.2631 to 38.1022 from reproductive to vegetative phase; in *M. schiedeanum* Chl *a* varied from l.579 to 2.9193, Chl *b* from 1.0394 to 5.6195 from reproductive to vegetative phase; carotenoids show a similar behaviour with lower values than chlorophylls. Foliar area was greater in *M schiedeanum* (from 134 to 343 cm^2) than *M. rubrum* (about 30% less); in reproductive phase some plants were observed with leaves in both species, more degradated in *M. rubrum*; this species had generally 20-25% less biomass than *M. schiedeanum*.

P1212. Studies in Mexican Podostemaceae: Morphological and embryological correlation in Marathrum rubrum

D. Guzmán-Merodio, R. Luna-Ramos, M. Collazo-Ortega, A. Novelo-Retana, J. Márquez-Guzmán;
Universidad Nacional Autónoma de México, México, D.F., Mexico.

Species of the Podostemaceae family inhabit tropical river-rapids and waterfalls; these plants grow firmly attached to the rocks. For their appeareance, these organisms have been associated with mosses, briophytes and algae. Podostemaceae constitutes the largest family of strictly aquatic plants. Marathrum rubrum flowers were collected in the Horcones River, Jalisco, Mexico during flowering time (dry season) in 2003 and 2004. This work intends to correlate flower´s external morphology, flower´s position on the rock and the developmental stage of gynoecium and androecium. M. rubrum flowers were classified in five stages, according to the morphological characters they exhibit. The stages proposed were studied and characterized; the first stage begins when flowers still are in the spathella and the last one is when anthers have been lost and the pedicel acquires a brownish color. Ovules and anthers are fully developed since the first stage. Flower positioning on the rock is variable and is not associated with the developmental stage. Correlation exists between the flower length, external morphology and changes within the anthers.

P1213. Studies in Mexican Podostemaceae: Crossed pollination between two species of Marathrum

R. Luna-Ramos, S. Vázquez, M. Collazo-Ortega, A. Novelo-Retana, D. Guzmán-Merodio, J. Márquez-Guzmán;
Universidad Nacional Autónoma de México, México D.F., Mexico.

Podostemaceae (river weeds) is the largest family among aquatic angiosperms. Studies concerning reproductive systems within the family are scarce. Current studies for Marathrum rubrum Novelo & Philbrick and M. schiedeanum (Cham.) Tul. demonstrate the close relation between both species. The study was carried out in the Horcones and Las Juntas rivers, Jalisco, México. Outcrossing studies were conducted between M. rubrum and M. schiedeanum in order to establish the degree of incompatibility. Flowers of M. rubrum were pollinated with pollen from M. schiedeanum and vice versa, prior emasculation and bagging to prevent natural pollination. The presence of pollen tubes in the stigma and placenta was confirmed by observation of flower samples stained with aniline blue in both species. Experimental evidence indicates that incompatibility systems are absent in these particular outcrossings at least before the pollen tube comes in contact with the ovule.

P1214. Developmental anatomy of shoot in aquatic angiosperm Weddellina squamulosa (Podostemaceae)

S. Koi, M. Kato;
University of Tokyo, Tokyo, Japan.

Podostemaceae are a family of aquatic angiosperms growing on rock surfaces in rapids and waterfalls and comprise three subfamilies which about 270 species and about 47 genera. In subfamily Podostemoideae examined the shoot has no apical meristem and new leaves form successively at base of developing young leaves. In Tristichoideae the shoot has an apical meristem and the leaves are formed on its flank. Here we show the unique pattern of shoot developmemt of *Weddellina squamulosa*, the sole species of subfamily Weddellinoideae that is sister to Podostemoideae. The shoot is sympodially branched with branches oriented in a single plane. The shoot has an apical meristem of a tunica-corpus configuration, although it is eventually determinate. A new branch is formed near the base of a developing young shoot but not in the axil. Leaves are formed acropetally and tightly close to each other. Additional leaves are formed basipetally between developed leaves, while the leaves become separated by intercalary growth. The pattern of shoot branching and that of leaf development of *W. squamulosa* is compared with those of subfamilies Tristichoideae and Podostemoideae.

P1215. Molecular Phylogeny of Cameroonian and Ghanaian Podostemaceae

Y. Kita[1], R. Imaichi[2], G. Jean-Paul[3], G. K. Ameka[4], M. Kato[1];
[1]The university of Tokyo, Tokyo, Japan, [2]Japan women's university, Tokyo, Japan, [3]National Herbarium of Cameroon, Yaunde, Cameroon, [4]University of Ghana, Accra, Ghana.

All members of the Podostemaceae grow on rock surfaces in rivers, rapids, and waterfalls with swift running water. To survive in these extreme aquatic habitats, they have evolved unusual morphologies, such as flattened photosynthetic roots. The largest subfamily Podostemoideae has a pantropic distribution; previous molecular phylogenetic studies have analyzed a number of American,Asian species but only two from Africa (Madagascar) where molecular data is scanty. In this study, we examined the molecular phylogenetic relationship of about 20 Cameroonian and one Ghanaian species of the Podostemoideae. In the phylogenetic tree for the chloroplast *matK* gene, all our analyzed African and Madagascan species form a monophyletic group that is a sister clade to the Asian species. Our African species show morphological variation in the flower spathella (inverse vs. erect), plant size (acaulescent to having long shoot), and root (axial, ribbon-like or foliose). The morphological evolution of the African clade is discussed based on this phylogenetic analysis.

P1216. Application of Gliadin Markers to Estimate Biodiversity of *Triticum persicum* and *Triticum pyramidale.*

A. Kharabian Masouleh;
Islamic Azad University.Rasht Branch, Rasht, Islamic Republic of Iran.

We studied the genetic diversity of tetraploid wheats by examining seed storage protein markers at the Gli-A1 and Gli-A2 loci. High rates of electrophoretic polymorphism were detected at the loci studied in two selected species. In *T. persicum* a total of 72 allelic variants at 2 loci were detected, including 41 for Gli-A1 and 31 for Gli-A2 . In the *T. pyramidale* samples, 48 allelic variant were observed. The numbers of alleles were 28 and 20 for Gli-A1 and Gli-A2 respectively. A null allele was detected at the Gli-A1 locus in 1 sample of *T. pyramidale* from Iran. At the Gli-A2 locus of 1 genotype of *T.pyramidale* from Turkey another null allele also was found. No null alleles were observed in the *T. persicum* samples. This observation confirms that in some samples these loci are inactive or semi-active and then some subunits are lacked. Some Iranian populations of *T. persicum* showed high rates of variation, but this variability was not observed in the *T. pyramidale* samples.

P1217. Low variability of internal transcribed spacer rDNA and *trn*L (UAA) intron sequences of several taxa in the *Festuca ovina* aggregate (*Poaceae*)

K. Penksza[1], Z. Galli[2], E. Kiss[3], L. Sági[4], L. Heszky[3];
[1]Szent István University, Department of Landscape Ecology, GödöllŖ, Hungary, [2]HAS-SIU Research Group for Molecular Plant Breeding, GödöllŖ, Hungary, [3]Szent István University, Department of Genetics and Plant Breeding, GödöllŖ, Hungary, [4]Laboratory of Tropical Crop Improvement, Katholieke Universiteit Leuven, Heverlee-Leuven, Belgium.

Identification and classification of numerous *Festuca* species is still a difficult problem due to the close morphological resemblance. The most difficult fine fescues to identify belong to the *Festuca ovina* aggregate, which is the largest group in the genus *Festuca*. In order to evaluate the taxonomic value of DNA-based markers, sequence analysis of the internal transcribed spacer (ITS1-5.8S-ITS2) region and the chloroplast *trn*L (UAA) intron was performed in the ten most problematic fine fescues belonging to the *Festuca ovina* aggregate. Studied species from *F. ovina* group were: *F. pallens, F. vaginata*; species from the *F. valesiaca* group were: *F. dalmatica, F. pseudodalmatica, F. pseudovina, F. rupicola, F. valesiaca*; and species from the transitional group were: *F. javorkae, F. stricta, F. wagneri*.Intraspecific ITS variants were found in a single case while in other cases only intragenomic ITS polymorphisms were detected with 1-2 ambiguous positions. Among the sequences of the *trn*L (UAA) intron even intragenomic polymorphisms were not detected in any of the *Festuca* species studied. Thus, results do not appear to support the species status of these ten taxa.

P1218. A close phylogenetic relationship detected between *Poa* subg. *Andinae* of Patagonia and *Hookerochloa* and *Festucella* of Australia (Poaceae, Pooideae, Poeae): evidence from nuclear and chloroplast DNA sequences and morphology

L. J. Gillespie[1], **A. Archambault**[1], R. J. Soreng[2], S. W. L. Jacobs[3], H. Ma[4];
[1]Canadian Museum of Nature, Ottawa, ON, Canada, [2]Dept. of Botany, Smithsonian Institution, Washington, DC, United States, [3]National Herbarium of New South Wales, Sydney, Australia, [4]Kunming Institute of Botany, Heilongtan, Kunming, China.

Phylogenetic analysis of ITS and trnT-trnF sequences of *Poa* and allies revealed a southern hemisphere relationship between *P.* subg. *Andinae* (coastal and interior wetlands, Patagonia) and *Hookerochloa* and *Festucella* (both of mesic highlands, Australia). The latter two monotypic genera were recently transferred to the Australian-New Zealand genus *Austrofestuca*, all 3 spp. having similar multiflowered spikelets, glabrous ovaries, oval hila, and bearded calluses. However, while both nuclear and plastid data resolve *Austrofestuca* s.s. within *Poa*, ITS data shows a well supported clade of *P.* subg. *Andinae*, *Hookerochloa*, *Festucella*, and *Arctagrostis* (arctic) outside of *Poa* among elements of Alopecurinae, Poinae, and Puccinelliinae. In our trnTF analysis these four taxa plus east Asian montane genus *Aniselytron* (ITS unknown) form a paraphyletic assemblage with similar sequences in a Poinae-Alopecurinae clade excluding *Poa*. Morphological data also support a close relationship among *P.* subg. *Andinae*, *Hookerochloa*, and *Festucella*, but a connection with the 1-flowered spikelet genera *Aniselytron* and *Arctagrostis* is not obvious.

P1219. Molecular phylogenetic investigations in the grass subtribe Poeae: Poinae and its relatives

J. Albrecht, E. Döring, M. Röser;
Institute of Geobotany and Botanical Garden, Martin Luther University Halle-Wittenberg, Halle, Germany.

First results on matK-based phylogenetic estimations in grasses belonging to the subfamily Pooideae tribe Poeae and its presumed neighbor tribes as outgroups are presented. Since (i) the highly diversified generic assemblage around Festuca (Poeae subtribe Loliinae) has recently been covered by molecular systematic studies of a dense taxonomic sampling and (ii) a comparable study in the tribe Aveneae has already been in progress, it became evident that similar approaches would be required also in further tribes and subtribes of the subfamily Pooideae. Our study aims at testing the “evolutionary lineages” suggested by the authors of different taxonomic concepts in Poeae and at including preferentially those genera related with Poa which have not yet been analyzed molecularly. It also contributes to assessing the phylogenetic position of further equivocally circumscribed allies of Poinae, such as Dactylidinae, Cynosurinae, or Sesleriinae.

P1220. Molecular phylogeny of the Poaceae tribe Aveneae

E. Döring[1,2], K. W. Hilu[2], M. Röser[1];
[1]Institute of Geobotany and Botanical Garden, Martin-Luther-University Halle-Wittenberg, Halle, Germany, [2]Department of Biology, Virginia Polytechnic Institute and State University, Blacksburg, VA, United States.

Phylogeny of the tribe Aveneae (Poaceae subfamily Pooideae) was examined using sequence data from the chloroplast gene matK. A broad sampling from the Aveneae was used, particularly taxa that were underrepresented in previous studies or proved difficult to place. The strict consensus tree shows that whereas current circumscription of subfamily Pooideae was confirmed, the delineation between Aveneae and Poeae was not. Some traditionally recognized subtribes of Aveneae or groups of genera commonly accepted as closely related were not resolved. Additionally, some large Aveneae genera appear as polyphyletic assemblages, e.g., Helictotrichon segregates into at least three different genera. The phylogenetic position of subtribe Duthieinae, usually considered to encompass the most “primitive” extant genera of Aveneae, will be discussed in relation to other Aveneae and to Stipeae.

P1221. Revision of the genus *Festuca* L. (*Poaceae*) in Italy

B. Foggi[1], G. Rossi[2], G. Parolo[2], M. A. Signorini[1], L. Pignotti[1];
[1]University of Firenze, Firenze, Italy, [2]University of Pavia, Pavia, Italy.

The beginnings of modern systematic studies on the genus *Festuca* in Europe can be considered the *Monographia Festucarum Europaearum* (Hackel 1882). For this reason an intensive study of the Hackel Herbarium in Wien (W) was started. In his systematic conception, the genus includes a modest number of species (28) articulated in a large number of infraspecific *taxa*. Following this work, nearly one hundred years later, the total number of species, reported by Markgraf-Dannemberg (1980, in Flora Europea) had increased from the 28 reported by Hackel, to 170, but this increase was not only due to the recognition of new entities, but simply to the raising to the rank of species of many infraspecific *taxa*. In Italy, unlike France or Spain, during the last century, systematic investigations on this genus are few. Since 1996, our research team has carried out taxonomic investigations on the genus *Festuca* in Italy, resulting in significant taxonomic rearrangements within critical groups and raising the number of *taxa* from 68 (reported in Flora d’Italia, Pignatti 1982) to roughly 100 entities.

P1222. Some results of taxonomy analysis of genus Festuca L. in flora of the Ukraine

I. Bednarska;
976, Lviv, Ukraine.

In the course of 1995 on 2004 analysis of systematic of genus Festuca in flora of the Western Ukraine (Polesye, Podolia, Carpathian mountains) has been undertaken. By the example of 130 populations of 15 species the anatomy-morphological differentiation narrowleaved festuque was investigated. About 5000 anatomic sections of leaf blades have been accomplished as well as measured 20 morphological parameters from which half is anatomic. Researches display that the existing biodiversity is far beyond traditional frameworks of species. However, no reason to describe new "fine" taxon because of continual nature of variability. The mass material has allowed to reveal geographical and ecological specialization of species. At the same time the wide polymorphism in the majority of species does not allow to mark out races precisely.

We share the point of view that in structure F. valesiaca agg and very heterogeneous F. rubra agg should be interpreted as subspecies. It is planned to expand region of investigations with application of new methods of researches. For today the specialized collection from almost 250 populations Festuca is created.

P1223. The origins and systematics of arctic polyploid alkali grass (*Puccinellia; Pooideae; Poaceae)* based on ploidy level and ITS sequences

L. L. Consaul[1], L. J. Gillespie[2], M. J. Waterway[1];
[1]McGill University, Macdonald Campus, Ste Anne de Bellevue, PQ, Canada, [2]Canadian Museum of Nature, Ottawa, ON, Canada.

Alkali grass (*Puccinellia*) is a common pioneering grass in coastal and alkaline areas of arctic and temperate regions. To test whether polyploid origins underlie traditional problems of species delimitation in the genus, we studied three putative arctic polyploid species comparing them to the five Nearctic diploid species. We measured ploidy level by chromosome counts and flow cytometry and analyzed the internal transcribed spacer (ITS) region by sequencing and analysis of restriction sites diagnostic for the diploid species. Our results suggest that *P. bruggemannii* may be an auto-tetraploid of the diploid *P. vahliana, P. angustata* an allo-hexaploid of the diploid *P. arctica* and an as yet unidentified parent, and *P. andersonii* an allo-octoploid with at least two of the same parents as *P. angustata*. Although evidence suggests that the latter two species have the same set of parents, multivariate analyses of data from field specimens and a common garden experiment suggest they are morphologically distinct. Yet, occasional octoploids have the morphology of *P. angustata* in the field, but change to the morphology of *P. andersonii* in the common garden.

P1224. Systematics of Dissanthelium Trin. (Poaceae: Pooideae)

N. F. Refulio-Rodriguez[1], J. T. Columbus[1], P. M. Peterson[2];
[1]Rancho Santa Ana Botanic Garden, Claremont, CA, United States, [2]National Museum of Natural History, Smithsonian Institution, Washington, DC, United States.

Dissanthelium, with about 20 uncertainly delimited species, is characterized by two florets per spikelet and glumes that generally exceed the florets. The genus is distributed at high altitudes in the central Andes of South America with exception of two species in North America. The position of *Dissanthelium* within subfamily Pooideae is unclear. Clayton & Renvoize (1986) placed it in tribe Aveneae along with other long-glumed taxa, whereas all other authors have placed it in Poeae. Using DNA sequences from the nuclear ribosomal ITS and chloroplast *trn*T-L-F and *rpo*B-*trn*C^{GCA} regions, we are investigating the phylogeny of *Dissanthelium* and its position in Pooideae. Results show that the genus is related to members of Poeae, specifically *Poa*, and that its long glumes represent a homoplastic character. In addition, in each phylogeny *Dissanthelium* is not monophyletic and its species are nested within *Poa*. However, most of the species form a clade, and the remainder are related to Andean gynomonoecious species of *Poa*. In addition to molecular data, we are gathering morphological (including micromorphology of the leaf and lemma), anatomical, and cytological data.

P1225. Molecular phylogenetic study of *Colpodium versicolor* and some other Aveneae and Poeae species.

A. V. Rodionov, E. S. Kim, E. O. Punina, E. M. Machs, N. B. Tyupa, M. A. Dobroradova, N. N. Nossov;
Komarov Botanical Institute, St.Petersburg, Russian Federation.

There are only few species of plants which have a remarkable low number of chromosomes, such as 2n=4. They are *Haplopappus gracilis* (Asteraceae; Astereae) and two species of grasses, *Zingeria biebersteiniana* (Poaceae; Aveneae) and *Colpodium versicolor* (Poaceae; Poeae). To study the origin of unusual two-chromosomes genome of *Colpodium* and *Zingeria* we have sequenced the internal transcribed spacers ITS1 and ITS2 as well as nuclear 5.8S rRNA genes of *Colpodium versicolor* and some other species of Aveneae and Poeae. The comparative analysis of ITS1+ITS2 sequences showed low genetic distance (p-distance) between *Colpodium versicolor* and *Zingeria biebiersteiniana* and revealed strong support for the monophyly of these grasses genera. These results suggest that the reduction of chromosome number in the process of chromosome translocations took place in the chromosome complement of a common ancestor of *Colpodium* and *Zingeria*. This work was supported by the grant RFBR 03-04-49477.

P1226. Phylogeny of tribe Aveneae Dumort. (Pooideae, Poaceae) inferred from nuclear and chloroplast sequence analysis

A. Quintanar[1], S. Castroviejo[1], P. Catalán[2];
[1]Real Jardín Botánico, Madrid, Spain, [2]Universidad de Zaragoza, Zaragoza, Spain.

Classical circumscription of tribe Aveneae has been evaluated through phylogenetic analysis of nuclear (ITS) and chloroplast (*trn*TF) data across 145 representatives of avenoid genera and of the main lineages of its sister tribe Poeae. Parsimony and Bayesian inferences concur in depicting a congruent topology for the 'Aveneae core group' that shows the sister relationships of Agrostidinae to the Koeleriinae/Aveninae clade, each group characterized by contrasting morphological features. The Aveneae clade is also formed by the close lineages Anthoxanthinae, Brizinae, and Phalaridinae. Several genera traditionally included within Aveneae are resolved either in an intermediate placement between the Aveneae and Poeae (Poinae) clades (*Avenula*, *Deschampsia*, Airinae and *Holcus*) or embedded within the Poinae clade (*Alopecurus*, *Antinoria, Beckmannia*, *Cinna*, *Dielsiochloa, Milium, Phleum*, *Ventenata* and others). Traditional diagnostic traits seem to be inadequate to classify 'natural groups' within the Aveneae-Poeae complex. Considering potential reticulation events, morpho-anatomical and molecular characters should be reevaluated.

P1227. The importance of leaf anatomical data in the characterization of *Anthoxanthum aristatum* Boiss. and *A. ovatum* Lag. (Poaceae) in sympatric populations

E. Sahuquillo Balbuena, M. Pimentel Pereira;
Facultade de Ciencias, Universidade da Coruña, A Coruña, Spain.

The genus *Anthoxanthum* L. includes several annual *taxa* that grow in dry and open habitats of S Europe and N Africa. Two of these species, *A. aristatum* and *A. ovatum*, can be found in sympatry in the Doñana National Park (SW Iberian Peninsula). Moreover, infraspecific *taxa* have been described in this area whose characterization remains controversial.

In this study we analyse the usefulness of anatomical data to differentiate these *taxa* when growing in mixed populations. Also, we try to evaluate the influence of environment on the anatomical traits, comparing these results with those obtained in allopatric populations. To attain these aims, 70 specimens from 6 populations were sampled and classified into taxonomical units. Subsequently, 22 anatomical leaf traits were measured. The similarity among samples was determined using the Phi coefficient and different multivariate analysis were applied to establish the relationships among samples (PCO and UPGMA clustering methods). To assess the influence of the environment on these traits CCA analysis was performed. Finally, the accuracy of some infraspecific *taxa* defined for these species has been analysed.

P1228. Problems of species of genus *Festuca* from ser. *Festuca* (*F. ovina* agg.) in Central Europe

K. Koci;
Department of Botany, Faculty of Science, Masaryk University Brno, Brno, Czech Republic.

The treatment of selected problems in the *Festuca ovina* - group in Central Europe is given. This group includes four species - *F. eggleri* Tracey, *F. supina* Schur, *F. filiformis* Pourret and *F. ovina* L., the latter being probably divided into two subspecies: the diploid subsp. *ovina* and the tetraploid subsp. *guestfalica*. Some morphological, anatomical and cytological characters were collected and analysed. A comparison of some morphological and anatomical characters among these species is given. Two ploidy levels, 2n=14+0-5B corresponding to *F. ovina* subsp. *ovina* and 2n=28 corresponding to *F. ovina* subsp. *guestphalica* and *F.* cf. *duernsteinensis* were confirmed in *F. ovina*. The diploid chromosome number was found in *F. filiformis* Pourret and the tetraploid chromosome number was found in *F. supina* Schur. Two ploidy levels, diploid 2n=14 and tetraploid 2n=28 were recorded in *F. eggleri* Tracey.

P1229. Phylogenetic studies and the radiation of the New and Old World festucoids (Loliinae, Pooideae, Poaceae)

L. A. Inda[1], J. G. Segarra-Moragues[1], P. M. Peterson[2], J. Müller[3], P. Catalán[1];
[1]University of Zaragoza, Huesca, Spain, [2]Smithsonian Institution, Washington, DC, United States, [3]University of Jena, Jena, Germany.

We conducted an independent and combined phylogenetic analysis of ITS and trnTF sequences on 168 representatives of New and Old World festucoids (Loliinae) to characterize biogeographical patterns. Nuclear and plastid derived trees using either parsimony or Bayesian algorithms support the major lineages and depict a monophyletic Loliinae. Ancient broad-leaved groups and the more recently evolved fine-leaved (FEVRE) clade have diploid species aligned basally. Diploid lineages distributed in the Mediterranean and Macaronesian regions likely gave rise to polyploid radiations in the Eurasian holartic region, Central and South America, and New Zealand. Within the FEVRE group, New Zealand taxa fall within the *Festuca* sect. *Aulaxyper* s.l. clade that incorporates the Macaronesian taxa and an American subclade. *Hellerochloa* and *Dielsiochloa* are included in the American subclade. *Vulpia* is polyphyletic since Euromediterranean and American species are derived from within different clades. Across the broad-leaved festucoid lineages American and Eurasian taxa are united in several subgeneric clades whereas the New Zealand taxa form a separate clade.

P1230. Systematic of Poaceae: an indication of gene duplication of GBSSI

J. Sanchez-Ken;
Royal Botanic Gardens, Kew, Richmond, United Kingdom.

Monophyly of Poaceae is well supported in most studies, with strong support for three early-diverging lineages, and the PACCAD clade, but only moderate support for a clade including rices, true bamboos, and bluegrasses. Most subfamilies are well supported primarily based on chloroplast data; however, relationships among subfamilies are largely still unresolved, especially within the PACCAD clade. Of the nuclear markers used to date (PHYB, GBSSI, ITS), PHYB is the only one with good resolution. Previous GBSSI analyses generated an odd topology, which was interpreted as the result of poor sampling. In this preliminary analysis increased taxon sampling for almost all subfamilies recovered again an odd topology in which several subfamilies within the PACCAD clade appear polyphyletic. Several sequences and the polyphyletic nature of some subfamilies within the clade provide a hint of a possible duplication event of the GBSSI gene that happened perhaps near the base of the PACCAD clade. Increased clone sampling and southern hybridization analyses are in progress to provide additional data about this possible gene duplication event.

P1231. Partial incongruence between nuclear ribosomal ITS and chloroplast *trn*T-*trn*F phylogenies of the bluegrass genus *Poa* and allied genera: new insights into reticulate evolution in Poaceae

L. J. Gillespie[1], A. Archambault[1], R. J. Soreng[2];
[1]Canadian Museum of Nature, Ottawa, ON, Canada, [2]Smithsonian Institution, Washington, DC, United States.

Poa, known for taxonomic difficulty, polyploidy and apomixis, is widely presumed to have evolved reticulately. Comparison of phylogenetic analyses of nuclear and cpDNA sequences illuminated both ancient and recent reticulation events, while deep structure in the genus is largely stable. *Poa* is monophyletic if subg. *Andinae* is excluded and several small Poinae genera are included. Five major *trn*TF clades diverge in the order: 1) subg. *Arctopoa* and sect. *Sylvestres* (ArcSyl); 2) sects. *Bolbophorum*, *Alpinae*, *Ochlopoa*, *Parodiochloa* (BAPO); 3) sects. *Secundae*, *Pandemos*, *Oreinos*, *Stenopoa*, *Tichopoa*, *Abbreviatae* (SPOSTA); 4) sects. *Poa*, *Macropoa* (PoM); and 5) sects. *Homalopoa*, *Madropoa*, *Dioicopoa* and related sections (HAMBADD). Taxa with different positions in the ITS analysis include: *P.* subg. *Arctopoa* outside of *Poa* with other Poinae and Alopecurinae; *P. trivialis* (sect. *Pandemos*) in BAPO; and the polyploid *P. abbreviata* in HAMBADD while diploid species of sect. *Abbreviatae* remained in SPOSTA.

P1232. Molecular phylogeny and divergence times of the A-genome species in *Oryza*: implications for origin of the cultivated rice

Q. Zhu, **S. Ge**;
Institute of Botany, Beijing, China.

The A-genome group in *Oryza* consists of eight diploid species and is distributed worldwide. The evolutionary relationships among species in this group have long been controversy and not well studied on sequence level mainly because of the lack of sufficient resolution for commonly used sequences. We sequenced introns of five nuclear genes located on different chromosomes for 37 accessions representing two cultivated and six wild species from the A-genome group. As expected, the intron sequences provide much higher (more than two times higher) informative characters than those of ITS. Phylogenetic analyses by Maximum parsimony and Bayesian inference indicated that all the species except for *O. rufipogon* and *O. nivara* formed a monophyletic group and the Australian endemic *O. meridionalis* was the earliest divergent lineage. Two subspecies of *O. sativa* (ssp. *indica* and ssp. *japonica*) formed two separate monophyletic groups, suggestive of their polyphyletic origin. Based on molecular clock approach, we estimated that the divergence of the A-genome group occurred ~ 2.0 MYA while the two subspecies (*indica* and *japonica*) separated ~ 0.4 MYA.

P1233. Triba Stipeae in Siberia.

E. G. Naumova;
Tomsk State University, Tomsk, Russian Federation.

Triba Stipae is represented in Siberia by 3 genus; Achnatherum, Stipa and Ptylagrostis, the most numerous and complicated to be Stipa (21 species), while Ptilagrostis (4) and Achnatherum (3). The species of Stipa are distributed in 5 sections, the largiest to be Stipa (8 species), Leiostipa (6), Barbatae and Smirnovia contain in 3, and Pseudoptilagrostis 1 species. The study has shown, that most of Stipa species are quite variable. The study of variability of Siberian species showed that the greatest biodiversity is founded within the South Siberian mountains. The study of its distribution has shown, that it is limited in Eurasian continent. Most of species are of Euroasian distribution (57.14 %), Asian group is less (38.10%). Stipa barchanica is endemic of S Siberia. Most of sections are represented mainly by Eurasian species, Leiostipa comprises Eurasian and Asian species in equal parts, Smirnovia and Pseudoptilagrostis contain only the Asian ones. 2 Siberian species of Achnatherum belong to Eurasian group, and 1 is Asian. All species of Ptylagrostis are Asian, I to be S Siberian endemic. Such a distribution is caused by the peculiarity of Siberian steppes forming.

P1234. Morphometry of the Festuca valesiaca agg. in Istria with the emphasis on F. illyrica MARKGR.-DANNENB. delimitation

A. L. Alegro;
Division of Biology, Faculty of Sciences, Zagreb, Croatia.

Possibility of recognition of the species F. illyrica MARKGR.-DANNENB. in the flora of Istria was studied. Precise analysis of species descriptions and the determination key, as well as field work have showed that there are no clear borders between this species and other members of F. valesiaca agg. In the analysis 316 individuals were taken into account and 20 characters were investigated. The data were analysed using multivariate and univariate statistical methods. It was possible to recognise only two groups corresponding with the species F. rupicola HEUFF. and F. valesiaca SCHLEICH. ex GAUDIN. Due to overlappings in the diagnostic characters with F. rupicola, the species F. illyrica could not be recognised as independet entity. The recognition between the species F. rupicola and F. valesiaca is possible only based on quantitative characters The most discriminative character in delimination of F. rupicola and F. valesiaca was the length of stommata.

P1235. Representatives of the genus *Alopecurus* L. (*Poaceae*) in Armenia

A. Nersesian;
Institute of Botany of the Armenian National Academy of Sciences, Yerevan, Armenia.

The genus *Alopecurus* L. in Armenia is represented by 9 species from 4 sections. Sect. *Alopecurus*: *A. arundinaceus* Poir., *A. armenus* (K. Koch) Grossh.; Sect. *Colobachne (*Beauv.) Griseb.: *A. textilis* Boiss subsp. *textilis*, *A. textilis* subsp. *tiflisiensis* (Westb.)Tzvel., *A. brevifolius* Grossh., *A. tuscheticus* Trautv., *A. aucheri* Boiss., *A. laguroides* Bal. (=*A. dasyanthus* Trautv.); Sect. *Alopecurium* Dumort.: *A.aequalis* Sobol.; Sect. *Pseudophalaris* Tzvel.: *A. myosuroides* Huds. According to the obtained data the feature of palea presence of *A. tuscheticus* (Aragats and Gegham floristic regions of Armenia) is very unstable in all Caucasian area (often palea is short, transparent or absent). *A. brevifolius* (Gegham, Darelegis, and Zangezur floristic regions) is very close to *A. textilis*, differing by habitus, lower part morphology, lemma shape. An additional diagnostic feature (lower cauline leaves congestion) is revealed for *A. arundinaceus* and *A. armenus*.

P1236. Comparative morphological, histological and molecular studies of Hungarian wheatgrass (*Elymus* and *Agropyron*) taxa

Á. Farkas, S. Stranczinger, M. Kocsis, A. Borhidi;
University of Pécs, Pécs, Hungary.

Comparative morphological, histological and molecular studies were carried out on four Hungarian wheatgrass species (*Elymus elongatus*, *E. repens*, *E. hispidus*, *Agropyron pectiniforme*) and the energy grass 'Szarvasi-1'. The cultivar, developed in Hungary, has gained more importance recently as a renewing source of energy.
The morphological features of the roots, the culms, the leaves and the spikes were described in detail. The histology of the culm and the leaf was also studied, describing the relative position of the vascular bundles and the sclerenchyma in the internodes and nodes, as well as the leaves. The proportion of different tissues was determined in each studied organ, in relation to the dry matter content.
Taking into consideration the standpoints of land utilization, economicalness and environment protection, it is important to clarify the systematic position and relationships of the taxa. DNA level studies (rpoA gene of plastid genom) made it possible to recognize not only the cultivar but also the *Agropyron* genus with debatable taxonomic situation. Phylogenetic analyses and bootstrapping were performed using PAUP (ver. 4.0; Swofford, 2002).

P1237. Biosystematic studies of the *Elymus repens* (L.) Gould (Poaceae, Triticeae): evidence from morphology, anatomy and AFLPs.

M. Szczepaniak;
W. Szafer Institute of Botany, Polish Academy of Sciences, Kraków, Poland.

Combined morphological, anatomical and molecular approaches were used to unravel variation within *Elymus repens*. Forty four populations were analyzed for 49 morphological and 26 anatomical characters. Multivariate morphometric analyses (PCA, ANOVA and CDA) provided significant support for recognition of three varieties of *E. repens*: var. *repens*, var. *aristatus* and var. *subulatus*. Genetic infraspecific diversity was assessed by Amplified Fragment Length Polymorphisms (AFLPs). Twenty AFLP multilocus phenotypes were observed in the 70 specimens analyzed, based on 104 (37.28%) polymorphic AFLP markers. The analyses of molecular variance (AMOVA) showed significant genetic differentiation among populations, but not significant among varieties. The low levels of AFLP variation indicated that conspicuous morphological variation of *E. repens* is caused by plasticity, somatic mutations and habitats changes. *E. repens* is an evolutionarily young species, of hybrid origin, in which microevolutionary processes continue. New combination was made: *Elymus repens* (L.) Gould var. *subulatus* (Roem. & Schult.) Szczepaniak, comb. nova.

P1238. Phylogenetic analysis of the "Briza Complex" (Poaceae - Pooideae)

L. Essi[1], T. T. Souza-Chies[1,2], H. M. Longhi-Wagner[1];
[1]Graduate Program of Botany, UFRGS, Porto Alegre, Brazil,
[2]Department of Botany, Porto Alegre, Brazil.

The genus *Briza* L. comprises 4 to 23 species, depending on the criteria adopted by the different authors. *Briza stricto sensu* includes only euroasiatic species, but considered in a broad sense it includes also the South American species, alternatively placed in genera like *Calotheca* Desv*.*, *Chascolytrum* Desv*.*, *Microbriza* Parodi ex Nicora & Rúg*.*, *Lombardochloa* Roseng. & Arr., *Poidium* Nees and *Rhombolytrum* Link. The circumscription of the so called "*Briza* Complex" remains controversal, although some analyses based on morphological data were already published, without solving the delimitation problems. The present work includes a phylogenetic analysis of this complex, based on both morphological and DNA data. Twenty seven morphological characters and three totally or partially sequenced DNA fragments were included: nuclear ITS, chloroplast *trnL* intron and *trnL-trnF* spacer. Parsimony and Maximum Likelihood analyses were performed with PAUP *, using distinct or combined matrices. The preliminar analyses confirm *Briza stricto sensu*, with strong bootstrap support, and an American clade, including all other genera.

Research supported by CNPq (Brazil)

P1239. Revision of the genus *Festuca* L. in Southern Transcaucasia

M. E. Oganesian;
Institute of Botany, Armenian National Academy of Sciences, Yerevan, Armenia.

The genus *Festuca* L. is represented in Southern Transcaucasia (Armenia and Nakhichevan) by 16 species belonging to 4 following subgenera. Subgen. *Drymanthele* V.I.Krecz. & Bobrov: *F. drymeja* Mert. & W.D.J.Koch, *F. altissima* All. Subgen. *Leucopoa* (Griseb.) Tzvelev: *F. sclerophylla* Boiss. ex Bisch. Subgen. *Schedonorus* (Beauv.) Peterm.: *F. gigantea* (L.) Vill., *F. pratensis* Huds., *F. arundinacea* Schreb. Subgen. *Festuca: F. woronowii* Hack. (with 2 subspecies: *woronowii* and *caucasica* (St.-Yves) E.B.Alexeev), *F. skvortsovii* E.B.Alexeev, *F. chalcophaea* V.I.Krecz. & Bobrov, *F. ruprechtii* (Boiss.) V.I.Krecz. & Bobrov, and 6 species belonging to *F.* aggr. *valesiaca* Schleich. ex Gaudin: *F. valesiaca* Schleich. ex Gaudin, *F. brunnescens* (Tzvelev) Galushko, *F. oreophila* Markgr.-Dann., *F. vagravariva* E.B.Alexeev, *F. saxatilis* Schur, *F. karsiana* E.B.Alexeev (reported for the first time from S.Transcaucasia (N.Armenia)). The presence of *F. rubra* L. in the region isn't confirmed.

P1240. Evaluation of genetic diversity in some bread wheat cultivars using SSR marker

M. Naghavi[1], M. Mardi[2], B. Fazelinesab[1];
[1]Tehran University, Karaj, Islamic Republic of Iran, [2]Biotechnology Institute, Karaj, Islamic Republic of Iran.

In the present study microsatellite markers were used for germplasm analysis and estimation of the genetic relationship and diversity between 21 genotype of persian breed wheat. 37 microsatellite markers, developed from *Triticum aestivum* sequence were selected for the analysis. The number of alleles per microsatellite marker varied from 2 to 10 (average 5.37) and a total of 199 alleles were detected. Gel scoring was with present(1) and absent(0) band. That was studing genetic diversity(DI) and polymorphism information content(PIC) and with average was 0.68 and 0.63 respectively . Genetic similarity was calculated with Nei and Lee and Jaccard and Simple Matching methods with average 0.201 and 0.325 and 0.725 respetcively. The highest levels of genetic similarity for genotypes were found in Ghods and Alnad genotype in the tree methods and lowest was in Bolani and Niknejhad with Nei and Lee and Jaccard methods but in Simple matching methods were in the Shain and Tajan cultivars. The result showed that all of the genotpye could be distinguished and clustered into 4 groups with nei and lee similarity method and UPGMA clustering method with programme NTSYS.

P1241. Cyto-Morphological study of some *Stipa* (Poaceae) species and populations in Iran

M. Sheidai, S. Attaei, M. Khosravi-Reineh;
Shahid Beheshti University, Tehran, Islamic Republic of Iran.

Morphometric and cytological studies were performed on several populations of Iranian Stipa species concerning polyploidy level, chiasma frequency and distribution, chromosomes association and segregation. The species and populations studied possessed 2n = 24, 36 and 44 chromosome number. The chromosome numbers of four species are reported for the first time. The populations and species studied differed significantly in their meiotic characteristics. Meiotic abnormalities observed included laggard chromosome formation, stickiness and cytomixis. Cytomixis led to the formation of aneuploid meiocytes. Unreduced pollen grains were observed in some of the species, which differed significantly in their size compared to the normal (reduced) pollen grains. Cluster analysis and ordination plot of the species studied based on morphometric and cytological characters supported Freitag taxonomic treatment of the group. Detailed description of the species is provided using statistical analysis.

P1242. Contrasting morphology and molecules in *Bouteloua media*, a polyphyletic species in the *B. curtipendula* clade (Gramineae, Chloridoideae).

M. E. Siqueiros-Delgado[1], J. T. Columbus[2];
[1]Universidad Autónoma de Aguascalientes, Aguascalientes, Ags., Mexico, [2]Rancho Santa Ana Botanic Garden, Claremont, CA, United States.

Bouteloua media is the tallest, most robust species in the *B. curtipendula* complex, a taxonomically difficult, mostly North American clade. Although 11 species are generally recognized in the complex, species circumscription is not clear cut. *Bouteloua media* is distributed from tropical Mexico to South America. In additional to size, the species is distinguished by a firm, knotty base, frequently pubescent leaves, lateral (axillary) inflorescences, many branches per inflorescence, and many spikelets per branch. Molecular phylogenies (ITS and *trnT-L-F)* of the complex show that representatives of *B. media* from southern Mexico, Central America, and South America are nested in the earliest-diverging clade, whereas plants from central and southern Mexico are positioned in the most derived clade. Sympatry of plants representing the northern and southern lineages occurs in Oaxaca, Mexico. The congruent phylogenies suggest that the morphological characters used to circumscribe this polyphyletic species are homoplasious, and that non-molecular, phylogenetically congruent characters should be sought out for taxonomic revision.

P1243. A genealogical approach reveals the impossibility of correct phylogenetic inference from chloroplast data in Hordeum (Poaceae)

S. S. Jakob, F. R. Blattner;
IPK Gatersleben, Gatersleben, Germany.

To analyze reasons for inconclusive results of earlier chloropast phylogenies in the grass genus Hordeum we established a genealogy of chloroplast haplotypes by sequencing the trnL-F region in 800 individuals, covering all 31 species of the genus. While the outcome of phenetic and parsimony analyses of 88 haplotypes were ambiguous, the network approach showed that in Hordeum ancient chloroplast types co-occur with their descendants. Moreover, we found up to 17 chloroplast haplotypes within single species and up to 7 species sharing single haplotypes. Ancient polymorphisms together with incomplete lineage sorting occurred preferentially in the rapidly speciating New World taxa of the genus, where shared chloroplast types have persisted for at least four million years. Far reaching extinction in Europe and the survival of chloroplast lineages in Asia and North America resulted in a phylogenetic tree that pronouncedly differs from nuclear estimations of species relationships. Thus, even for the deepest splits in the genus, reaching back more than nine million years, no safe phylogenetic inference from chloroplast data is possible in Hordeum.

P1244. Phylogeny of Chloridoideae (Poaceae) based on ndhF sequences (cpDNA)

H. L. Bell, J. T. Columbus;
Rancho Santa Ana Botanic Garden, Claremont, CA, United States.

Chloridoideae (Poaceae) are a well-supported clade comprising ca. 140 genera and 1500 species distributed in the tropics and subtropics. The subfamily contains a few large and many small and monotypic genera. Analysis of *ndhF* sequences from 58 genera and 73 species, representing all tribes (*sensu* Clayton and Renvoize 1986), places *Triraphis mollis* as sister to three major clades. The next diverging lineage includes the large genus *Eragrostis*, Uniolinae, and Pappophoreae (excluding *Pappophorum*). The third diverging clade includes *Spartina*, the large genus *Sporobolus*, and *Zoysia*. The remaining clade includes most of the genera within the subfamily, including *Chloris* and relatives, *Bouteloua*, *Muhlenbergia* and *Pappophorum*. All tribes excluding Orcuttieae (three genera) and Lepatureae (one genus) are not monophyletic. However, morphological synapomorphies have been identified for most of the major clades. The *ndhF* phylogeny suggests considerable homoplasy in inflorescence form, a character that has been widely employed in grasses for tribal circumscription.

P1245. Historical retrospective, systematic and biogeography of Leandra Raddi (Melastomataceae) from Brazil.

M. D. R. Souza[1], J. A. Baumgratz[2,3];
[1]Universidade Federal de Santa Catarina, Florianópolis, Brazil, [2]Instituto de Pesquisas Jardim Botânico do Rio de Janeiro, Rio de Janeiro, Brazil, [3]Bolsista CNPq, Rj, Brazil.

Leandra, with ca. 250 spp., is distributed from southern Mexico and Antilles to the northern Argentina. The last revisions of this group dates of the 19th century and it commonly presents taxonomical complex and several herbaria specimens are identified as species of another genus. It has been recognized as monophyletic group and closely related to Clidemia, Miconia and Ossaea. This project presents a retrospective of Leandra history, standing out the classifications and the fragility of the sections circunscriptions and propositions of new synonyms and species. Leandra is characterized mainly by the terminal and pseudo-axillary inflorescences, the floral buds with acute to acuminate apex, the petals with attenuate-acuminate to -acute apex and fleshy fruits of the bacidium type, polyspermic. In Brazil, it is represented by ca. 200 spp. that occurr in different ecossystems, from sea level to high and cloud forests, in tropical rain forests. The largest concentrations of species are in the Southeast (73%) and South (34%) regions, and the smallest is in the Central region (4%). There are 166 spp. restricted to Brazil and from these 83 represent punctual endemism.

P1246. Structure of the puzzling female inflorescence of *Amphipterygium* and comparison of the flower structure with *Pistacia* (Anacardiaceae)

J. B. Bachelier, P. K. Endress;
University of Zurich, Zurich, Switzerland.

Amphipterygium and relatives were originally placed in their own family Julianiaceae mainly because of their unique female inflorescences. Later, overall structure, wood anatomy and flavonoid chemistry prompted their inclusion in Anacardiaceae, and this was supported by molecular phylogenetic studies. Our aims were (1) to reveal the enigmatic structure of the female inflorescence and (2) to compare the female flower and its bizarre ovule with similar ones in other Anacardiaceae. The female inflorescence is a few-flowered thyrse comprising regularly one or two cymose units, each of which develops into a samaroid structure. The flattened part is the peduncle and the globose part is an involucre. The involucre is almost closed and contains three to five collateral flowers but only one will produce a seed. During development, the flower bases are deformed to a saddle-like shape by the differential growth of the basal inner part of the involucre. The unitegmic ovule with two lateral and one large basal appendage is highly similar to that in *Pistacia*. The placement of *Amphipterygium* in a clade with *Pistacia* is also highly supported by other reproductive features.

P1247. Taxonomic revision of *Galipea* Aubl. (Rutaceae, Galipeae)

J. R. Pirani;
Universidade de São Paulo, São Paulo, Brazil.

The neotropical genus **Galipea** Aubl. is marked by its carpels connate and fruit syncarpous before dehiscence, by a long and thin corolla tube, and by its androecium with only two fertile stamens, bearing anthers that are sterile at base above point of attachment to filament, appendaged at base, connate by their sterile bases and appendages. A morphological and taxonomic revision of the group lead to the recognition of 16 species, from which 7 are new, with **G. carinata**, **G. congestiflora**, and **G. revoluta**, all from Brazil, already published in 2004. The species can be separated by vegetative and reproductive characters, expressed in an identification key. Morphological descriptions, and comments on habitats, geographic distribution, taxonomic relationships and variability are presented. Although the distribution of the genus extends from Costa Rica in Central America to Brazil and Bolivia, all species show restrict distribution areas, some of them being narrow endemics.

P1248. Phylogeny of *Eucalyptus* subgenus *Eudesmia* based on molecular and morphological evidence

A. Gibbs;
The University of Melbourne, Melbourne, Australia.

Eucalyptus (family Myrtaceae) is a ubiquitous genus of the Australian landscape. *Eucalyptus* subgenus *Eudesmia* contains 26 taxa, in tropical and arid regions of Australia. Stellate hairs, pith glands, stamens usually in four bundles, and free sepals on the buds and fruit of most taxa traditionally define the subgenus. A molecular phylogenetic parsimony analysis is presented based on the *psb*A-*trn*H region of the chloroplast genome, and the internal transcribed spacer (ITS) region of the nuclear ribosomal DNA. Morphological characters of trichomes, seeds, fruit, flowers, seedlings and fruit wall anatomy were also coded and analysed. Three main clades with strong bootstrap support were resolved: 1 *E. baileyana* - *E. tetrodonta* clade (4 taxa), 2 *E. miniata* clade (5 taxa), and 3 *E. roycei* - *E. erythrocorys* clade (17 taxa). Clades 1 and 2 are distributed in northern Australia from the Kimberley to eastern Queensland, and clade 3 is distributed in southwest Western Australia and deserts.

P1249. Phylogeny of *Pilocarpus* (Rutaceae) and stochastic mapping of characters

P. Dias, J. R. Pirani;
Universidade de São Paulo, Instituto de Biociências, Laboratório de Sistemática Vegetal, São Paulo, Brazil.

Pilocarpus is a neotropical genus of 17 species distributed from Mexico to Brazil and Argentina. Differently from its allied genera, *Pilocarpus* is marked by its racemes and anthers bearing a dorsal gland. We investigate the phylogeny of *Pilocarpus* using a set of 104 morphological characters, partitioned into four subsets (leaf, flower, fruit, and others) to allow across-partition rate independence. Symmetric Markov models were assumed as priors for all characters and computer simulations were performed to address both mapping and phylogenetic uncertainty. We found that: (1) *Pilocarpus* is highly supported as monophyletic, with *P. microphyllus* being sister to all other species; (2) The simple-leaved species plus *P. pauciflorus* (a species with unifoliolate compound leaves) form a clade; (3) The species with pinnately compound leaves are not monophyletic; (4) The species with versatile anthers and superposed ovules form a moderately supported clade. Computer simulations showed different degrees of asymmetry among characters (specially whithin the leaf and flower partitions), and suggest a potentially directional evolution for some of them. FAPESP

P1250. Phylogenetic relationships of *Begonia* (Begoniaceae) with emphasis on the Chinese species: evidence from ITS Sequences

C. I. Peng[1], S. C. Hsu[1], W. C. Leong[1], A. B. Matheson[2], D. T. Thomas[2], J. Q. Y. Xiang[2];
[1]Research Center for Biodiversity, Academia Sinica, Taipei, Taiwan Republic of China, [2]Department of Botany, North Carolina State University, Raleigh, NC, United States.

Begonia is one of the most diversified genera in angiosperm, with ca. 1400 species in 65 sections in Africa, Asia, and America. About 150 species in 9 sections occur in China. Phylogenetic analysis of 156 ITS sequences representing 148 taxa from 36 sections (70 taxa in 7 sections from China) from all continents was conducted to elucidate the phylogenetic relationships within the genus. The resulting trees show that the African taxa form a series of basal branches and the Asian species are divided into several unequal clades successively diverged after the African taxa. Species from America and S. Africa form a clade sister to a large, poorly resolved Asian clade containing most species from sections *Platycentrum*, *Diploclinium*, *Reichenheimia*, *Sphenanthera*, and *Leprosae.* The Chinese species do not group according to their sections. None of the more well-sampled sections in China is suggested to be monophyletic. Possible rapid diversification in mainland Asian *Begonia* is inferred. The results suggest an African origin of *Begonia* and an Asian origin of the American-S. African clade. Reevaluation of infrageneric classification is desirable.

P1251. Morphological phylogeny of *Cucumis-Cucumella* (Cucurbitaceae)

J. H. Kirkbride, Jr.;
USDA, ARS, SBML, Beltsville, MD, United States.

A phylogenetic hypothesis was developed for 44 *Cucumis-Cucumella* species using 122 morphological characters. *Oreosyce africana* and *Mukia maderaspatana* served as outgroups. Qualitative and quantitative characters yielded 104 trees with 967 steps, consistency index (CI)=0.3681, and homoplasy index (HI)=0.6319, and qualitative characters alone yielded 8 trees with 805 steps, CI=0.3801, and HI=0.6199. *Cucumis* was polyphyletic, and *Cucumella* paraphyletic, sensu Farris. *Cucumella* species were transferred to *Cucumis*, making it a monophyletic group. When the *Cucumis-Cucumella* species were reanalyzed with the known hybrid *Cucumis* × *hytivus*, it had little affect on the phylogenetic hypothesis, and its hybridity and parentage could not be deduced from the results. Aculei on the fruit, used as a defining character in all previous subgeneric classifications, are very labile, and have been lost eight times during species evolution. It is a very useful character for species identification, but should not be used in the infrageneric classification.

P1252. Comparative carpology and systematic of the family *Malvaceae*

K. K. Dzhalilova, A. P. Melikian;
Moscow State University, Moscow, Russian Federation.

The family *Malvaceae* is characterized by considerable variety of fruit types. There are typical polyfollicles with elongated receptacle, capsules, and disintegrated fruits, which split into monospermous mericarps. The anatomical structure of pericarp sufficiently differs in various fruit types in representatives of the family. Pericarp structure of different types of disintegrated fruits sufficiently differs ant it is impossible to treat them as schizocarpic fruits. The ultrasculpture of fruit surface is also considerably varies. Basing on the analysis of received carpological data we have to conclude that *Malvaceae* should not be divided into tribes, as it is accepted in most systems. Our materials imply the necessity of subdivision the family into seven separate and well-defined by complex of carpological characters subfamilies. These families are *Malopoideae*, *Gossypioideae*, *Hibiscoideae*, *Malvoideae*, *Philippodendroideae*, *Sidoideae*, and *Urenoideae*.

P1253. A new classification for Onagraceae

W. L. Wagner[1], **P. C. Hoch**[2], P. H. Raven[2];
[1]Smithsonian Institution, Washington, DC, United States, [2]Missouri Botanical Garden, St. Louis, MO, United States.

Onagraceae comprise a moderate sized but well-known plant family that is well-delimited within the order Myrtales, closely related to Lythraceae. Recent analyses of molecular sequence data support many aspects of the classification of Onagraceae derived from earlier morphological analyses, but suggest several changes, especially in the large tribe Onagreae. In particular, the genus *Camissonia* is not monophyletic, and is best treated as five generic lineages (*Camissonia*, *Chylismia*, *Chylismiella*, *Eulobus*, and *Taraxia*), each defined with one or more morphological synapomorphies. On the other hand, *Oenothera* is strongly supported as a monophyletic lineage, but only with the addition of several traditionally segregated genera. Thus, *Calylophus*, *Gaura*, and *Stenosiphon* all now fall within the expanded *Oenothera*, re-defined morphologically by presence of an indusium on the style and a lobed or peltate stigma. Tribe Onagreae appears to have arisen from northern Mexico, proliferating into either western North America (*Xylonagra*, *Clarkia, Gayophytum*, the *Camissonia* complex, and parts of *Oenothera*) or central and eastern North America (most of *Oenothera*).

P1254. Relationships among major clades of the expanded Malvales: the contribution of *ndhF* data.

W. L. Applequist[1], P. P. Lowry II[2];
[1]Missouri Botanical Garden, St. Louis, MO, United States, [2]Museum National d'Histoire Naturelle, Paris, France.

Relationships among major lineages of the expanded Malvales are poorly understood. Two previously published *rbcL* analyses showed very different topologies, both weakly supported. In Fay et al. (1998), the bixaceous clade (*Bixa*, *Diegodendron* and Cochlospermaceae) was basal; Thymeleaceae and Sphaerosepalaceae together were sister to the rest (core Malvales and a clade containing Dipterocarpaceae and other families, including *Neurada*). In Alverson et al. (1998), *Neurada* was the basal lineage; Sphaerosepalaceae were sister to the bixaceous clade and Thymelaeaceae to the dipterocarp clade (excluding *Neurada*). To clarify the relationships of Sphaerosepalaceae, cpDNA sequences from relevant lineages were generated and obtained from GenBank. Preliminary analyses of the 5' portion of *ndhF* suggested that Sphaerosepalaceae were sister to the core Malvales, contradicting both *rbcL* trees. As with *rbcL*, the broader topology varied depending upon choice of outgroups and key branches were weakly supported, reinforcing the theme that rapid radiation followed by extensive divergence has hampered elucidation of phylogenetic history in this group.

P1255. Is dioecy ancestral in Cucurbitaceae and monoecy derived?

L. Zhang[1], A. Kocyan[2], M. P. Simmons[1], S. S. Renner[2];
[1]Department of Biology, Colorado State University, Fort Collins, CO, United States, [2]Ludwig Maximilians University Munich, Munich, Germany.

Based on 10 loci from the three plant genomes, we earlier reported that Cucurbitales consist of (Anisophylleaceae ((Begoniaceae, Datiscaceae, Tetramelaceae [BDT]), (Coriariaceae, Corynocarpaceae), (Cucurbitaceae)). A possible position of Cucurbitaceae (represented by 11 genera from all major lineages) as sister to the BDT clade has 74% jackknife support. The placement of Cucurbitaceae, and whether Fagales or Rosales are sister to Cucurbitales, greatly influences the inferred evolution of monoecy and dioecy, the typical sexual systems in Cucurbitales. With Rosales sister and Cucurbitaceae sister to BDT, dioecy is inferred to be ancestral in Cucurbitaceae, which fits with basal clades in the family indeed being dioecious. With the mainly monoecious Fagales sister to Cucurbitales, the ancestral sexual system in Cucurbitaceae becomes ambiguous because Anisophylleaceae and Corynocarpaceae/Coriariaceae are monoecious or perfect-flowered. Sexual systems in cucurbits are exceptionally labile, however, and parsimony may underestimate switches even if the true phylogeny were known.

P1256. Phylogenetic study of the polyphyletic genus *Leandra* (Miconieae: Melastomataceae), based on DNA sequence data:

C. V. I. Martin[1,2], F. A. Michelangeli[1];
[1]The New York Botanical Garden, Bronx, NY, United States, [2]IRD-MNHN Herbarium Cayenne, Cayenne, French Guiana.

The Melastomataceae is a tropical family including around 4000 species that are divided into 12 tribes. The tribe Miconieae is strictly neotropical, and has close to 2000 species in 30 genera. Previous phylogenetic analyses of the Miconieae have shown that many genera are derived from within a paraphyletic *Miconia*. However these studies have only included six species of *Leandra* a genus of 250 species characterized by acute petals and terminal inflorescences. In spite of this limited sampling, it has been shown that *Leandra* is most likely not monophyletic. In this study we present results of an analysis that includes data from two loci (one nuclear, one plastid), with and expanded sampling for this genus. Even though *Leandra* is clearly polyphyletic, and embedded in the phylogenetic structure of *Miconia*, some distinct and well supported clades do exist. Some of these clades correspond to sections or groups previously recognized. One such group is composed by species from section *Tschudya*, which is characterized by seeds with an appendage. The monotypic genus *Platycentrum* (which at times has been recognized as *Leandra*) is recovered within another clade of *Leandra*.

P1257. Rosaceous evolution in the Okanogan Highlands, Washington, USA and British Columbia, Canada

M. L. DeVore[1], **K. B. Pigg**[2];
[1]Georgia College & State University, Milledgeville, GA, United States, [2]Arizona State University, Tempe, AZ, United States.

Examinations of the evolution of major angiosperm families often rely on a fossil record consisting of a few members being represented in widely disparate locations. However, in the case of Rosaceae, a major episode of the initial diversification of the family is documented in the Eocene upland floras of the Okanogan Highlands. These lake deposits of northeastern Washington, USA, and British Columbia, Canada contain well preserved compression material of flowers, fruits and leaves representing over a dozen rosaceous taxa. Among those recognized, are both extant (Prunus, Amalanchier, Spirea) and extinct (Stonebergia) genera of all four of the traditionally recognized subfamilies.

The diverse floras at Republic, Washington and One Mile Creek and related localities in British Columbia provide a snapshot of a group undergoing major radiation. The Okanogan Highlands was a key segment of a migrational route for multiple exchanges of North American and Asian taxa. The complexity seen in Eocene Rosaceae suggests that microevolutionary processes documented in present-day members of the family may have been pivotal to early evolution of Rosaceae.

P1258. The genus Rubus L. (Rosaceae Juss.) in the flora of West Ukraine

V. I. Honcharenko;
Ivan Franko National University of Lviv, Lviv, Ukraine.

The genus Rubus in the flora of the West Ukraine is represented by 31 species. First time for the flora of West Ukraine it was adduced 6 species: R. divaricatus, R. opacus, R. praecox, R. orthostachys, R. gothicus, R. haesitans and subspecies R. nessensis ssp scissoides. From the list of blackberries of the regional flora have been excluded R. chamaemorus, R. macrophyllus, R. radula, R. carpinifolius, R. pyramidalis, R. vestitus, R. koehleri, R. kuleszae, R. camtostachys, R. mollis, R. serpens, because of absence of herbarium speciments, that prove their location in the West Ukraine; their previous inclusion in the list of species was connected probably with incorrect definition. The botanical-geographical and ecological-geographical analysis of the species of the Rubus in flora of West Ukraine are carried out. Analysis of the present distribution of blackberries in West Ukraine gets an evidence that great part of found species are blindet to Karpathians and Rostotche, where one of the diversity centrum of the Rubus in Ukraine is situated.

P1259. Molecular phylogeny and biogeography of the genera *Mespilus* L. and *Crataegus* L. (Rosaceae)

E. Lo[1], T. A. Dickinson[2];
[1]Department of Botany, University of Toronto, Toronto, ON, Canada,
[2]Royal Ontario Museum, Toronto, ON, Canada.

Crataegus is one of the largest genera within Rosaceae subfamily Maloideae. We have used two nuclear (*ITS, LEAFY* intron 2) and four chloroplast (*trnG/S, psbA/trnH, trnH/rpl2, and rpl20/rps12*) regions to infer phylogenies with which to test the existing sectional classification of the genus. Our sample consists of 133 accessions representing 66 species of *Crataegus* in 15 sections from both the Old and New World. In addition, 18 accessions representing the two species ascribed to the closely related genus *Mespilus*, together with species of *Amelanchier*, *Malus*, and *Aronia* as outgroups, are included. Besides clarifying relationships between *Mespilus* and *Crataegus*, our results indicate that some sections (e.g. *Brevispinae*) may not be monophyletic. Strong biogeographic patterns are observed among sections: (1) the western North American section *Douglasii* is sister to the East Asian *Sanguineae*; (2) section *Crataegus* of western Eurasia is closely related to the Asian *Hupehensis* and *Cuneatae*; (3) the co-occurrence of several sections in eastern North America such as *Cordatae*, *Microcarpae*, *Coccineae, Crus-galli* and *Aestivales* is not due to their monophyly.

P1260. Intraspecific variability of European *Rosa* (sect. Cinnamomeae) and delimitation of the species.

I. A. Schanzer[1], G. Y. Klinkova[2];
[1]Main Botanic Garden, Moscow, Russian Federation, [2]Volgograd State Pedagogical University, Volgograd, Russian Federation.

In Russian literature *Rosa majalis* is usually split into 4 to 5 separate species basing on fruit shape, indumentum, and glandulousness of various parts of the plant. Recently some of the European botanists seem to be inclined to support such a point of view, too. The analyses of infra- and interpopulational variability of these characters revealed that all the morphs described as species can occur within a single population. Numerous intermediates between them do exist. Neither clear pattern in geographic distribution of these morphs, nor a significant correlation between variable characters can be observed. Similar combinatory patterns of variability exist in related species *R. acicularis* and *R. alpina*. Delimitation of these species is possible by characters other than fruit shape and pubescence, such as growth form, leaflet number, shoot's armature, pedicel length, etc. Two neglected taxa of the sect. Cinnamomeae however occur in European Russia, mostly in cultivation. One of them differs from R. majalis in armature and flower characters and is of still unknown origin. The other is probably the Linnean *R. pendulina*, an early cultivar of N American *R. blanda*.

P1261. Promiscuity in the Andes: using AFLP and morphological data to examine species relationships in Polylepis R. & P. (Rosaceae, Sanguisorbeae)

A. N. Schmidt-Lebuhn, M. Kessler;
Albrecht-von-Haller-Institute of Plant Sciences, Göttingen, Germany.

Polylepis R.&P. is a genus of small to large trees distributed along the Andes from Venezuela to Argentina. It is especially notable for including representatives reaching the highest elevations among woody plants worldwide. In the present study, AFLP and morphological data were used to reconstruct the phylogeny of the genus. Results from the morphological analysis correlate well with earlier hypotheses about evolution in the genus, showing a progression from large trees with numerous, thin-textured leaflets, and many-flowered inflorescences to reduced growth size, few, thick-textured leaflets, and few flowers per inflorescence. While a basic phylogenetic signal is also discernible in the AFLP analysis, relationships at the tips of the AFLP trees seem to be dictated mainly by geographic proximity rather than systematic affiliation. This structure is interpreted as indicative of frequent hybridization and introgression, raising the question how species with extensive geographical ranges maintain their apparent morphological cohesiveness.

P1262. Bracteoles in Crataegus Systematics

K. Dvorsky, J. B. Phipps;
University of Western Ontario, London, ON, Canada.

The inflorescence bracteoles of *Crataegus* (Rosaceae) were investigated to determine their value in hawthorn systematics. Studies to date have revealed: (1) two significantly different bracteole types occur, a symmetric kind found in all species and an asymmetric kind found only in Asiatic species; (2) there is considerable variability in texture, size, width, venation, and glandularity within the symmetric kind; (3) preliminary analysis of the data indicates the potential for a valuable elucidation of the existing taxonomy; (4) studies on their function found evidence to suggest that bracteoles in *Crataegus* are the site of extrafloral nectaries that serve to decrease the number of floral visits made by ants. Now that different species of *Crataegus* have been found to possess characteristic bracteole forms, bracteoles can begin to be used routinely in taxonomic keys. It is expected to have morphometric analyses available at the congress.

P1263. Phylogenetic relationships in tribe Spiraeeae (Rosaceae) inferred from nucleotide sequence data

D. Potter, S. M. Still;
University of California Davis, Davis, CA, United States.

Tribe Spiraeeae has generally been defined to include *Aruncus*, *Kelseya*, *Luetkea*, *Petrophyton*, *Sibiraea*, and *Spiraea*. Recent phylogenetic analyses of Rosaceae have supported the monophyly of a group including those genera (although *Sibiraea* has not yet been sampled) plus *Holodiscus*, formerly classified in Tribe Holodisceae because fruits in this genus are achenes rather than follicles. *Spiraea*, with 50-100 species distributed throughout the north temperate regions of the world, is by far the largest and most widespread genus in the group. The remaining genera have one to several species each and most of them are confined to North America. Phylogenetic analyses of nucleotide sequences from the nuclear (ITS) and chloroplast (matK, trnL-F) genomes support monophyly of a group including *Kelseya*, *Petrophyton*, and *Spiraea*, which is sister to a clade including the other genera. Within *Spiraea*, none of the three sections defined by Rehder based on inflorescence morphology is supported as monophyletic. Phylogenetic analyses suggest that there have been several biogeographic events involving vicariance or dispersal between the Old and New Worlds within this group.

P1264. Taxonomy of The Old World *Crataegus* on The Model of The Turkish *Crataegus*

A. A. Dönmez;
Hacettepe University, Faculty of Science, Department of Botany, 06532-Beytepe/Ankara, Turkey.

Turkey is an important diversity center for the genus Crataegus Section Crataegus because it lies in an area between the three main phytogeographical regions, namely, the Euro-Siberian, Mediterranean and Irano-Turanian regions. In addition to this, the country is characterized by a wide range of topographical structures and of vegetation cover, and diverse climatic features.

This study includes all the Old World Crataegus taxa. Both taxonomical and nomenclatural studies on the section have been continuing.

The most important problem for the taxonomy of the Crataegus taxa is probably hybridization. This has been frequently observed during the field studies in Turkey and several intermediate specimens have been collected by the present author. However, some of the taxa which have been formerly proposed as hybrid origin do not seem to be so according to field observations on their biogeography, flowering trait and other features. This study is intended to discuss the latest situation of the taxonomy of the Old World Crataegus taxa, some of the special problems, and possible future works for a better taxonomy of the genus.

P1265. Molecular diversity and phylogenetic position of the genus Sibiraea within the family Rosaceae

T. Grebenc[1], **D. Ballian**[2], G. Božiļ [1], H. Kraigher[1];
[1]Slovenian Forestry Institute, Ljubljana, Slovenia, [2]University of Sarajevo, Sarajevo, Bosnia and Herzegovina.

Croatian sybirea (Sibiraea croatica Deg.) is a rare and endemic species described from western Balkan region, representing a tertiary relict in regional flora. Only a few data is known about the biology and genetics of this IUCN protected species. We have studied Croatian and Altaic sybirea (S. altaiensis (Laxm.) C. K. Schneider) by comparing the genetic diversity and differentiation of two S. croatica populations from the Balkan region with two populations of S. altaiensis from regions of southern Russia and Siberia. Based on the molecular analyses of ITS regions in nrDNA we propose Croatian sybirea only as an ecotype of Altaic sybirea, yet retaining its high need for protection. The observed low genetic diversity is also supported with only a few morphological differences between taxons. The phylogenetic analysis of ITS regions in nrDNA positioned sybirea into the tribe Spireae, equally to its position previously determined by morphological characteristics.

Acknowledgements: We would like to thank V. Melnik, J. Franjic and M. Konnert for advice, material, lab.facilities and support. The study was part of the r. p. P4-0107 of the Slovenian Forestry Institute.

P1266. First phylogeny of *Sabicea* and its allied genera inferred from ITS data

S. A. Khan[1,2], S. G. Razafimandimbison[3,4], B. Bremer[3,4], U. Meve[1], S. Liede-Schumann[1];
[1]Department of Plant Systematics, University of Bayreuth, D-95440 Bayreuth, Germany, [2]Department of Botany, Jahangirnagar University, Savar, Dhaka-1342, Bangladesh, [3]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Norbyvägen 18 D, SE-752 36, Uppsala, Sweden, [4]The Bergius Foundations at the Royal Swedish Academy of Science, P.O. Box 50017, SE-104 05, Stockholm, Sweden.

Sabicea is the type genus of the tribe Sabiceeae presently placed in the subfamily Ixoroideae (Rubiaceae). This pantropical genus has its centre of diversity in African mainland with 82 species, followed by the Neotropics with 63 species, Madagascar with 6 species, and São Tomé and Principe with 3 species. *Sabicea* has been circumscribed by a usually scandent habit, axillary inflorescences, valvate corolla lobes, (2-)3-5 locular ovary with numerous ovules in each locule, and fleshy fruits. Recognition of *Sabicea* as a separate genus has never been challenged, but its monophyly has never been tested using molecular-based phylogenies. In this first phylogenetic study of *Sabicea* and its allies we perfom parsimony analyses based on ITS data to test the monophyly of *Sabicea*. Our analyses show that the current delimitations of *Sabicea* and *Pseudosabicea* do not form monophyletic units. Neotropical *Sabicea* is resolved as monophyletic, whereas African *Sabicea* seem to be para- or polyphyletic.

P1267. Phylogeny of the "*Hedyotis* group" (Rubiaceae)

T. J. Motley;
The New York Botanical Garden, Bronx, NY, United States.

Phylogenetic studies have shown the tribe Hedyotideae is paraphyletic. The tribe Spermacoceae is nested within the Hedyotideae. Some authors have suggested an emended Spermacoceae to include these two tribes and the Knoxieae, Manettieae, and Triainolepideae. Other authors have suggested a separate Knoxieae and Spermacoceae (Spermacoceae, Manettieae, and "*Hedyotis* group"). The *Hedyotis* group is a polyphyletic assemblage of 41 genera and over 800 species. Further complicating the circumscription of the group is that the two largest genera *Hedyotis* and *Oldenlandia* are polyphyletic. This study used *trnL*, *rps16*, and ITS data to examine the phylogeny of the group using a broader, more comprehensive sampling. Preliminary results indicate that lineage-sorting has a strong correlation to biogeographic distributions. Genera such as *Arcytophyllum* and *Houstonia* are forming monophyletic lineages; however, other new groups are being resolved that are not define by clear morphological synapomorphies.

P1268. Phylogeny and classification of Ixoreae (Rubiaceae: Ixoroideae)

A. Mouly[1], B. Bremer[2], J. Florence[3], J. Jérémie[1];
[1]UMS 0602 Taxonomy and Collections - Botany - Muséum National d'Histoire Naturelle, Paris, France, [2]The Bergius Foundation at the Royal Academy of Sciences, Stockholm, Sweden, [3]US 084 BIODIVAL : Tropical plants biodiversity : knowledge and valorisation - Institut de Recherche pour le Développement, Antenne MNHN, Paris, France.

The tribe Ixoreae, of the subfamilly Ixoroideae s.l. (Rubiaceae), as presently circumscribed (Andreasen & Bremer 2000) contains ca. 400 species and 6 genera (Captaincookia, Doricera, Ixora, Myonima, Scyphiphora and Versteegia) shrubs and trees. The pantropical genus Ixora is the largest genus with 300 to 400 species, some of which are commonly cultivated as ornamentals throughout the world. The monophyly of its current circumscription has never been tested before. The authors perform phylogenetic analyses using sequencing data from two chloroplast (rps16 and trnT-F) and one nuclear (ETS) markers and morphological data to test the monophyly of Ixora and Ixoreae. The study includes all genera placed in Ixoreae, all genera classified in Pavetteae s.s., and several taxa from the remaining tribes of Ixoroideae s.l. The resulting phylogenies will also be used to assess the phylogenetic relationships between the Ixoreae genera.

P1269. Paraphyly of Paederieae, and recognition of Putorieae (Rubiaceae)

M. Backlund[1], B. Bremer[2], M. Thulin[1];
[1]Evolutionary Biology Centre, Systematic Botany, Uppsala, Sweden, [2]Bergius Botanic Garden, Stockholm, Sweden.

The tribe Paederieae (Rubiaceae), until recently comprising 15 genera, has been regarded as paraphyletic in recent studies. To address this issue a molecular data set of *rbcL*, *rps16*, and *trnT-F* nucleotide sequences has been retrieved and analysed. The result unambiguously corroborates the suggestion that the Paederieae indeed is paraphyletic, and a grouping into two distinct clades is highly supported. One of these clades, Paederieae *s.str.,* comprises the type genus *Paederia* together with the East Asian genera *Spermadictyon*, *Serissa*, and *Leptodermis*. Furthermore, *Paederia* divides into one Asian and one African group.
The genera *Putoria*, *Gaillonia,* (and its segregates), *Plocama*, and *Aitchisonia* form the other clade. This group has *pro parte* been recognized earlier, under the available name Putorieae. The sister group of the Putorieae are the tribes Theligoneae and Rubieae, the latter including *Kelloggia*, earlier placed in Paederieae. Some of the clades within Putorieae have a strong support from the molecular data, but they do not always correspond to the previously recognized genera and taxonomic changes seem inevitable.

P1270. Evolutionary history of the plant genus Pagamea Aubl. (Rubiaceae) in tropical South America - molecular markers, morphology and geographical variation.

A. Vicentini[1,2];
[1]University of Missouri Saint Louis, Saint Louis, MO, United States, [2]Missouri Botanical Garden, Saint Louis, MO, United States.

Pagamea comprises ca. 50 species (10 undescribed) of trees and shrubs that occur in forests and scrublands of nutrient-poor soils (white sands) throughout tropical South America. Pagamea is sister to Gaertnera, whose phylogenetic history indicates a recent rapid radiation throughout the Paleotropics. The molecular phylogenies of chloroplast (rps16_intron; rpl20-5â€™rps12) and nuclear (NOT, PER42) markers are contrasted with patterns of morphological variation and the geographical distribution of species. Phylogenetic results indicate a rapid diversification for Pagamea, though an older history than that of Gaertnera. These also indicate a dynamic biogeographical history, and incongruence between nuclear and chloroplast data suggest hybridization. Morphological clusters conform to monophyletic species for the most part, but there is also misleading morphological convergence. Dioecy has evolved multiple times and variation in breeding system occurs even at the population level. Results highlight the importance of combining molecules, morphology and geography for understanding species-level patterns and processes.

P1271. The Malagasy representatives of Ixora (Rubiaceae)

P. J. De Block;
National Botanic Garden of Belgium, Meise, Belgium.

Ixora (Ixoreae - Rubiaceae) is a large genus (300-400 species) of shrubs and small trees from humid forests. The genus is pantropical but species diversity is highest in Asia and Oceania. No world monograph of Ixora exists but recent publications include geographically restricted revisions, e.g. of the continental African species.

A revision of the Malagasy species of Ixora is underway. The genus is represented in Madagascar by c. 30 species, all endemic and many as yet undescribed. This number is slightly lower than that for the African mainland, but morphological variation is much greater. The following trends are found in the Malagasy species and absent on the continent:

- solitary flowers
- flowers up to 20 cm long (versus < 10 cm long in Africa). No observations are available but pollination of these long narrow flowers must be effected by hawkmoths.
- four-locular ovaries versus bilocular ones. This character is correlated with very large ovaries and calyces.
- large fruits

Once the revision is finished and species delimitations clear, the path is free to learn more about the affinities of the Malagasy species of Ixora and understand their radiation on the island.

P1272. Phylogeny and breakdown of distyly correlated with polyploidization in *Damnacanthus* (Rubiaceae).

A. Naiki[1], H. Nagamasu[2];
[1]Osaka Museum of Natural History, Osaka, Japan, [2]The Kyoto University Museum, Kyoto, Japan.

Damnacanthus is a small genus, is comprised of eight species, and is distributed mainly in laurel forests of the Sino-Japanese Region. Some species of *Damnacanthus* are distylous, and others have flowers with long styles and short stamens with few exceptions. In *Damnacanthus*, diploid ($2n = 22$) and tetraploid ($2n = 44$) counts were obtained by somatic chromosome observations. A strong correlation exists between chromosome number and occurrence of distyly. Regardless of taxa in *Damnacanthus*, distylous populations are diploid, and monomorphic populations are tetraploid. Molecular phylogenetic analysis using some non-coding chloroplast DNA regions suggests multiple origins of polyploidization in *Damnacanthus*. Tetraploids appear in different lineages with diploids in the present molecular phylogenetic tree. Thus, polyploidization seems to have caused the breakdown of distylous to monomorphic flowers.

P1273. Lectotypification of *Callicocca ipecacuanha* Brot. and neotypification of *Cephaelis acuminata* H.Karst., with reference to the drug Ipecac

H. J. De Boer, **M. Thulin**, J. J. Wieringa;
Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden.

The main pharmacopoeias cite the roots of *Cephaelis ipecacuanha* (syn. *Callicocca ipecacuanha* Brot.) together with the roots of *Cephaelis acuminata* H.Karst. as the sources of the crude drug ipecac (European Pharmacopoeia, 2002, 2004; United States Pharmacopeia, 2004; British Pharmacopoeia, 2003; Japanese Pharmacopoeia, 2001). Ipecac is an important emetic and expectorant used in case of poisoning, mainly in children. However, *C. acuminata* does not occur in botanical literature, except in connection with the original description, and this falls entirely within the variation of the widespread and variable *Cephaelis ipecacuanha*. *Callicocca ipecacuanha* was described from Brazil, but no type specimen has been found and the name is here lectotypified with an illustration from the protologue. For *Cephaelis acuminata*, described from Colombia, no original material is extant, and a recent specimen from Colombia is here selected to serve as neotype.

P1274. The molecular approach of different taxonomical levels in Rubiaceae

S. Stranczinger[1], J. L. Szentpéteri[1], A. Borhidi[1,2];
[1]University of Pécs, Pécs, Hungary, [2]Institute of Ecology and Botany, Hungarian Academy of Sciences, Vácrátót, Hungary.

The aim of this study was: 1. Separating three genera of Rondeletia complex; 2. The justification of the species level in the *Hintonia* genus; 3. The better cognition of interior separation of *Randia* genus.

A molecular phylogeny was constructed using nucleotide sequences of internal transcribed spacer (ITS) regions of nrDNA and of the rps16 intron of the cpDNA. A phylogenetic tree was constructed from the nucleotide sequence alignment using PAUP* 4.0.

The *rps*-16 intron seems to be useful to identify different genera. By analyzing this sequence, *Arachnothryx*, *Calicosae*, *Rogiera* genera were well separated within Rondeletia complex, Rondeletieae tribe; *Hintonia* genus within Cinchoneae tribe; *Randia* genus within Gardenieae tribe

With the analysis of ITS sequence, significant polymorphism manifested at specific level in case of all the studied species. This shows the sequence's possible utility in species' identifying.

During the study of both sequences we found two, well separated groups between *Randia* species selected for this research. After this result we found also morphological characteristics, which differentiate the two groups above.

P1275. Grapevine (Vitis spp. L.) Old Varieties and Land Races Conservation in Slovakia

K. Miticka, B. Stehlikova, J. Brindza, E. Chovancova, B. Brezinova, Z. Kothayova;
Institute of Biodiversity Conservation and Biosafety, Nitra, Slovakia.

The part of the National program of plant genetic resources for food and agriculture is also conservation and sustainable use of old varieties and land races of grapevine. Therefore the monitoring, inventory control, reproduction and long term conservation of genotypes is provided. In the process of evaluation were analyzed 35 quantitative and qualitative characters for a leaf, bunches, a berry and seeds. For these characters has been determined following variability ranges - the length of a bunch stalk (30.67 - 43.87 mm), the weight of a single bunch (71.4 - 200 g), the length of a bunch (88.20 - 181.67 mm), the width of a bunch (63.73 - 111.93 mm), the number of berries per bunch (35 - 178 no), the number of seeds per 100 berries (130 - 315 mm no), the weight of 100 dried seeds (1.67 - 6.45 g). Duplicated genotypes are preserved in the clonally repository. The important genotypes are reproduced for practical use. Experimental data and image documentation are prepared for information system *GENOTYP*DATA *Vitis.*

P1276. Wild grapevine (Vitis vinifera ssp. silvestris) in Europe: Distribution, ecology, growth strategy and threats

C. Arnold[1], A. Schnitzler[2], M. Lopez[3], R. Ocete[3], C. Fraissl[4], F. Gillet[5];
[1]NCCR Plant Survival/ University of Neuchâtel, Neuchâtel, Switzerland, [2]UFR of Fundamental and Applied Sciences/University of Metz, Metz, France, [3]Laboratory of Applied Entomology/University of Sevilla, Sevilla, Spain, [4]National Daunau Auen GmbH, Orth and der Donau, Austria, [5]ECOS/ Federal Institute of Technology Lausanne (EPFL), Lausanne, Switzerland.

Wild grapevine (Vitis vinifera ssp. silvestris) used to be widely distributed across Europe, but today its populations are fragmented and reduced to less than one hundred individuals. Morphologically and genetically, this crop-related species can be clearly differentiated from cultivars. It is adapted to many different environments in Europe such as floodplains or colluvial forests, but at the local scale is found in similar environments (of vegetation and soil). The largest populations are located in Austria where the floodplain dynamic and forest management still allow a sexual reproduction. Silviculture has a direct impact on the disappearance of wild grapevine, while river management, the introduction of pests, diseases and American species have a greater yet indirect impact. Specific examples of European populations as well as measures of conservation will be given.

P1277. Wild grape biodiversity detected by DNA molecular markers

M. Labra[1], F. Grassi[2], S. Imazio[3], S. Citterio[1], F. De Mattia[1], A. Scienza[3], S. Sgorbati[1];
[1]University of Milano Bicocca, Milano, Italy, [2]Botanical Garden of University of Milan, Milano, Italy, [3]DIPROVE University of Milano, Milano, Italy.

The *Vitis vinifera* L. species includes: *V. vinifera* ssp. *silvestris*, the wild subspecies, distributed in the spontaneous vegetation in West-Asia, Mediterranean basin and Central and Southern Europe, and *V. vinifera* ssp. *vinifera*, related to cultivated varieties including about 8000 accessions. Wild grape is dioecious species grows in humid soils, like river banks, where it is leaned to the arboreal vegetation. In recent years, the maintenance of genetic variability within wild grape populations is at risk due to decline of wetland areas, with the conversion of land to agriculture. To preserve genetic diversity of this species, we analysed the genetic variability in several wild grape populations collected from different European and Middle East regions, by using SSR markers. Results provide information about population genetic structure and gene flow among different grape populations and identify areas harboring high levels of wild grape variability. These data are able to define the suitable conservations strategy.

P1278. Phylogeography of *Viola Persicifolia*

K. van den Hof, B. Gravendeel, R. van der Meijden;
National Herbarium of the Netherlands, Leiden, The Netherlands.

Viola persicifolia (Violaceae) is a wide spread but rare plant species occurring throughout Europe with the exception of the Mediterranean and arctic Europe. It is paleotetraploid and the parental species of several closely related allopolyploids (*V. canina*, *V. lactea*, and *V. pumila*). Two infraspecific taxa have been described: *V. persicifolia* var. *persicifolia* and var. *lacteaeoides*. The latter one is only known from The Netherlands and might be one of its few endemics.We are studying the phylogeography of *V. persicifolia* in order to gain insight into its dispersal routes across Europe and its arrival in The Netherlands. We hope to find out (1) whether the distribution area of *V.* var. *lacteaeoides* is restricted to The Netherlands, and (2) whether *V.* var. *lacteaeoides* is either a relict population of a larger distribution area that existed in the past, or a local genotype that originated *in situ* in the valley of the IJssel river. In this presentation, results of a preliminary study using a chloroplast marker will be shown.

P1279. Origin of the Parma Violet cultivars (Violaceae)

M. Henry[1], V. Malécot[2], T. Marcussen[3], J. Munzinger[4], R. Yockteng[5];
[1]Laboratoire de Botanique et Mycologie, Faculté de Pharmacie, Nancy, France, [2]UMR A 462 - Institut National d'Horticulture, Angers, France, [3]Centre of Ecological and Evolutionary Synthesis (CEES), University of Oslo, Oslo, Norway, [4]Laboratoire de Botanique (NOU), Centre IRD, Nouméa, New Caledonia, [5]Laboratoire Ecologie, Systématique et Evolution, Université Paris-Sud, Orsay, France.

In order to clarify the relationships among Parma Violet cultivars and wild species we conducted a phylogenetic study based on ITS and allozymes markers. These cultivars are characterized by fragrant abnormal flowers with 20-40 floral pieces and stoloniferous habit. Based on ITS data, Parma Violets are nested in an unresolved *Viola alba* and *V. sintenisii* clade, and two groups of cultivars can be identified. One of these two cultivar groups is characterized by its highly polymorphic ITS sequences that may be related to vegetative propagation. The remaining group had homogeneous ITS sequences and may result form cuttings from rare seedlings. With allozymes, the cultivars showed strong relationships to either of two species, based on allozymic composition and the presence of shared private markers. four private markers connected the Parma Violets to the variable *V. alba* complex, one to the West Asian *V. sintenisii*, and one to both *V. alba* and *V. sintenisii*.These results imply an assigment to *V. Alba* for the Parma Violet cultivars, most probably *Viola alba* ssp. *dehnhardtii*. They, most likely originated once and loss of heterozygosity is due to rare events of sexuality.

P1280. How much we know about violets from Argentina?

A. M. Sanso[1,2], C. C. Xifreda[3], M. N. Seo[2];
[1]Facultad de Ciencias Veterinarias. UNICEN, Tandil, Argentina, [2]Depto. Cs. Biológicas. FCEN. Universidad de Bs. As., Buenos Aires, Argentina, [3]LEBA FCNyM. Universidad de La Plata, La Plata, Argentina.

The cosmopolitan *Viola* L. genus is represented in Argentina by near 50 species, mainly native ones and only four adventitious entities. Some species, the “yellow violets” from section *Chilenium*, are one of the most common components of the Patagonia and Tierra del Fuego rain-forests. Other taxa belonging to the very interesting section *Andinium* occur in argentine northwestern, at high altitudes, mostly between 3000-4000 m above sea level. We know very little about these last species, most of them, endemic, confined to small geographical areas and difficult to be collected.

In order to assess utility of different morphological, anatomical and cytological characters for the classification, we present preliminary data gathered from a screening study taking in account some representative species. We also provide data concerning species distribution. Selected characters as chromosome numbers and pollen morphology observed at SEM, are discussed. Leaf and seed anatomical features are highlighted, showing the results their potential value in taxonomic and evolutive studies.

P1281. *Corynostylis* a true violaceous neotropical genus.

A. Fernandez[1,2];
[1]Insttituto Venezolano de Investigaciones Cientificas, Caracas, Venezuela, [2]Universidad Central de Venezuela, Fac. de Ccs. Instituto de Biologia Experimental, Postgrado en Botanica, Caracas, Venezuela.

Violaceae is a medium sized cosmopolitan family, that grows in almost all terrestrial environments with amazing morphological plasticity. More than 50 % of the species belong to the putatively derived tribe Violeae (worldwide) and share the commonest characters that distinguish the violets. *Corynostylis* is a tipical violeaean neotropical genus with 4 shrubby or lianiform species, it possess alternate serrulated leaves, deciduous stipules, strongly zygomorphic, resupinated entomophilous flowers, quincuncial sepals aestivation, apotact petals, anterior petal wider and long spurred, free staments, calcarate and villous dorsal glands, laminar connective scales, tricarpellate ovary, curved style, 3 valvate woody capsule, numerous seeds compressed and sub square. Species and their distribution are: *C. arborea* (Belize, Bolivia, Brazil, Colombia, Costa Rica, Ecuador, French Guiana, Guyana, Mexico, Nicaragua, Panama, Peru, Surinam, Trinidad (introd), Venezuela), *C. carthagenensis* (Colombia, Venezuela), *C. pubescens* (Bolivia, Brazil, Venezuela) and *C. volubilis* (Brazil, Colombia, Peru, Venezuela) with a possibly new from Venezuelan Amazonas.

P1282. The Digitalization of Rare Wall Chart Collections (the largest digitalized collection in Europe)

M. Skalický;
Czech University of Agriculture Prague, Prague, Czech Republic.

Our department owns valuable complete and also non-complete collection of pictures on general and systematic botany - *Botanische Wandtafeln* (published from 1874 to 1914, Berlin, Paul Parey), *Pflanzenphysiologische Wandtafeln von Frank und Tschirch* (published from 1889 to 1894, Berlin, Paul Parey), *Botanical Atlas by Arnold & Carolina Dodel-Port* (published from 1878 to1883, Switzerland) etc. Most of these pictures have an invaluable worth. All these wall pictures (about 600 pieces) have been digitalized. The digitalization enables the students to understand complicated morphological-anatomical structures of plants as well as to recognize characteristic signs of representatives of plant families. Every picture was retouched and supplemented by scientific commentaries. The picture database is placed on the web pages of the department.

The studies were financed from grants of Higher Education Development Fund 1097/2002, 816/2004.

P1283. The life and scientific achievements of Emil Godlewski Snr (1847-1930) - a Polish plant physiologist

I. Krzeptowska;
Institute of Botany, Jagiellonian University, Cracow, Poland.

Emil Godlewski Snr (1847-1930) was a Polish scientist, who contributed to the development of plant physiology worldwide, as a modern and separate branch of botanical sciences which emerged at the mid-19th century. He authored many publications, some of them are considered today to be 'classics'. He carried out his first experiments in plant physiology during a half-year stay at the well-known laboratory of Professor Julius Sachs in Würzburg, Germany (1872). From that time on, he devoted all his time to this discipline, working in Polish universities and other higher education institutions in Cracow, Lvov, Dublany (near Lvov) and Pulawy. He earned also high recognition as educator and organizer of scientific activities.

E. Godlewski worked on several topics in the field of plant physiology, including: photosynthesis, respiration, growth, etiolation, metabolic transformations of protein, water transport, nitrification and mineral nutrition. He also published works on agrochemistry. The merit of his achievements can be also measured by the fact that numerous academies of sciences and learned societies in Poland and abroad made him their member.

P1284. E. Janczewski’s materials on Ribes taxonomy at the Jagiellonian University.

K. Kulpinski;
Botanical Garden, Jagiellonian University, Krakow, Poland.

Edward Janczewski (1846-1918) was a plant anatomist and taxonomist, professor of the Jagiellonian University (Krakow). His “Monographie des Groseilliers” on genus Ribes was the first wide taxonomical analysis of this genus. Published almost a century ago (1907), it retained most of its value as the best source of information on this genus, regardless of the fact that only half of the world species were described. The Institute of Botany at the Jagiellonian University owns a vast collection of materials Janczewski used during his work on the monograph. It includes herbarium, microscope preparations and some living plants cultivated at the University’s Botanical Garden. Some of those materials were used by Janczewski to describe new taxa. The main aim of the first part of my project is to create digital database of all materials, then analyse them regarding their importance. The results of this part will be then used in the next phase, in which I will try to evaluate the real influence Janczewski had on Ribes taxonomy, and also on plant taxonomy as a science. I will also try to describe current state of Ribes taxonomy and summarize changes in it since Janczewski’s monograph.

P1285. The element nitrogen in the philatelic world

H. Bothe;
Botanisches Institut, Universität Köln, Köln, Germany.

Stamps issued world-wide provide an excellent opportunity to display diverse aspects of the element nitrogen. Copies of stamps issued over the years in the world will be shown on this poster with four spaces. The poster describes the discovery of the element nitrogen from the beginning on, the occurrence of the element nitrogen in selected organic molecules as well as the impact of nitrogen on pollution both in the soil and on the atmosphere. In addition, processes like dinitrogen fixation or denitrification will be demonstrated on stamps. Diverse plants (legumes and others) which live in symbiosis with dinitrogen fixing bacteria (*Rhizobium, Frankia*) will be shown. Examples of carnivores will also be displayed. The copy of each stamp displayed is supplemented with a text explaining the relevance of the stamp with respect to the element nitrogen. The presentation will also be available on CD.

P1286. The original Willdenow’s collection in Herbarium of Saint-Petersburg University (LECB)

V. A. Bubyreva[1], V. V. Byalt[2], L. V. Orlova[2], A. V. Zhuk[1];
[1]St.Petersburg State University, St. Petersburg, Russian Federation,
[2]Komarov Botanical Institute RAS, St. Petersburg, Russian Federation.

The Herbarium of Saint-Petersburg State University (LECB) is one of the oldest Russian Herbarium and includes about 850000 specimens. Several years ago in the separate A.G.H. Bongard’s collection we have found herbarium specimens with handwriting of C.L. Willdenow (it was confirmed by P. Hiepko from Berlin). This fact is not known for most of scientists nor Russia nor world wise. In 2004 under support of the Presidium Russian Academy of Sciences grant “The visualisation of J. Boeber and C.L. Willdenows’ specimens preserved at St. Peresburg university (LECB)” we have looked through the whole Bongard’s collection (ca. 250000 specimens) and found 1088 original Willdenow’s specimens of 54 famillies of the Higher plants. It is possibly the specimens were received by Bongard not directly from Willdenov as Bongard was young scientist when the first was yet alive. Preliminary study of specimens have shown that near 100 authentic Willdenow’s specimens of 23 families preserved in LECB and several names were not included in “Herbarium Willdenow Alphabetical Index”, 1974.Thank to this fact importance of LECB collection strong increased

P1287. Phylogenetic study of *Antrodia* and other related genera based on analysis of LSU and SSU nuclear rDNA

S. Wu[1], Z. Yu[2], C. Chen[1];
[1]National Museum of Natural Science, Taichung, Taiwan Republic of China, [2]School of Life Science, Yangtze University, Hubei, China.

Antrodia is polypore genus with almost 40 species, causing a brown rot in wood. This study aims in evaluating generic status of *Antrodia*, as well as its phylogenetic relationships with other polypore genera with more or less similar characters. Phylogenetic analysis of this study was based on sequence data from LSU and SSU nuclear rDNA. All studied *Antrodia* species form a poorly supported lineage (*Antrodia* s.l.), which also accommodate species of some other genera. Three monophyletic groups could be identified in this lineage. The group of *Antrodia* s.s. accommodates many species of *Antrodia*, and *Fomitopsis* and *Piptoporus*. The second group represents the genus *Amyloporia*, characterized in having bitter taste of fruiting body and amyloid skeletal hyphae. The third group represents the genus *Fibroporia*, characterized in having fruiting body with rhizomorphic margin. Independence of a recently proposed genus, *Taiwanofungus*, was supported in this analysis. *Antrodiella* and *Diplomitoporus* are two white-rot genera resembling *Antrodia* by sharing general morphological features. The result indicates that these two genera are not closely related to *Antrodia*.

P1288. Three taxonomic forms of *Dictyostelium purpureum* from Taiwan and molecular phylogeny of dictyostelids in East Asia

Z. Y. Yeh, U. F. Wang, Y. P. Tan;
National Taiwan Normal University, Taipei, Taiwan Republic of China.

Twelve isolates of *Dictyostelium purpureum* were obtained from various sites of forest soils in Taiwan. Among them, three taxonomic forms of *D. purpureum* were discovered based upon morphological characteristics. One was “temperate form”, the second was “subtropical form” and the third form was newly found and was named “medial form”. Molecular phylogenetic analysis was performed also in this study. Nuclear ribosomal DNA- ITS2 sequences of the three forms of *D. purpureum* and another 27 dictyostelid isolates from Taiwan and East Asia were analyzed and phylogenetic tree was constructed by PAUP program. Three forms of *D. purpureum* can be clustered into 3 groups. The tested 39 isolates of *Dictyostelium* are split into two well-supported clades based on polar granule present isolates and polar granule absent isolates. Polar granule is one of the most important characters and may be considered to serve as a taxonomic criterion on the subgenus rank under *Dictyostelium.*

P1289. Biodiversity studies of Leotiales in Taiwan

M. L. Wu;
Graduate School of Environment Education, Taipei Municipal Teachers College, Taipei, Taiwan Republic of China.

Leotiales is a very important family of discomycetes in the resources of bioactive metabolites. More than 2,000 species of Leotiales are currently known. However, regional mycoflora were mostly investigated in Europe and North America but not southern part of the world including Taiwan. Studies of the Leotiales in Taiwan during 1919~2004 are briefly reviewed. There were 54 species of Leotiales in 6 families and 24 genus had been reported from Taiwan. They may be from the area of general deciduous or mixed deciduous and coniferous forests to the area with high acidity soil weathered in warm volcano mist. The habitats and hosts of the known species have been analyzed based on published information. In order to glance at progress on studies of Leotiales in Taiwan, a list of reported species, genus and the researchers with publications related to this kind of fungi are provided. The ecological and morphological characteristics of the Leotiales reported in Taiwan as well as 4 newly recorded species will be discussed.

P1290. Taxonomic Studies on Species of *Russula* in Taiwan

E. F. T. Tschen;
National Museum of Natural Science, Taichung City, Taiwan Republic of China.

Russula (Russulaceae) is one of the major mycorrhizal macrofungal genera that occur in broad-leaved, mixed and conifer forests in Taiwan. A taxonomic study of *Russula* (Russulaceae) has been undertaken in Taiwan during 2000-2002, based on specimens collected at 500-2,500 m altitude. A total number of 17 species were obtained from this study. They are: Subgenus *Compactae: Russula nigricans, R. delica*. Subgenus *Russula: R. cyanoxantha, R. virescens*, *R. amoena*, *R. violeipes*, *R. alboareolata* (Sect. *Heterophyllae*), *R. castanopsidis* (Sect. *Pachycystides*), *R. foetens*, *R. subfoetens*, *R. laurocerasi*, *R. senecis* (Sect. *Ingratae*), *R. emetica*, *R. betularum*, *R. sanguinea*, *R. fragilis* (Sect. *Piperinae*), *R. xempelina* (Sect. *Polychromae*). *R. violeipes*, *R. subfoetens*, *R. betularum* and *R. xempelina* are reported for the first time in Taiwan. *R. alboareolata, R.*

castanopsidis and *R. senecis* are E Asia species, only distributed in Japan, Korea, China and Taiwan.

P1291. Diversity and Molecular Phylogeny of ballistoconidium-forming yeasts from China

F. Y. Bai, Q. M. Wang;
Systematic Mycology and Lichenology Laboratory, Institute of Microbiology, Chinese Academy of Sciences, Beijing, China.

From the ballistoconidium-forming and related basidiomycetous yeast strains isolated from plant material collected in representative regions of China, more than 90 species belonging to 14 genera have been identified based on phenotypic and molecular characterization. Approximately one third of the species identified were new to science. The high frequency of new species isolation indicates that the species diversity of basidiomycetous yeasts in nature is very high and that a considerable number of new taxa remain to be found.

The phylogenetic relationships of the new basidiomycetous yeast species from China with described species were revealed from 18S rDNA, ITS region and 26S rDNA D1/D2 domain sequence analyses. Several new distinct clades in different lineages of basidiomycetous yeasts have been recognized by the addition of new species to existing phylogenetic trees. The new clades are significant to reclassify the basidiomycetous yeast species into more homogeneous groups.

P1292. *Verticillium* is still polyphyletic

W. Gams[1], R. Zare[2];
[1]Centraalbureau voor Schimmelcultures, Utrecht, The Netherlands, [2]Plant Pests & Diseases Research Institute, Tehran, Islamic Republic of Iran.

Section *Prostrata*, was treated by Zare and Gams (*Nov. Hedw.*, 2000-01). Three new genera, *Lecanicillium*, *Simplicillium* and *Haptocillium* were introduced. Section *Verticillium* is not closely related to sect. *Nigrescentia* and, after the proposed conservation of *Verticillium* with *V. dahliae* as conserved type (Gams *et al*., *Taxon*, 2005), this species is now reclassified in *Acrostalagmus* as *A. luteo-albus* (Link : Fr.) Zare, W. Gams & Schroers (Zare *et al*. *Mycol. Res.*, 2004). Section *Nigrescentia* comprises the important plant-pathogenic species *V. dahliae* and *V. albo-atrum* plus a few other weaker plant pathogens. In this project, section *Albo-erecta* with erect conidiophores and mainly fungicolous species around *V. fungicola* is being investigated using classical and molecular techniques. Some 140 isolates from all over the world are examined. The results show an extensive variation among isolates examined; the observed relationships correlate with the ecology of the isolates, suggesting the need for further generic segregation. At least three new genera will have to be introduced, but no new anamorph-teleomorph connection is yet found.

P1293. Preliminary study on relationships among genera in the Pyronemataceae (Ascomycetes, Fungi)

C. Y. Liu, **W. W. Zhuang**;
Key Laboratory of Systematic Mycology and Lichenology, Institute of Microbiology, Chinese Academy of Sciences, Beijing, China.

The Pyronemataceae contains a large group of operculate discomycetes. Five subfamilies and many tribes have been designated based on morphological features. To investigate the relationships among genera of the family, 18S nrDNA partial sequences of 24 genera were analyzed and a neighbor-joining tree was obtained with *Saccharomyces cerevisae* as outgroup. Our results indicated that 3 major clades are recognized. One represented by taxa of *Acervus* . The second clade consists of 2 sister groups, *Otidea* and *Otideopsis* as one together with but obviously not close-related to *Lamprospora*, *Leucoscypha*, *Neottiella*, *Octospora* and *Rhodoscypha* sharing similar anatomic structures and inhabitation. The largest clade contains rest of the genera tested, in which 2 groups are distinguishable with only 33% bootstrap support. One is of *Scutellinia, Aleuria, Melastiza, Humaria, Trichophaea, Trichophaeopsis, Jafnea, Sowerbyella* and *Cheilymenia* in which hyphoid hairs or setae exist on receptacle surface; and the other consists of *Geopyxis, Paurocotylis*, *Tarzetta*, *Pulvinula* and *Chalazion*. The family, as currently defined, might not be monophyletic.

P1294. A white form of Auricularia fuscosuccinea from Lacandonia tropical forest, Chiapas, Mexico.

S. Sierra[1], **J. Cifuentes**[1], F. Ruan-Soto[2], R. Mariaca[3];
[1]Sección de Micología, Herbario FCME, Facultad de Ciencias, UNAM., Mexico City, Mexico, [2]El Colegio de la Frontera Sur (ECOSUR)., San Cristóbal de Las Casas, Chiapas, Mexico, [3]El Colegio de la Frontera Sur (ECOSUR), San Cristóbal de Las Casas, Chiapas, Mexico.

Auricularia species have tough to rubbery gelatinous and auriform (from Latin auriculae = ear) basidiomes. All are saprotrophic and grow in trunks of trees (alive or dead). Cultivation has been developed mainly in Asian countries. Records on edibility back from 200-300 B.C. in China. In the Dictionary of Fungi (Kirk et al., 2002) are considered aproximately 15 species worldwide and the Index of Fungi listed 124 names published. Kobayasi (1981) described 15 species and 5 forms. From the Neotropics seven species are reported (Lowy, 1971). Species delimitation has been based on the internal structure of basidiome (Lowy, 1952).

A white form of Auricularia fuscosuccinea is described for the first time from the Tropical Forest in the state of Chiapas, Mexico. White forms have been described so far only for A. auricula f. albicans (Hirneola auricula-judae var. lactea), A. polytricha f. leucochroma and A. delicata f. alba. The main characters of this form are basidiome colour, abhimenial hairs length, context internal structure and size of basidia and spores. It was found growing on unidentified trunk in Lacanjá-Chansayab, Ocosingo Municipality.

P1295. Molecular evidence for the taxonomic status of Lycopersicon within sect. Petota.

N. Y. Komarova, **V. Hemleben**, R. A. Volkov;
ZMBP, University of Tübingen, Tübingen, Germany.

Members of the genus Solanum L., the largest of the genera of the family Solanaceae, have been frequently used as an important model system for studies on structural and functional genomics. Hence, clear understanding of phylogenetic relationships and evolutionary trends within the genus is necessary for appropriate interpretation of the genomics data and to enlarge the efficiency of breeding programs involving wild genetic material. To clarify the taxonomic status of tomatoes (Lycopersicon ssp.) and their relationship to other members of Solanum, in particular to potatoes (sect. Petota), the organization of the rDNA external transcribed spacer (5’ ETS) was studied in 35 wild and cultivated Solanum/Lycopersicon spesies. Sequence analysis showed that evolution of the 5’ ETS within the group proceeded mainly by amplification/duplication of structural elements. Phylogeny reconstruction confirmed that tomatoes definitely belong to the sect. Petota having a common ancestor with Central American/South American primitive potatoes.

P1296. Introgression and Paralogy of ETS in Myrtaceae?

P. G. Wilson, M. M. Heslewood;
National Herbarium of New South Wales, Sydney, Australia.

Sequence data from the external transcribed spacer (ETS) region within the tribe Chamelaucieae provides a highly resolved phylogeny more congruent with morphology than that based on chloroplast data. However, numerous instances of intraspecies polymorphism occur indicating incomplete gene conversion. Polymorphisms are usually single base substitutions but indels and multiple polymorphisms also occur. Intraspecies variants have not been recorded in the disparate genera *Metrosideros*, *Syzygium* and *Kunzea* from other tribes in the family, although there is a possibility that they may occur in *Eugenia*. The phenomenon is not uniform across the tribe - some taxa show no variation indicating that nrDNA arrays within individuals are homogeneous. Where variation occurs, copy number may be unequal; this could be a PCR artefact but may reflect the ongoing process of homogenization. Polymorphisms are usually random but some closely related taxa share multiple polymorphic sites, indicating relatively recent introgression.

P1297. Non-concerted ITS evolution in the genus *Mammillaria* (Cactaceae)

D. Jung, A. Peterson;
Martin Luther University, Halle, Germany.

The ITS region: ITS1+5.8S rRNA+ITS2 of the ribosomal DNA belongs to a multiple gene family with hundreds of tandemly repeated copies. Thus, it should be subjected to concerted evolution.

Our research deals with 21 out of over 300 *Mammillaria* species representing plants from all subgenera (expect Cochemiae) as well as the sections and series of the large subgenus *Mammillaria*.

The molecular study revealed several different copies of the ITS region (sequence, lenght) on individual level. The main differences were observed within the 5.8S rRNA genes. Some of these belong to apparently functional genes whereas others are probably non-functional. The constructed Neighbour-joining tree shows, that ITS regions of different *Mammilliaria* species containing putative 5.8S rRNA genes cluster within the tree, whereas pseudogenes are distributed all over.

Our result of non-concerted ITS spacer evolution in Mammillaria is against the traditional assumption of concerted evolution.

P1298. Subnucleolar localization of rDNA and NopA100 are affected by clinorotation

M. A. Sobol[1,2], F. Gonzalez-Camacho[2], V. Rodriguez-Vilarino[2], E. L. Kordyum[1], F. J. Medina[2];
[1]Institute of Botany of NASU, Kyiv, Ukraine, [2]Centro de Investigaciones Biologicas (CSIC), Madrid, Spain.

Plants are the main object in investigations of gravity role in life on Earth. Now this research has taken on special significance when long-term expeditions to the Moon and Mars are planned. Plant cell nucleolus is known to reflect the level of cell metabolism and to monitor the influence of environmental stimuli on a cell. We studied root meristematic cell nucleoli of two-day *Pisum sativum* seedlings grown in the control and under clinorotation with immunogold electron microscopy. In the control, the labeling with anti-DNA and anti-NopA100 antibodies was revealed in a nucleolus on FCs and DFC. FCs were considerably more densely labeled than DFC. Under clinorotation, we showed a redistribution of rDNA and NopA100 between FCs and DFC in a nucleolus as compared to the control. FCs and DFC were much more labeled with an anti-DNA antibody and contained significantly less quantity of NopA100 than in the control. The alterations in localization of rDNA and NopA100 in the nucleolar subcomponents testify about a decrease in the level of rDNA transcription and processing of rRNA allowing us to propose lowering the functional activity of a nucleolus influenced by clinorotation.

P1299. Phylogeny and evolution of flower characters in European *Heracleum* L. (Apiaceae: Apioideae)

M. Zych;
Warsaw University Botanic Garden, Warsaw, Poland.

The genus *Heracleum* consists of approx. 80 species distributed mainly in Asia and Europe. The paper analyses all European taxa for their phylogenetic relationships and evolution of morphological characters associated with reproduction. Phylogenetic trees inferred from ITS rDNA sequences show that all European taxa fall within *Heracleum* clade (as opposed to Asiatic *H. rigens*, which is closer related to *Zosima orientalis*). All members of *H. sphondylium* complex, as described in Flora Europaea, cluster together, which is a result of identical ITS sequences. The same situation is found in *H. mantegazzianum* and *H. pubescens* branch. Several mountain species (*H. minimum, H. carpaticum, H. ligusticifolium*, and *H. austriacum*) form a distinct clade supported by high bootstrap value. Most of the 46 studied morphological characters were homoplastic, except flower color and flower symmetry. The analyses suggest that taxa with greenish actinomorphic flowers (eg *H. sphondylium* subsp. *sibiricum*) are evolutionary advanced contrary to ancestral taxa with white zygomorphic flowers.

P1300. Systematic Studies of *Vallisneria* L. in South Korea

H. R. Na[1], H. K. Choi[1], H. C. Shin[2];
[1]Ajou University, Suwon, Republic of Korea, [2]Department of Biology, Soonchunhyang University, Chungnam, Republic of Korea.

The morphological and molecular systematic studies of *Vallisneria* L. (Hydrocharitaceae) in South Korea were conducted to identify infraspecific taxa showing variation of seeds. Total 221 individuals of *V. asiatica* Miki and *V. denseserrulata* Makino were collected from 22 different regions of Korea, and 61 morphological characters were examined for the principal component analysis (PCA) and unweighted pair group method with arithmetic mean (UPGMA) analysis. The internal transcribed spacer (ITS) region of the 18S-25S nuclear ribosomal DNA repeat was sequenced from 25 individuals (11 males and 14 females) of *Vallisneria* in Korea, and maximum parsimony trees were generated from the ITS sequences including those of *V. americana*, *V. nana*, *Nechamandra alternifolia* and *Hydrilla verticillata* as outgroups. As the results of our studies, *V. asiatica* Miki var. *protuberancis* Na *et* Choi is characterized as a new variety and *V. denseserrulata* Makino var. *spinulosa* (Yan) Na *et* Choi is recognized as to need the new combination.

P1301. Photosystem II gene sequences of psbB and psbC clarify the phylogenetic position of Vanilla (Vanilloideae, Orchidaceae)

M. C. Molina[1], K. M. Cameron[2];
[1]Dpto. Matemáticas y Física Aplicadas y CC. Naturaleza. URJC, Móstoles, Madrid, Spain, [2]The Lewis B. and Dorothy Cullman Program for Molecular Systematics Studies, The New York Botanical Garden, Bronx, NY, United States.

Nucleotide sequences of the plastid genes psbB and psbC were obtained for 34 taxa representing nearly all genera currently classified within Vanilloideae (Orchidaceae). These genes code for two proteins that make up the Photosystem II and have only rarely been used for reconstructing phylogenetic relationships among plants. Nucleotide variation within each of these genes is sufficient to resolve the major relationships among most Vanilloideae and the combined two-gene tree is fully resolved and highly supported at the genus level. These gene trees demonstrate with a high degree of confidence (95% jackknife support) that a clade of mostly achlorophyllous tropical vines including Pseudovanilla and Erythrorchis are the sister group to Vanilla. The two New Caledonian endemic genera of Vanilloideae are sister to this pair, and Epistephium is sister to all Vanillieae. With this new interpretation of vanilloid orchid relationships in hand, it is possible to re-examine the evolutionary pattern of such characters as winged seeds, unilocular ovaries, and climbing habit within Orchidaceae.

P1302. Molecular systematics and biogeographic patterns in Thunbergioideae s.l. (Acanthaceae) based on phylogenetic analyses of nuclear and chloroplast sequence data

A. Borg[1], L. McDade[2], J. Schönenberger[1];
[1]Department of Botany, Stockholm University, Stockholm, Sweden,
[2]The Academy of Natural Sciences, Philadelphia, PA, United States.

Thunbergioideae s.l. formerly were divided into two subfamilies, the Thunbergioideae and the Mendoncioideae, or even were considered to constitute two separate families. Recent morphological and molecular studies support the reduction of Thunbergioideae and Mendoncioideae to a single subfamily within Acanthaceae. However, relationships within Thunbergioideae s.l have been little studied and are still poorly understood. The family consists of five genera. The largest of which, the genus *Thunbergia*, contains about 100 species restricted to tropical and subtropical regions of Africa and Asia. *Mendoncia,* the second largest genus, contains around 60 species and is most diverse in Central and South America, but also includes a few African representatives. The main goals of the present study are to test 1) whether earlier, morphology-based subgeneric divisions of *Thunbergia* are congruent with molecular evidence; 2) whether Asian *Thunbergia* species form a monophyletic group; 3) whether New World and Old World *Mendoncia* species are reciprocally monophyletic; and 4) to answer the question about the likely geographical origin of the group as a whole.

P1303. A phylogenetic study of water-hemlock (*Cicuta*; Apiaceae tribe Oenantheae)

C. S. Lee[1], S. R. Downie[2];
[1]Department of Life Science, Ewha Womans University, Seoul, Republic of Korea, [2]Department of Plant Biology, University of Illinois at Urbana-Champaign, Urbana, IL, United States.

The genus *Cicuta* is the most virulently poisonous group of flowering plants native to the north temperate zone. The most recent treatment recognized four species (*C. maculata*, *C. douglasii*, *C. bulbifera*, and *C. virosa*), with *C. maculata* divided into four varieties. The evolutionary relationships among these taxa, and the characters best to distinguish them, are unclear. We present the results of a phylogenetic analysis of morphological characters and DNA sequences from the nuclear rDNA ITS region. Data from the chloroplast 5'exon trnK-rps16-trnQ-psbK-psbI region are currently being obtained. Preliminary results suggest that the

North American *C*. *bulbifera* and the circumboreal *C*. *virosa* are each monophyletic, the latter species sister to all other taxa. *Cicuta douglasii* is highly polyphyletic, with all examined accessions but one arising within *C*. *maculata*. This single accession is from central California and is successively basal to *C*. *virosa* in the cpDNA-derived trees. Within *C*. *maculata*, only western North American var. *angustifolia* is retained as monophyletic; all other taxa comprise a morphologically heterogeneous *C*. *maculata* var. *maculata*.

P1304. Molecular and morphological variation in Myosotis laxa Lehm. in the Baltic Sea region and the status of M. laxa ssp. baltica

S. Pihu, E. Kook, M. Öpik, Ü. Reier;
Institute of Botany and Ecology, Tartu, Estonia.

Two subspecies of *Myosotis laxa* Lehm. (Boraginaceae, genus *Myosotis* section *Palustres*): *M.l.* ssp. *baltica* (Sam.) Hyl ex Nordh. and *M.l.* ssp. *caespitosa* (Schultz) Hyl. ex Nordh., were studied using both morphological and molecular characteristics. rDNA ITS1 and ITS2 sequences, which have been proved to work in the section *Palustres*, were used. *M. l. ssp. baltica* is considered to be a microendemic taxon in the Baltic Sea region. In some publications it has been stated not to occur in the southern part of the Baltic Sea region (Estonia incl.). In the present work it was proved that 'typical' specimens belonging by morphological features to ssp. *baltica* are occurring in Estonia also. A continuous variation from ssp. *baltica* to ssp. *caespitosa* can be recorded here as well as it was described on the material originating mainly from Sweden. As the result of molecular analyses it occurred that morphologically typical specimens of two subspecies often do not differ genetically. The hypothesis of one center of origin is therefore not true. *M.l.* ssp. *baltica* is probably developing from an ecotype to a new microendemic taxon in several places separately.

P1305. A phylogenetic study of endemic Iranian Umbelliferae based on rnDNA ITS sequences

E. I. Terentieva[1], **T. H. Samigullin**[2], C. M. Valiejo-Roman[3], M. G. Pimenov[1];
[1]Botanical Garden of Moscow State University, Moscow, Russian Federation, [2]A.N. Belozersky Institute, Moscow State University, Moscow, Russian Federation, [3]A.N. Belozersky Institute of Moscow State University, Moscow, Russian Federation.

Taxonomic diversity of the Umbelliferae in Iran is one of the highest in Asia. Our present aim is to check taxonomic relationships in some Iranian Umbelliferae, especially in endemic genera, using the independent criterion of nrDNA ITS-sequencing. As a result, 34 species from 26 genera were subject in molecular taxonomic analysis of the Umbelliferae for the first time. Phylogenies were constructed by neighbor-joining, parsimony analysis and Bayesian methods. Some results are unexpected. The analysis of resulting phylogenetic trees indicates that: (1) *Haussknechtia*, one of the most enigmatic genera among Iranian Umbelliferae, is the closest relative of *Demavendia* and *Zeravschania*; (2) new described monotypic genus *Mozaffariania* Pimenov & Maassoumi is the close relative of *Ferula-Leutea* clade; (3) *Ducrosia anethifolia* in all trees is situated in the basal position of enlarged *Heracleum*-clade; (4) *Calyptrosciadium*, a small Irano-Afghanian genus, is a new member of *Komarovia*-clade. In the cases of *Ducrosia, Mozaffariania, Haussknechtia, Demavendia* and *Calyptrosciadium* molecular data throw some light on the taxonomic affinity of genera studied.

P1306. Polyphyly of tribe Laserpitieae and its inclusion in tribe Scandiceae subtribe Daucineae (Apiaceae): inference from fruit morphology and rDNA ITS data

A. Wojewódzka[1], K. Spalik[2];
[1]Warsaw University Botanic Garden, Warszawa, Poland, [2]Department of Plant Systematics and Geography, Warsaw University, Warszawa, Poland.

Tribe Laserpitieae (family Apiaceae) is comprised of species that are characterized by dorsally compressed fruits with winged secondary (vallecular) ridges. Phylogenetic analyses using rDNA ITS sequence polymorphism data have shown that all member genera of Laserpitieae fall within tribe Scandiceae subtribe Daucineae. Both in MP and NJ trees, a majority of Laserpitieae form a grade in relation to the spiny-fruited members of Daucineae. Several others are nested within the paraphyletic *Daucus*. The genus *Laserpitium* appears to be polyphyletic and includes at least four clades. Mapping of fruit characters on the phylogenetic tree suggests that winged fruits are plesiomorphic for Daucineae (with Laserpitieae included). Switches from anemochory (winged fruits) to zoochory (spiny fruits) and back to anemochory occurred several times on diverse branches of the tree. All analyzed characters from fruit morphology and anatomy appear to be homoplastic.

P1307. Polyphyly of the genus *Ferula* (Apiaceae) and the affinity of most of its members to tribe Scandiceae based on rDNA ITS sequence variation

R. Kurzyna-Młynik[1], R. Kopacz[1], A. Wojewódzka[2], A. A. Oskolski[3], K. Spalik[1];
[1]Department of Plant Systematics and Geography, Warsaw University, Warszawa, Poland, [2]Warsaw University Botanic Garden, Warszawa, Poland, [3]Botanical Museum, Komarov Botanical Institute, Sankt Petersburg, Russian Federation.

The genus *Ferula* is traditionally placed in tribe Peucedaneae. Recent molecular investigations using rDNA ITS sequence variation have revealed that the genus is polyphyletic with its type, *F. communis*, and two other species, *F. assa-foetida* and *F. tingitana*, placed in the apioid superclade while the other species formed a clade within tribe Scandiceae. We sequenced the rDNA ITS region from 50 other accessions of *Ferula* and performed phylogenetic analyses using MP and NJ. In the trees obtained from those analyses, all newly sequenced taxa have arisen within tribe Scandiceae. These species formed a well-supported clade. However, the affinities within this clade remain unresolved. This clade formed a polytomy with other lineages of Scandiceae corresponding to subtribes Scandicinae, Daucinae, and Torilidinae. Another addition to Scandicinae turned out to be *Glaucosciadium cordifolium*. In these trees, it constituted a separate lineage with no immediate relatives.

P1308. Phylogenetic relationships within *Chaerophyllum* (Apiaceae) as inferred from nuclear rDNA ITS sequence variation

M. Piwczynski[1], K. Spalik[2];
[1]Department of Plant Taxonomy and Geography, Nicolaus Copernicus University, Torun, Poland, [2]Department of Plant Systematics and Geography, Warsaw University, Warszawa, Poland.

The phylogenetic relationships among the members of the genus *Chaerophyllum* (tribe Scandiceae, family Apiaceae) were estimated from the nucleotide sequence variation in the ITS1-5.8S-ITS2 rDNA region using maximum parsimony, neighbour-joining and maximum likelihood methods. Thirty-eight species were sampled. Those with a broad geographic distribution were represented by several accessions in the analyses. Three major clades were inferred corresponding to the recently redefined or established sections: *Chaerophyllum*, *Dasypetalon*, and *Chrysocarpum*. The monotypic sect. *Physocaulis* appeared to be sister to sect. *Chaerophyllum*. With the exception of *C. heldreichii*, all newly sequenced taxa occurred in section *Chrysocarpum* with the Himalayan *C. villosum* placed sister to the remaining members of this section. *Chaerophyllum prescottii*, often regarded as a subspecies of *C. bulbosum*, appears to be a distant relative of the latter. A new addition to sect. *Chaerophyllum* is *C. heldreichii*, endemic to Greece.

P1309. Phylogeny and biogeography of the Pacific genus *Meryta* (Araliaceae) based on ITS and ETS sequence data

F. Tronchet[1], G. M. Plunkett[2], J. Jérémie[1], P. P. Lowry II[3,1];
[1]Muséum national d'Histoire naturelle, Paris, France, [2]Virginia Commonwealth University, Richmond, VA, United States, [3]Missouri Botanical Garden, St. Louis, MO, United States.

The combination of simple leaves and a dioecious sexual system found in the genus *Meryta* is unique within Araliaceae. *Meryta* comprises ca. 30 arborescent species, all endemic to one or a few islands in the Pacific, with its center of diversity in New Caledonia (11 endemic spp.). Recent family-wide phylogenetic analyses have placed *Meryta* as sister to the Pacific *Schefflera* subclade within the *Polyscias-Pseudopanax* clade, one of 3 major araliaceous lineages. A preliminary study of *Meryta* using ITS and ETS sequence data from ca. half its species provided good resolution, confirming the monophyly of the genus, in which two subclades are indicated, and indicating that 3 segregate genera are nested well within *Meryta*. A more detailed analysis with nearly exhaustive sampling further suggests that colonization in the Pacific involved a series of long-distance dispersals to relatively young volcanic islands, primarily from New Caledonia, but also at least once from either Fiji or New Zealand.

P1310. A molecular systematic investigation of *Heracleum* L. (Umbelliferae, Apiaceae subfamily Apioideae) and related genera in the Sino-Himalayan region based on phylogenetic analysis of nuclear (ITS) DNA sequences

J. Paik, M. F. Watson;
Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom.

The taxonomic delimitation of *Heracleum* is difficult. Recent molecular phylogenies have provisionally identified a well supported '*Heracleum* clade' within the Apioid superclade which also includes other genera. In order to test the monophyly of *Heracleum* we analysed additional ITS sequences of *Heracleum* and related genera from the *Heracleum* clade (*Pastinaca*, *Malabaila*, *Zosima, Tetrataenium* and *Tordyliopsis*). The data matrix is analysed using maximum parsimony. The preliminary results of our phylogenetic study confirm previous reports that *Heracleum* is not a monophyletic group, comprising at least two distinct lineages. Within the *Heracleum* clade there are at least three large clades, the core *Heracleum* clade, the *Malbaila-Pastinaca* clade and the *Zosima-Heracleum* clade. The ITS sequences provide valuable characters for inferring relationships within the *Heracleum* clade. However, to fully understand the relationships in this clade further sampling is required.

P1311. Phylogeny of Mesoamerican Vanilla: Implications for the origins of V. tahitensis.

P. Lubinsky;
University of California, Riverside, Riverside, CA, United States.

Vanilla Swartz (Orchidaceae) is a pantropical genus of about 120 species of hemi-epiphytic and saprophytic herbs. The cured fruits of only three species, *V. planifolia*, *V. tahitensis* and *V. pompona*, are commercially exploited as sources of natural vanilla. *Vanilla planifolia* and *V. pompona* are both Neotropical endemics whose centers of distribution are Mesoamerica. In contrast, wild individuals of *V. tahitensis* are unknown, and a hybrid origin between *V. planifolia* and *V. pompona* has been suggested. The evolutionary and geographic relationships among the 12 Mesoamerican *Vanilla*, and origin of *V. tahitensis* have not been examined in the context of a robust phylogeny. We sequenced both nuclear (ITS region of nrDNA) and chloroplast (non-coding regions) genomes to determine the relationships of these taxa and to test the hypothesis of a hybrid origin for *V. tahitensis*. Monophyly of Mesoamerican *Vanilla*, relationships among them, and origin of *V. tahitensis* will be discussed.

P1312. Phylogeny and Recent Differentiation in the European Alpine/Lowland Complex of *Myosotis Alpestris*

J. Štepánková[1], V. Štepánek[2,1], **H. Dvoráková**[1,3];
[1]Institute of Botany, Pruhonice u Prahy, Czech Republic, [2]Institute of Microbiology, Prague, Czech Republic, [3]Faculty of Science, Charles University, Prague, Czech Republic.

The biogeographic history of the European alpine plant species has been only infrequently investigated using molecular methods so far. The goal of this project is to asses phylogeny of the *Myosotis alpestris* group - generally to contribute to our knowledge of the impact of Quaternary climatic changes on the plant diversity in the European mountain regions. Combining molecular phylogenies (derived from ITS region of nrDNA and from cpDNA) with information from morphology and karyology will be provided insight to the biogeographic and evolutionary history of the complex. Samples from locations throughout the European high mountains are used for analyses. The 14 populations have been examined karyologically, the diploid chromosome number for *Myosotis stenophylla* was found for the first time. Preliminary results of cpDNA analysis and nucleotide sequences of ITS regions demonstrate conspicuous difference between diploid and tetraploid cytotype. However, phylogenetic divergence within particular cytotypes is very low.

Grant no. IAA6005312 supported by Grant Agency of the Academy of Sciences of the Czech Republic

P1312a. A molecular phylogenetic perspective on the ecology, phylogeny and life history of *Actinotus* (Apiaceae).

M. J. Henwood[1], A. D. Marchant[2], A. J. Perkins[2];
[1]The University of Sydney, Sydney, Australia, [2]National Herbarium of NSW, Sydney, Australia.

Actinotus is a morphologically and geographically diverse genus of largely Australian herbs and sub-shrubs. The genus occupies a range of habitats and includes a variety of life histories and reproductive strategies. This study used chloroplast DNA sequences (*trn*L-F) to place all species of *Actinotus* within a broader, ordinal context. The *trn*L-F sequences were combined with nuclear (ETS) sequences to investigate morphological character state changes within *Actinotus*, and to raise hypotheses relating to the evolution of reproductive and life history attributes. *Actinotus* and a number of endemic Australian genera nested within a redefined "Mackinlayoideae". Several sub-clades were revealed within *Actinotus*, many correlating with geographic regions or habitats. The annual life-history, for example, evolved once within the genus and is restricted to a clade of largely semi-arid and/or fire-ephemeral species. The alpine and semi-arid species independently evolved an homogamous breeding system, along with a reduction in the number of stamens per flower. These and other insights are presented within a molecular phylogenetic framework.

P1313. Taxonomical study of diatoms of khandesh of Maharashtra (India).

A. N. Patil;
Nutan Maratha Art's and Science College,Jalgaon, Jalgaon, India.

Very few workers have paid attention on taxonomical study of diatoms in Maharashtra. Diatoms are microscopic unicellular or colonial algae distinguished by the complex structure of their cell walls which are usually strongly impregnated with silica. Collections as far as possible should be made throughout the year. The diatoms are collected from puddles, ditches ,lakes and river of khandesh area of Maharashtra (India). In present investigation forty two species of diatoms were recorded. In present study, the diatoms are mainly represented by the species of Fragillaria, Synedra, Caloneis, Eunotia, Mastogloia, Gyrosigma, Anomoeoneis, Stauroneis, Naricula, Pinnularia and Cymbella. In present study out of 14 gerera of diatoms Cymbella, Gyrosigma and Pinnularia are dominant as compared to other genera. The pinnate type of diatoms were dominant over the centric diatoms in present investigation.

P1314. Epiphytic algae of some lichen species

T. Mikhailyuk, S. Kondratyuk;
M.H. Kholodny Institute of Botany NAS of Ukraine, Kyiv, Ukraine.

Data on epiphytic algae (EA) growing on lichen thalli are rather scarce and incidental. 36 samples of lichen thalli of 3 model species (Aspicilia cinerea, A. contorta var. hoffmannii, Candelariella vitellina) from granitic outcrops of Ukraine were the material of the study. Samples were provided from 12 model plots, 6 of which are situated in dry conditions of the upper portions of slope, another 6 - in wet conditions of slope along river. 43 species (Cyanoprocaryota - 15, Chlorophyta - 27, Eustigmatophyta - 1) were found with the use of cultural methods. Geminella terricola, Stichococcus bacillaris, Fottea stichococcoides, Desmococcus olivaceus, Elliptochloris bilobata, E. subsphaerica, Klebsormidium flaccidum, found to be the most widely distributed among EA. The highest species diversity of EA is recorded for C. vitellina (36 species), less on A. contorta (26), A. cinerea (22). Species content of EA found to be rather close to content of lithophilic algae of granite outcrops of the same plots. Distribution of EA and lithophilic algae along the river bank slope is rather similar. But there is a number of EA, which are absent among lithophilic algal group.

P1315. Two thermophilic cyanobacteria living in the thermal baths of Montegrotto Terme (Padova, Italy)

I. Moro, F. Merlo, M. Di Bella, N. Rascio, C. Andreoli;
Department of Biology, Padova, Italy.

The therapeutical specificness of thermal mud of the euganean territory (Italy) is due to a maturation process which involves the development of a rich and differentiated biotic community of cyanobacteria and diatoms on the surface and inside the mud.

While the diatoms colonize both the surface and the entire thickness of the mud, the cyanobacteria grow mainly in the surface of the mud, forming blue-green mats.

Among the cyanobacteria, the most widespread species belong to Oscillatoriales, and among them Phormidium sp. ETS-05 is the only species up to now characterized.

In this research we report the morphological and molecular (16S and ITS rDNA) features of other two cyanobacterium strains. One of them is another form belonging to Oscillatoriales: genus Leptolyngbya. The other strain instead is a Cyanobacterium species, a new finding of the Synechococcaceae (Chroococcales) in the Italian thermal muds.

These new strains were isolated from the thermal baths of the Garden Hotel of Montegrotto Terme (Padova). During the sampling the temperature in the baths was about 50°C.

P1316. The Marine Diatom Genus *Pseudauliscus* Schmidt: A Light and Electron Microscopical Study of the Diatoms *P. peruvianus* and *P. radiatus* from the northeastern Gulf of Mexico, with Comments on Lectotypication and Systematics

A. Prasad[1], J. A. Nienow[2], K. A. Riddle[1];
[1]Florida State University, Tallahassee, FL, United States, [2]Valdosta State University, Valdosta, GA, United States.

Diatoms resembling *Pseudauliscus peruvianus* (Kitton ex Ralfs) Schmidt and *P. radiatus* (Bailey) Schmidt were common in collections from coastal marine habitats of Florida and Alabama over a period of several years. An examination of permanent slides from the Adams Collection (British Museum) and the Bailey Collection (Harvard) confirmed our identification of the diatoms and provided an opportunity to clarify the status of the species. Slide BM Adams GC1486 and slide 1979 from the Bailey collection were designated as the lectotypes for *Eupodiscus*(?) *peruvianus* Kitton ex Ralfs and *Auliscus radiatus* Bailey, respectively. SEM observations of the Florida material revealed the fine structure of ocelli and areolae, and the morphology and location of the rimoportulae in both species. The occurrence of cells of *P. peruvianus* with nuclei and plastids indicates that the species is extant and common along the northeastern coast of the Gulf of Mexico. Structural differences between the two species may require placing *P. radiatus* in a separate genus.

P1317. Phylogeny of unicellular red algae, *Cyanidium caldarium* and related algae living in acid hot springs

H. Nagashima, T. Suzuki;
Tokyo University of Science, Noda, Chiba Prefecture, Japan.

Unicellular red algae, *Cyanidium caldarium* strain RK-1 and *Galdieria sulphuraria* strain M-8 were isolated from some acid hot springs in Japan. *C. caldarium* is distributed most widely in the acid hot springs, but *G. sulphuraria* is found only in the limited areas. Another unicellular red alga, *Cyanidioschyzon merolae* strain JV-95 was isolated from acid hot springs in Java, Indonesia. They have been now classified as Cyanidiaceae, Rhodophyta by some investigators. In this report, nucleotide sequences of the nuclear-encoded small-subunit 18S ribosomal RNA genes are determined on the algae, *C. caldarium* strain RK-1, *C.merolae* strain JV-95 and *G. sulphuraria* strain M-8, and their phylogenetic positions are discussed by comparing their 18S rRNA gene sequences among other algae. The phylogenetic tree of the gene indicates that *C. caldarium* and *C.merolae* form a single cluster, and *G. sulphuraria* forms another cluster within Rhodophyta. This suggests that *Galdieria* may be far from another two algae phylogenetically in more than family level. The taxonomic positions of these algae are discussed here.

P1318. The systematic review of the order *Chaetocerotales* (Bacillariophyta)

R. M. Gogorev;
Komarov Botanical Institute, St. Petersburg, Russian Federation.

Order *Chaetocerotales* includes diatom taxa, having special morphological element of frustule - seta (horns). In classification systems genus *Chaetoceros* was placed in family *Chaetoceraceae* as a unique one, together with *Bacteriastrum*, with *Attheya* and *Bacteriastrum*, or together with *Bacteriastrum* and *Acanthoceros*. Round et al. (1990) have put *Chaetoceros* into family *Chaetocerotaceae* Ralfs together with *Bacteriastrum* and *Gonioceros*, genera *Acanthoceros* and *Attheya* - in families *Acanthocerataceae* and *Attheyaceae*. Later, *Gonioceros* species have been transferred in genus *Attheya*. In their classification family *Chaetocerotaceae* has been considered independent and placed in order *Chaetocerotales*. In last classification system (Nikolaev, Harwood, 2000, 2001, 2002) above-stated genera and fossil genus *Chasea* were allocated into single family *Chaetocerotaceae*, into order *Chaetocerotales* together with monotypic family *Leptocylindraceae*. In my opinion, in family *Chaetocerotaceae* it is necessary to include some fossil genera.

P1319. The relationship between soil macro elements and the distribution of heterocystous cyanobacteria in paddy fields, wheat fields and a woodland in Iran.

A. Ahmadi moghdam, **b. nowruzi**;
Department of Biology, Faculty of Sciences,, Kerman, Islamic Republic of Iran.

Despite the occurrence of paddy fields, wheat fields and woodland in Iran, less attention has been paid to the role of cyanobacteria in these ecosystems. In this study an attempt was made to growing soil inoculums on BG-11 medium. The incidence of cyanobacteria with N, P, K, C, pH and EC of soils was also determined. Totally twenty species were identified in paddy fields, twelve in wheat fields and three in woodland. The results showed that species of Nostoc and Anabaena are ubiquitous in all sites except one of paddy field stands, where its EC was the highest and *Calothrix stagnalis* was the only species found in the stand. It is suggested that this strain is probably resistance to salinity. This is supported by statistical analysis of species number and frequency with EC that showed negative correlation. The forest had higher percentage of N, P, K, and C than other regions and differed mainly in number of species and also there isn't any branching species in this region. The scarcity of algae in forest can be probably limited by low pH and EC. However soil analysis showed that phosphorous amount has a highly positive correlation with the frequency of cyanobacteria in all stands.

P1320. Depth Distribution of Epipelic Algae in Sediments of Anzali Lagoon, Iran.

T. Nejadsattari, F. Fallahian;
IAU Science & Research Unit, Tehran, Islamic Republic of Iran.

Abstract

Depth distribution and population dynamics of epipelic algal assemblages on sediments was investigated at four sites, in the Anzali Lagoon , Iran, between September 2000 and August 2001. Triplicate core samples were taken from sediments by using a sampler with 4 cm ID. The sediment was sectioned at 4, 0.5 cm intervals, and fixed by 5 ml 0.5% glutaraldehyde. Species with intact chloroplast were enumerated using Sedgwick Rafter Cell. In this study, 65 species were identified, that belong to 26 genera comprised in four classes. Species diversity of Bacillariophyceae was higher than Cyanophyceae, Chlorophyceae and Euglenophyceae. Among Bacillariophyceae *Nitzschia* with 11 and *Navicula* with 10 species had highest species diversity. The study revealed that members of Bacillariophyceae had the highest cell numbers (10^6 cells cm^{-2}) in February and members of Cyanophyceae was more abundant (140×10^3 Cells cm^{-2}) in August. Due to specific environmental conditions, 0-0.5 cm depth had more cells in comparison with other depths. Occurrence of epipelic algae in deeper sediments (1.5-2 cm) suggested that these algal assemblages might have heterotrophic nutrition.

P1321. Microphytoplankton in the marine Lake Mir, the Dugi Otok island, Croatia

N. Jasprica, M. Caric;
Institute of Oceanography and Fisheries, Dubrovnik, Croatia.

In order to characterize the microphytoplankton (MICRO) structure and abundance of the marine Lake Mir, analyses were performed in monthly intervals from November 1999 to November 2000. Sampling was carried out at one station in the lake, at the surface (0.5 m) and the bottom (7 m). The Chl *a* concentration was ranged from 0-1.59 mg m^{-3}. MICRO abundance ranged from 0.9 x 10^{3} - 6.8 x 10^{5} cells L^{-1}. Three peaks of MICRO were observed throughout the year; in November 1999 and April 2000 (mostly diatom *Cyclotella* sp.), and in July 2000 (mostly dinoflagellate *Scrippsiella trochoidea*). The MICRO abundance in the lake was similar to those recorded in the highly productive coastal zones of the Middle and South Adriatic. There was a predomination of small diatoms in spring, while dinoflagellates increased in number during summer. These patterns did not differ widely from the general succession pattern in coastal Adriatic areas and in the Mediterranean.

P1322. Epilithon structure in the Chusovaya river

P. G. Belyaeva;
Institute of Ecology and Genetics of Microorganisms, UB RAS, Perm, Russian Federation.

As a result of investigations of epilithon in the Chusovaya river within the summer 2003, 126 taxons of the algae of the class below the genus were identified: Bacillariophyta - 74, Chlorophyta - 37, Cyanophyta - 15. It was found that similar diatomaceous algae were prevailed in phytoperiphyton communities of stony grounds in different sections of the river.

In ecological aspect the algoflora fouling was formed by cosmopolites (69%) and boreal species (14.3%). Total composition of flora according to Kolbe's halobity system was typical for the fresh water: 66.7% were insensible to salt content in water, 14.3% were drimophilous, and 4% were halophobes. With respect to active water reaction alkaliphils (38%) and insensible (22.2%) were prevailing. Over the half of algae detected (55.7%) appeared to be the indices of water saprobity, among which the indicators of б-mesosaprobic extent of contamination prevailed.

Largest biomass of algae fouling was observed on stony grounds at rifts (4.1 g/m2); it was considerably lesser on littoral grounds at reaches (1.8%), and epilithon of the reach medials was characterized by even lower quantitative development (1.1 g/m2).

P1323. Cyanoprocariota from ultrasaline littoral rock pools of the English Channel coastline

A. A. Ulanova;
St. Petersburg State University, Biology and Soil Sciences Faculty, St. Petersburg, Russian Federation.

Cyanobacteria mats were collected from supralittoral limestone rock pools at Dancing Ledge (a disused stone quarry located right on the English Channel's sea edge on the Isle of Purbeck's coast Dorset) in September 2002. The geological structure of the ledge is sedimentary limestone contains many fossils. The salinity level of these pools was from 60 to 300 psu.

A total 118 species and varieties of 38 genera from 3 orders and 8 families were identified. The assemblage is composed mainly of temperate littoral species and cosmopolitan marine species. Caloneis, Lyngbya and Porhyrosiphon genera present the largest number of species. The composition of the cyanoprocariota assemblage consists of two ecological groups - polyhalobous and mesohalobous species, and indicates that polyhalobous taxa dominate over the mesohalobous forms. Species as Scytonematopsis fuliginosa (Tild.) Kom. Et Anagn. and Caloneis contarenii (Zanard.) Born. Et Flah. had highest salinity tolerance (up to 300 psu) in assemblage and were highly productive. These taxa were most abundant in studied material.

P1324. *Laminariocolax aecidioides* (Phaeophyceae), epi-endophytic in *Undaria pinnatifida* (Phaeophyceae) in patagonian coasts of Argentina

M. C. Gauna, **N. V. Pizani**, E. R. Parodi;
Universidad Nacional del Sur e IADO, Bahía Blanca, Argentina.

Laminariocolax aecidioides has been considered like an epi-endophytic organism of the kelps of the North Pacific, Artic and European coasts, extending its distribution to the South hemisphere. The thalli of *U. pinnatifida* infected by this species were collected in the intertidal zone of the patagonian coasts of Argentina. On cuticle of the kelp the infection developed as dark spots of 1 - 2 mm that covered partially fronds and sporophyles. In the cortical and medullar zones of *U. pinnatifida*, the infectants cells occupied the intercellular spaces without penetrating in the host cells. The thallus of *L. aecidioides* formed a postrate layer of filaments on the surface of the host. The reproductive structures were formed in the erect system. The uniloculars sporangia were uniseriate, ovoid and exhibited basal or apical dehiscence, and the pluriloculars were extended. The invasion was neither associate to ruptures or perforations in the thalli of kelp, although it was well-known a predominance of the thalli of *L. aecidioides* related to the openings of the glands of mucilage and depressions of the epidermic layer of the host. PGI B24/077 (UNS) - PIP 2771/00 (CONICET)

P1325. Airborne fungal spores concentration and the effect of meteorological factors in Ankara, Turkey(2003-2004)

N. Pinar, T. Çeter, A. Yıldız, D. Cansaran;
Faculty of Science, Ankara, Turkey.

Airborne fungal spores were collected with a Burkard spore trap in Ankara, Turkey from Jan 2003 to Jan 2004. The sum of the annual totals of the daily concentration of fungal spores, belonging to 35 taxa, were 429.264. These taxa namely Botrytis, Fusarium, Nigrospor, Pitomyces, Drechslera, Epicoccum, Torula, Stemphylium, Periconia, Curvularia, Exosporium, Spegazzinia, Tetracoccasporium, Timenticola, Dictiyosporium, Melanomma, Didium, Peospora, Coprinus, Agrocybe, Gonoderma, Boletus, Puccinia, Ustilago, Didymella, Leptosphaeria, Peranospora, Xylaria, Chatemium, Venturia, Ascobolus, Melanospora, Sporomiella, Paraphaeria, Cladosporium and Alternaria. A fungal spore calendar was prepared for one year and seasonal periodicites were recorded. The results have correlated with meteorological condition. Relative humidity, tempature and rainfall showed significant fungal spores concentrations.

P1326. ITS Structure in Peronosporaceae (Oomycetes) and its possible implications for the phylogeny of Downy Mildews

M. Thines, O. Spring;
Institute of Botany, Stuttgart, Germany.

The non-coding ITS region is often screened for phylogenetic studies on and below the generic level and revealed polymorphisms and structure variation in several taxa. No such data is available for Peronosporaceae with pyriform haustoria, like Bremia lactucae, Plasmopara halstedii and Pl. viticola. Total ITS length was 2587bp, and a restriction-ligation technique uncovered four tandemly arranged elements (TAEs) of 322bp each and a possible marker region for these repetitive elements. The TAEs are found neither in Phytophthora nor in Peronospora spp., were ITS consists of 900bp. The TAEs showed variation in Pl. halstedii populations of different pathotypes, while other parts of the ITS were uniform. Other species of Plasmopara and Bremia revealed lengths of ITS up to 3kB. These lengths are derived from similar insertions, which may become a tool to trace the phylogeny of downy mildews. A comparative analysis of TAEs in Pl. halstedii, Pl. viticola and B. lactucae will be presented.

P1327. Geologic history of epiphyllous fungi with affinities to the Loculoascomycetes

J. L. Garcia Massini;
Southern Methodist University, Dallas, TX, United States.

Symbiotic interactions in nature are important driving forces that promote diversification and influence the biogeographic patterns of the entities involved. Accordingly, parasitism and saprotrophism would not be single isolated biological interactions, but exchangeable dynamic relationships that, as influenced by the environment and the intrinsic biology of each individual involved, include all other forms of symbiosis. Although fungi have a long history, their frequent occurrence in the fossil record as dispersed individuals and the recurrent lack of preservation of their diagnostic features encumbers establishment of affinities with extant members. Notwithstanding, fungi are obligate heterotrophic organisms that are dependent on the presence of other biological individuals for existence. As a result, the occurrence of fungi in past ecosystems may have been determined by the presence of certain taxa of other organisms. In this contribution, the geographic distribution of epiphyllous fungi throughout the Tertiary and part of the Mesozoic is evaluated and correlated with the occurrence of host plant taxa and particular climatic conditions.

P1328. Endophytic fungi in *Brosimum alicastrum* (Moraceae) and *Hampea trilobata* (Malvaceae) leaves in Calakmul Biosphere Reserve, Campeche, México.

M. Del Olmo Ruiz, J. Cifuentes Blanco, G. Vidal Gaona;
Herbario FCME, Sección de Micología, Facultad de Ciencias, UNAM, Mexico City, Mexico.

It is expected to found in tropical regions most of the undiscovered endophytic fungal species (Spyreas *et al.*, 2001) because the high diversity of plant species and vegetation types (Fisher *et al*., 1995) represent a broad potential substrate and habitat.

The study was carried out at the Calakmul Biosphere Reserve, the biggest and best preserved in Mexico (Martínez *et al*., 2001), sampling leaves of *Brosimum alicastrum,* a dominant and well distributed species in Mexican tropical forests (Pennington and Sarukhán, 1998) and *Hampea trilobata,* an endemic species in the Yucatan peninsula (Fryxell, 1988).

Tree leaves were surface sterilized, and endophytic fungi were isolated with specific culture media. Strains identification was made with traditional taxonomic methods.

We found more than 30 endophytic species, 306 strains were isolated from *Brosimum alicastrum* with 27% colonization frequency and 388 from *Hampea trilobata* with 33% colonization frequency. It is also presented a host preference analysis and a comparison of the found fungal species with those reported in other plant species from tropical regions (Rodrigues 1994, Arnold & Herre 2003).

P1329. Cryptic basidiomycetes in a crustose lichen symbiosis

J. Blaha, M. Grube;
Institute of Plant Sciences, Karl-Franzens-University, Graz, Austria.

Crustose lichens of the Lecanora rupicola group are the host of several lichenicolous fungi and lichenicolous lichens. Apart from these other accessory fungi were detected in thallus areoles during a phylogenetic investigation of the Lecanora rupicola group. Apparently, these fungi may live more or less cryptically and without external symptoms of degradation as endolichenic fungi in lichens. So far no sexual structures were detected and the classification of these fungi relied on molecular sequence analyses. Diverse fungi of the Tremellales are involved in such associations, but none of them belong to groups already known to occur on other lichens. A posteriori inspection indicates that infected thallus areoles are slightly more convex than the adjacent areoles to hypertrophized. Symptomless fungal infections of lichens by basidiomycetes may possibly be a widespread, but underestimated phenomenon.

P1330. Biodeterioration of archaeological textile dyes by the fungi and bacteria in Iran

A. Nasirian;
Research Center for Conservation of Cultural Relics, Tehran, Islamic Republic of Iran.

Introduction:we have assessed the potential of fungi and bacteria and a laccase from this organism to continuously degrade textile dyes. Material and methods:100 samples were isolated from archaeological textile of Iranian museum and in 2004 in Iran.we have kept them in 5-20 days,one sample was chosen for control.Result: we have succeeded to recognize fungi and bacteria species:Ba subtilis, Ps aeruginosa, Thio thiooxydans,Ph chrysosporium, Pe chrysogenum, Geo candidum,As foetidus, As niger, As flavus, Trich reezei, Ceph acremonium, Rhiz delemar, Pe restericum.Finally we have researched activities of laccase thereon textile in Ba subtilisAs foetidus,As niger,Ph chrysosporium ,substrate (2-6 dimethoxy phenol).Beginning of discoloration in the first several days and decreasing of colorization after one week in As niger and As foetidus, after two weeks in Ph chrysosporium and after 20 days in Ba subtilis. Conclusion:Activities of laccase were studied with sectrophotometric examination in different times and recoded according to wave length. We have observed in As niger 428 nm that 90% is discolored, in Ph chrysosporium 370 nm that 71% is discolored.

P1331. *Geosmithia* fungi - dry spored entomochoric fungi associated with bark beetles, description of diversity, host specificity and pathogenicity

M. KolaSík;
Institute of Microbiology CAS, Institute of Microbiology CAS Laboratory of the Physiology, Prague 4, Czech Republic.

Phloemophagous bark beetles are vectors of different fungi. We have studied bark beetles associated with the fungi of the genus *Geosmithia*. We collected 162 wood samples infested by 40 bark beetle species from 150 locations in central Europe and Mediterranean. Isolates of *Geosmithia* spp. (about 1000) were classified into 23 morphotypes characterized by micromorphology and RAPD patterns (RAPDtypes). Some RAPDtypes were determined as *G. putterillii* and *G. lavendula* and several new species was described. It was confirmed that most studied bark beetles (*Ernoporus tiliae*, *Hylesinus* spp. *Hypoborus ficus, Scolytus intricatus*, *S. rugulosus*) carry specific range of RAPDtypes. Vector specificity of geosmithias proves that these fungi are entomochoric. In *G. lavendula*, we discovered its highly specialized vector, *Hypoborus ficus*, parasitizing fig trees in Mediterranean. Geosmithias are primary colonists of a fresh phloem rich in sugars and are not able to utilize complex carbon sources. Some tested cultures strongly inhibited *in vitro* root and stem growth in young plants of garden cress; therefore phytopathogenic potential of geosmithias cannot be excluded.

P1332. Fungal diversity in *Calluna vulgaris* (L.) HULL

A. Pietrowski, D. Persoh;
Department of Plant Systematics / Mycology, University of Bayreuth, Germany.

Biologically active secondary metabolites are produced by numerous endophytic fungi and may be involved in fungus-host plant interactions as well.

The diversity of *Calluna vulgaris* (Ericaceae) inhabiting fungi was characterised by molecular methods. Fungal strains were grouped by ITS/5.8S nrDNA sequence data and the 18S nrDNA was sequenced for representatives of each ITS genotype. The sequences were aligned with all publicly available high quality SSU nrDNA sequence data of Ascomycetes.

A range of individual host plants derived from different habitats and physiologically standardized clonal plants were used.

Molecular phylogenetic analyses of endophytic as well as epiphytic fungi revealed a wide spectrum of fungal phylotaxa at the host-specific and site-specific level.

The production of secondary metabolites by endophytic fungi in plants was characterized by various phytochemical methods. In addition, endophytic fungi obtained from mycelial outgrowth from surface-sterilized healthy-looking host tissues, were tested for their antimicrobial and enzymatic properties in culture.

P1333. The effects of the disaccharides on *Morchella* conica Pers. mycelium development

P. GULER, E. G. UREGEN;
Kirikkale University, Kirikkale, Turkey.

The effects of the disaccharides on *Morchella* conica Pers.
mycelium development

Morchella conica mycelium was used, sucrose and maltose was chosen as disaccharides and 0.25%, 0.50%, 0.75%, 1.00% and 1.25% concentrations have been added to wheat agar, potato dextrose agar, malt extract agar and complete medium yeast agar. The radial growth speed, morphologic specifications, radial growth ratios, colonization period and pigmentation of mycelium were taken as criteria.

The development period of mycelium in wheat agar was completed in 4 days and the mycelium were very thin. The colonization period of the mycelium were determined; 7 days in potato dextrose agar, 5 days in malt extract agar and 5 days at complete medium yeast agar. The development of the mycelium; at potato dextrose agar was dense and circular, at malt extract agar and in complete medium yeast agar was rhizomorphic. Mycelium had developed very well at sucrose medium and formed creamy and light yellow pigmentation. At maltose medium the mycelium development was good and light yellow and light brown pigmentations were noticed.

Key Words: *Morchella conica*, mycelium development, disaccharide.

P1334. Pneumocystis nomenclature

S. A. Redhead[1], M. T. Cushion[2], J. K. Frenkel[3], J. R. Stringer[4];
[1]ECORC, Agriculture & Agri-Food Canada, Ottawa, ON, Canada, [2]Univ. Cincinnati College of Medicine, Dept. Internal Medicine, Cincinnati, OH, United States, [3]Univ. New Mexico, Santa Fe, NM, United States, [4]Univ. Cincinnati College of Medicine, Dept. Molecular Genetics, Biochem. & Microbiol., Cincinnati, OH, United States.

Pneumocystis, causal agent of a pneumonia (PCP) in immuno-compromised individuals, has defied classification. Initially, it was mistakenly included in the lifecycle of the protozoan *Trypanosoma cruzi* causing Chaga's Disease. Separately described, *Pneumocystis* was believed to be a protozoan covered by the zoological code. Having only 3 codes, botanical, zoological and bacteriological, bizarre nomenclatural situations arise when the 3 kingdom system applies to microorganisms, e.g. rumen chytrids, mycetozoans, microsporidians. Molecular phylogenies reveal new relationships and taxa can 'switch' kingdoms, resulting in cascading nomenclatural changes. *Pneumocystis* exemplifies one extreme because it combines 'misclassification' in the 'animal' kingdom and initial inclusion in the lifecycle of a protozoan that led to the mixed element description of *Schizotrypanum* and its type, *T. cruzi*, representing two 'kingdoms'. Additionally, reduced morphology and host-specificity hinder subgeneric classification causing debate regarding the name for the human pathogen, *P. jirovecii*, often called *P. carinii*. Nomenclatural resolutions are detailed.

P1335. Buellia subalbula - studies of a complex species group from semi-arid to arid regions

F. Bungartz[1], U. Grube[2];
[1]Botanische Staatssammlung München, München, Germany, [2]Institute of Plant Sciences, Karl-Franzens-Universität, Graz, Austria.

Preliminary studies indicate that Buellia subalbula, as previously often identified, represents a species group of anatomically, morphologically and chemically, similar, but not identical taxa from semi-arid to arid regions. All taxa have one-septate ascospores and heavily pruinose, rimose thalli containing large amounts of Ca oxalates. The type specimen from Angola contains norstictic acid and an aeruginose apothecial pigment reacting strongly violet with HNO3. Exciple and epihymenium of specimens from the Mediterranean, coastal Baja California and Southern California are less strongly aeruginose, but still show the distinct reaction. In contrast, the reaction is almost undetectable or entirely absent from a group of Australian specimens that are not strictly confined to coastal habitats. Another group of Australian specimens lacks both norstictic acid and the aeruginose pigment, but instead contains xanthones. Some of these thalli seem to be parasitic on a thin, gray, inapparent thallus containing only norstictic acid and showing no trace of the aeruginose apothecial pigment. The taxonomic status of all these taxa will be further investigated.

P1336. Biological diversity of lichens in Caucasus and their protection

V. Novruzov;
Ganja State University, Ganja, Azerbaijan.

The study of the Caucasian lichens began more than 200 years ago. During these years, more than 300 works on lichenology and geobotany have been published. At present time on the territory of Caucasus 1300 taxons are known which are related to 126 kinds and 49 families.

The Caucasus in its rich nature has extremely various landscape, geological structure, climate, orography which promoted the development of specific flora here, including the discovery of the new lichens. For the last century 65 new taxons have been described from Caucasus. The new species as a genofund of aboriginal flora must be included in the "Red Book of Azerbaijan". Among the lichens of Caucasus there are species, which are under the threat of local disappearance and even general destruction.

The rapid change of the surrounding cenotic situation under the influence of the abiotic, biotic and especially, anthropogenic factors on the Caucasus, brought to the disappearancs of many relicts, endemic species. Some of them are left as a herbarium, others reduced their areal.

We hope, that the XVII International Botany Congress will play an important role in solving of this problem.

P1337. Katalalixar: Liverworts Paradise

J. A. V. Cuvertino Santoni;
Museo Nacional de Historia Natural (collaborator), Santiago, Chile.

The rainy-temperate forests of Chile hold a very rich core of biodiversity, with a special richness of cryptogams, often exceeding that of vascular plants. The taxonomic singularity and biogeographical interest of the bryophytes associated to these forests, particularly in Katalalixar, have a direct relation to the long geological history of the continent and oceanic climate. The liverwort diversity in the studied area concentrates for more than the 50% in the forest floor, setting up a surprising biomass which also entirely covers tree trunks up to 5-6 meters and 20 cm thick. In addition, an important number of species grow on rocks and logs in the intertidal zone of the fjord system. Phytogeographically, a 57% of the species is endemic to the forested ecosystems of southern South America, while the subantartic element represents a 27%. At generic level, a 42% of the flora has a wide distribution on the globe, while only the 8% results to be endemic. The distribution of the species restricted south to 48° lat S and the species having disjunctions to the northern Chile and the Neotropics have a particular interest.

P1338. 'Bartramia stricta' Brid. (Bartramiaceae) in the Mosel valley - a relict from the postglacial temperature optimum?

D. Quandt[1], S. Lenz[1], M. T. Pham[1], K. Salomo[1], J. Schäfer[1], L. Symmank[1], **J. P. Frahm**[2];
[1]Technische Universität Dresden, Dresden, Germany, [2]Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany.

The Mediterranean moss Bartramia stricta Brid. was first discovered in Germany in 1932 and subsequently recorded from a dozen localities in the Mosel valley area. Molecular studies were started with the aim to test its status as relict from the postglacial temperature optimum (10,000 yrs b.p.). Phylogenetic analyses based on sequence data of chloroplast trnSGGA - trnFGAA region revealed that the sterile populations have nothing in common with the Mediterranean, British or North American populations of B. stricta. In contrast, a close relationship to populations of Anacolia laevisphaera (Tayl.) Flow. in Grout is indicated by the molecular analyses. Moreover, the German populations are morphologically identical to A. laevisphaera. Therefore, the German specimens have to be referred to A. laevisphaera, a tropical montane species. This is a first example of a bryophyte species which has been added new to the flora of Europe due to a molecular study.

P1339. Molecular variation in *Isothecium alopecuroides* (Lam. ex Dubois) Isov., including a deviating form from Morocco

I. Draper[1], F. Lara[1], V. Mazimpaka[1], L. Hedenäs[2];
[1]Universidad Autónoma de Madrid, Ciudad Universitaria de Cantoblanco, Spain, [2]Swedish Museum of Natural History, Stockholm, Sweden.

In course of identification of epiphytic bryophyte samples from Morocco, an *Isothecium* with characteristics of *I. alopecuroides* (Dubois) Isov. and, to a smaller degree, *I. algarvicum* W.E. Nicholson & Dixon was found. Problems with attributing the plant to any *Isothecium* species, and the known large morphological variation in *I. alopecuroides*, suggested that molecular studies were needed to evaluate patterns of relationships in this complex.

A total of 87 samples were studied, of which 12 belong to the Moroccan plant, 56 to *Isothecium alopecuroides* from different regions of Europe, 1 to *I. alopeuroides* from China, 2 to *I. algarvicum*, and the rest to other *Isothecium* species, which were used as outgroup: 2 of *I. subdiversiforme* Broth., 4 of *I. myosuroides* Brid., 4 of *I. myosuroides* var. *brachythecioides* (Dixon) C.E.O. Jensen, 2 of *I. stoloniferum* Brid., 1 of *I. cristatum* (Hampe) H. Rob. and 3 of *I. holtii* Kindb.

The tRNA-Gly and ITS markers were investigated and revealed molecularly distinct populations of *I. alopecuroides* in Morocco, Eastern Europe, and some Western and Northern European localities.

P1340. A revision of the genus *Thamnobryum* (Musci) of Japan

T. Kagenishi, H. Tsubota, T. Yamaguchi, H. Deguchi;
Depertment of Biological Science, Graduate School of Science, Hiroshima University, Higashi-hiroshima-shi, Japan.

A taxonomic revision was made on Japanese species of the genus *Thamnobryum*, based on morphological and molecular data. Eight species were recognized to occur: *T. alopecurum* (Hedw.) Nieuwl. ex Gangulee (*Thamnium planifrons* Broth. & Yasuda, syn. nov.), *T. coreanum* (Cardot) Nog. & Z.Iwats., *T. subseriatum* (Mitt. ex Sande Lac.) B.C.Tan, *T. cymbifolium* (Cardot) Kagenishi, stat. nov. (*Thamnium sandei* var. *cymbifolium* Cardot; *Thamnium sandei* var. *angustifolium* Nog., syn. nov.), *T. coreense* (Cardot) Kagenishi, comb. et stat. nov. (*Thamnium sandei* var. *coreense* Cardot; *Thamnium sandei* var. *imbricatum* Nog., syn. nov.), *T. plicatulum* (Sande Lac.) Nog. & Z.Iwats., *T. incurvum* (Nog.) Nog. & Z.Iwats., and *T. neckeroides* (Hook.) E.Lawton (New to Japan!). The following characters were newly recognized to be of important taxonomic criteria additional to the characters previously evaluated for the distinction of species: papillosity of leaf cells, cell wall thickenings of stem, structure of costa, and sexuality. A key to the Japanese species was given.

P1341. The complex thalloids - evolving simply

D. G. Long[1], L. L. Forrest[2], M. L. Hollingsworth[1], A. Clark[1], D. B. Schill[1];
[1]Royal Botanic Garden Edinburgh, Edinburgh, United Kingdom, [2]Dept. of Plant Biology, Southern Illinois University, Carbondale, IL, United States.

A molecular phylogeny was produced for 36 species (26 genera) from the Marchantiopsida and two species from the Blasiaceae, and rooted using seven species from *Haplomitrium*, *Treubia* and *Apotreubia*. Sequence data were generated for the chloroplast genes *rbc*L, *rps*4 and *psb*A, the nuclear ribosomal LSU and the mitochondrial gene and intron *nad*5.

Combined analyses of these support the monophyly of the complex thalloids and the sister relationship of the Blasiaceae. There is little support for early branches within the Marchantiopsida, although the Sphaerocarpales resolve as the first diverging lineage.

Lunularia and *Neohodgsonia*, taxa with complex archegoniophores, also diverge early, while simpler taxa lacking archegoniophores, i.e. *Riccia*, *Ricciocarpos* and *Monoclea*, nest deep within the group, implying morphological reduction in some of the more phylogenetically advanced lineages. A *Marchantia/Preissia* (Marchantiaceae) clade is supported as sister to all remaining complex thalloids. The families Cleveaceae and Aytoniaceae are monophyletic, but their largest genera *Athalamia* and *Asterella* are not.

P1342. Reconstructing Evolution in the Metzgeriales Schljakov subord. Pallaviciniineae R. M. Schust., the "Vascularized" Liverworts

B. J. Crandall-Stotler, L. L. Forrest, R. E. Stotler;
Southern Illinois University Carbondale, Carbondale, IL, United States.

Multigene analyses of the simple thalloid liverworts resolve a monophyletic clade comprising the Hymenophytaceae R. M. Schust. and Pallaviciniaceae Mig., a synapomorphy of which is the differentiation of strands of elongate, hydrolyzed cells in their gametophytes. Six well supported lineages are resolved within this clade, but the genera *Pallavicinia* Gray, *Symphyogyna* Nees & Mont., *Moerckia* Gottsche and *Podomitrium* Mitt. are paraphyletic. To test whether there are morphological characters that are better predictors of the evolutionary relationships within the group than those currently used to define genera, a combined analysis of molecular and morphological data has been conducted, and morphological character evolution has been reconstructed on the combined tree. Oil body morphology, spore wall architecture and some features of perichaetial organization are predictive of several of the paraphyletic lineages, while variations in strand cell anatomy are not. Sporophyte-investing structures and capsule wall anatomy are phylogenetically informative, but there is substantial homoplasy in perigonial organization and plant habit.

P1343. A Revision of the Colombian species of *Polytrichadelphus*

A. Aponte, E. Linares;
Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Bogotá, Colombia.

A revision of the Colombian species of *Polytrichadelphus* (Polytrichaceae: Musci) is presented. The genus is very variable morphologically. Seven species are recognized in Colombia: *Polytrichadelphus abriaquiae*, *P. aristatus*, *P. ciliatus*, *P. giganteus*, *P. longisetus*, *P. purpureus* and *P. valenciae*; they are distributed mainly in cloud forest and paramo vegetation, and are adapted to a number of different substrates.

A numerical taxonomic study of the genus was carried out. Cluster Analyses with the unweighted pair group method using arithmetic averages (UPGMA), as well as ordination methods (Principal Component Analysis) were used to establish phenetic relationships among species and to obtain the most important characters for their delimitation. A total of 20 morphological characters were studied in 114 Colombian samples of the genus, of which 92 were used for the numerical analysis.

An artificial identification key to the Colombian species is provided. The following information is given for each taxon: morphological description, geographical distribution (with maps), ecology, and general observations. Each species is illustrated and a list of specimens examined is included.

P1344. A revision of the genus *Dimerodontium* (Bryophyta) with considerations about familiar position using cpDNA

P. S. Camara[1,2], R. E. Magill[1];
[1]Missouri Botanical Garden, Saint Louis, MO, United States, [2]Universidade de Brasilia, UnB, Brasilia, Brazil.

The genus *Dimerodontium* was firstly described by William Mitten in his work entitled "*Musci Austro Americani*" in 1869. Between the year 1877 and 1956, a total of 14 names were added to this genus. Even though the genus has some characters distinct from Fabroniaceae, its original familiar position was never challenged. For the first time a comprehensive study including a monograph of the genus and molecular phylogeny based on cpDNA is presented. A new definition of the genus is proposed with three species *D. mendozense* Mitt., *D. pellucidum* Mitt. and *D. balansa* Müll Hal. Eleven new synonyms are also presented. New rbcL sequences were obtained for the genus *Dimerodontium* and *Fabronia*, the remaining sequences used in the study were downloaded from the GenBank. Data were analyzed under maximum parsimony and maximum likelihood criteria using PAUP 4.0.b10. Results under both criteria do not support a monophyletic Fabroniaceae as traditionally circumscribed; *Dimerodontium* appears as sister group of a clade containing *Fabronia, Gollania, Abietinella, Stereophyllum* and *Entodontopsis*.

P1345. Molecular cytological comparative analysis of *Pellia* species (Hepaticae).

M. Orzechowska, J. Maluszynska, D. Siwinska;
Dept.of Plant Anatomy and Cytology, University of Silesia, Katowice, Poland.

Pellia borealis is one of the first described allopolyploid liverwort, originated after hybridization of two allopatric taxa *P. epiphylla* S and *P. epiphylla* N. Allopolyploid origin of *P. borealis* is well documented by molecular and isoenzyme markers, but cytogenetic evidences are still lacking. Detailed chromosome analyses of polyploid and ancestors genomes have been carried out. Haploid gametophyte of *P. epiphylla* S and *P. epiphylla* N has 9, while *P. borealis* 18 chromosomes. Differential chromosome staining like DAPI/CMA3 and C-band allowed identifying some chromosomes of progenitors in hybrid karyotype. That confirmed allopolyploid origin of *P. borealis.* Only one locus 26S rDNA was determined on *P. borealis* chromosomes by FISH. It is supposed that some rearrangements occurred in polyploid genome and locus of rRNA genes from one progenitor have been lost. Flow cytometry estimation of genome size of studied species showed that *P. borealis* nuclear DNA content is almost sum of *P. epiphylla* N and *P. epiphylla* S content.

P1346. Anatomical and ultrastructural innovations in *Leiosporoceros dussii* (Steph.) Hässel

J. C. Villarreal[1], R. J. Duff[2], K. S. Renzaglia[1];
[1]Southern Illinois University Carbondale, Carbondale, IL, United States, [2]University of Akron, Akron, OH, United States.

The genetic isolation of *Leiosporoceros dussii* from all other hornworts is corroborated by unique morphological features, which are detailed in this study. *Nostoc* occurs in median schizogenous canals that run the length of the thallus and are distinctly different from the globose colonies of other genera. The cyanobacteria invade sporelings through stomata-like clefts near the growing tip; no clefts are visible in older plants. *Nostoc* strands elongate and branch in synchrony with apical growth. Sporophytes contain extensive sporogenous tissue with small, smooth spores in isobilateral tetrads. The abundant pseudoelaters are highly elongated with thick cell walls. Spore wall deposition is initiated by plates of tripartite lamellae, giving rise to the external exine that is subsequently obscured by sporopollenin. This first report of tripartite lamellae in hornworts solidifies this feature as a synapomorphy for land plants. When molecular and morphological data are considered collectively, *Leiosporoceros* provides essential clues in reconstructing the evolutionary history of bryophytes.

P1347. Brotherus' and Fleischers' view of the Lembophyllaceae: better than molecules?

V. Buchbender[1], **S. Olsson**[2,1], R. Tangney[3], S. Huttunen[2], D. Quandt[1];
[1]Technical University of Dresden, Dresden, Germany, [2]University of Helsinki, Helsinki, Finland, [3]National Museum and Gallery, Cardiff, United Kingdom.

During the last century the moss family Lembophyllaceae has undergone fundamental changes in its familial delimitation, and yet the generic and familial level relationships are still poorly understood. Originally, the Lembophyllaceae contained four genera: *Lembophyllum, Camptochaete*, *Dolichomitra*, and *Isothecium* (Brotherus 1909). Later, Brotherus´ concept of the Lembophyllaceae broadened, and by 1925 he included another 8 genera. This resulted in a seemingly heterogeneous assemblage being criticized by several later researchers arguing that the included genera show very little similarity. Here we present a generic revision of the Lembophyllaceae based on *trnL-F*, *psbT-H* and ITS2 sequence data that clearly reveals that the current circumscription of the family is too narrow and that several genera, which have been placed in other families, such as *Bestia*, *Dolichomitra*, *Dolichomitriopsis*, *Isothecium*, *Fallaciella*, *Rigodium*, and *Tripterocladium*, should be re-included in the Lembophyllaceae.

P1348. A molecular phylogeny of the genus *Leucobryum* (Leucobryaceae, Musci) in Asia and the Pacific

E. Oguri, H. Tsubota, T. Yamaguchi, H. Deguchi;
Department of Biological Science, Graduate school of Science, Hiroshima University, Higashi-hiroshima-shi, Japan.

Leucobryum includes ca. 180 species, and is widely distributed in the world. Yamaguchi (1993) monographed Asian *Leucobryum*, and noted several important taxonomic characters for species recognition. However, there still remains the taxonomic ambiguity of the circumscription of species. The aim of the present study is to determine the phylogenetic relationships among species of *Leucobryum* in Asia and the Pacific. Our study corroborates evidence that 1) *Leucobryum* is a monophyletic entity including some species of *Schistomitrium*; 2) four major clades: the *L. juniperoideum*-clade, *L. scabrum*-clade, *L. bowringii*-clade, and *L. sanctum*-clade can be recognized; 3) the *L. sanctum*-clade was morphologically distinguishable from the other three clades by leaves with distinct auriculate alar regions; and 4) the distribution of perichaetia on the stem, the proration of abaxial leaf cells at leaf apex, and the central strand of stem were proved to be important characters which reflecting phylogeny.

P1349. Botanical Diversity

G. T. Dabhade;
Birla College, Kalyan, India.

Mosses which play a key role in the formation of natural biotic community & indicative of forest condition were abundant at Khandala and Mahabaleshwar in the *Western Ghats of India*. Eversince Sedgwick (1909), Dixon (1911) & Bruhl (1931), etc. - research on mosses was neglected. In addition to this scenario, forest of said localities have been succumbed by human interference. Survival of many mosses have been threatened. Therefore an attempt has been made to reinvestigate them.

It appears that Mahabaleshwar possess 30 terricolous, 27 saxicolous, 34 corticolous, 5 lignicolous, 1 aquatic saxicolous mosses. Khandala possess 16 terricolous, 16 saxicolous, 15 corticolous, 2 lignicolous taxa. Some of them indicate high degree of adaptability in their habitat. Fruiting Archidium indicum, Diaphanadon procumbens were new to this region. Moss Flora of Mahabaleshwar is much more rich than that of Khandala due to conducive climatic condition such as high altitude (4500 Ft.) & high rainfall (200 inches).

P1350. Origin and subdivision of Plagiochila (Jungermanniopsida: Plagiochilaceae) in tropical Africa

J. Heinrichs;
Albrecht von Haller Institute of Plant Sciences, Göttingen, Germany.

Plagiochila with about 450 species is the largest genus of Hepatics. Centre of diversity are the humid tropics of Asia and tropical America. The *Plagiochila* flora of tropical Africa is rather poor, possibly as a result of extensive drought periods over the Pleistocene which could have resulted in the extinction of parts of the local hepatic flora.

Phylogenetic analyses of chloroplast gene *rps*4 and nrITS sequences of *Plagiochila* lead to a well supported topology with African species nested in six predominantly tropical clades. The majority of African species belongs to *Plagiochila* sect. *Vagae*. Several species occur both in the Neotropics and Africa. ITS sequence similarities indicate that their ranges are the result of long distance dispersal rather than vicariance. Molecular data provide some evidence for long-range dispersal events eastwards across the Atlantic, originating from the Neotropics.

P1351. Taxonomic and phylogenetic positions of the genera *Brotherella*, *Pylaisiadelpha* and *Wijkia* (Sematophyllaceae)

H. Tsubota[1], P. J. Dalton[2], R. D. Seppelt[3], H. Deguchi[1];
[1]Department of Biological Science, Graduate School of Science, Hiroshima University, Higashi-hiroshima-shi, Japan, [2]School of Plant Science, University of Tasmania, Hobart, Australia, [3]Australian Antarctic Division, Kingston, Australia.

Although often discussed, the taxonomic position of the genera *Brotherella* Loeske ex M.Fleisch., *Pylaisiadelpha* Cardot and *Wijkia* H.A.Crum (Sematophyllaceae) is still unclear. The monophyly of these three genera is tested, and *Wijkia* appears as a polyphyletic entity. Analyses of morphological and phylogenetic data show that only *Wijkia extenuata*, the type of the genus *Wijkia*, which occurs in continental Australia, Tasmania, and New Zealand, should be treated as a member of the subfamily Heterophylloideae of the family Sematophyllaceae. It is suggested that Asian species of *Wijkia* should be treated as members of the genus *Brotherella*. Alar cells proved to be an important character in separating *W. extenuata* from other species of the genus *Wijkia*. We consider that the Sematophyllaceae should be subdivided into three subfamilies: Sematophylloideae, Heterophylloideae, and Pylaisiadelphioideae.

P1352. Molecular Systematic Study of Conocephalum (Hepaticae)

H. Miwa[1], I. J. Odrzykoski[2], H. Akiyama[3], R. Sabirov[4], H. Takahashi[5], N. Murakami[1];
[1]Department of Botany, Graduate School of Science, Kyoto University, Kyoto, Japan, [2]Department of Genetics, Adam Mickiewicz University, Poznan, Poland, [3]Division of Phylogenetics, Museum of Nature and Human Activities, Hyogo, Japan, [4]Institute of Marine Geology and Geophysics, Sakhalin Scientific Center, Yuzhno-Sakhalinsk, Russian Federation, [5]The Hokkaido University Museum, Hokkaido University, Hokkaido, Japan.

Bryophytes are small land plants with a simple morphology. Therefore, we can predict the existence of several biologically distinct units or cryptic species within the morphological species of bryophytes. In our previous study, we found three rbcL types in Asian Conocephalum japonicum (Thunb.) Grolle and also got several evidences strongly suggesting that these types are cryptic species which are reproductively isolated (Miwa et al. 2003, 2004). In this study, we tried to examine rbcL sequence variations from 6 cryptic species of C. conicum (L.) Dumort. formerly recognized by allozyme analyses (Odrzykoski and Szweykowski 1991, Akiyama and Hiraoka 1994). As a result, we could discriminate the six cryptic species based only on their rbcL sequences. In addition, we found a sample of C. conicum which is probably a new cryptic species from Sakhalin because it has quite distinct rbcL sequence from any of the formerly known 6 cryptic species. It was shown that rbcL sequence variations were also useful in finding cryptic species of C. conicum.

P1353. Bryophytes on cliffs and talus slopes of south-western Moravia (Czech Republic)

S. Kubešová;
Department of Botany, Moravian Museum, Brno, Czech Republic.

Bryophyte flora of rock habitats and talus slopes was studied in south-western Moravia (Czech Republic). The total number of species was 140 (23 liverworts, 117 mosses) for cliffs and 93 (20 liverworts, 73 mosses) for talus slopes (26 study sites). The most frequent species on both habitats were *Dicranum scoparium*, *Hedwigia ciliata*, *Hypnum cupressiforme*, and *Pohlia nutans*, on cliffs also *Cephaloziella divaricata*, *Ceratodon purpureus*, and on talus slopes also *Barbilophozia barbata*, *Grimmia ovalis*, *Pleurozium schreberi*, and *Polytrichum formosum*. Ten threatened bryophytes were recorded for cliffs and four for talus slopes. Temperate and subboreal chorological types were the most frequent for cliffs and temperate, boreal, and subboreal on talus slopes. Among the growth-forms, rough mat and short turf types were the most often both on cliffs and talus slopes. The most frequent life strategies were perennials and colonists both on cliffs and talus slopes.

P1354. Phylogeny of Grimmia Hedw. (Grimmiaceae, Bryopsida) : reproductive strategies influence recombination rates

A. Streiff[1], M. J. Price[2], N. Galland[1];
[1]University of Lausanne, Lausanne, Switzerland, [2]Conservatoire et Jardin Botaniques de la Ville de GenÃ¨ve, GenÃ¨ve, Switzerland.

In this work we investigate the phylogenetic relationships among 33 species of Grimmia Hedw. using two plastid DNA sequences (trnL-trnF & rps4) and 52 morphological characters. The combined analysis of the sequence and morphological data and using Funaridae and Dicranidae species as outgroup supports the monophyly of the family Grimmiaceae and indicates that Grimmia, as currently defined in literature, is paraphyletic. Two clades are present in the tree, one containing the species traditionally placed in the subgenus Rhabdogrimmia Limpr. and one containing the remaining Grimmia species. These clades obviously differ neither in their geographical nor ecological characteristics. An analysis, using 120 trnL-trnF sequences and representing the 33 Grimmia species, shows a difference in the intraspecific variability of the two clades : 'Rhabdogrimmia' contains asexual well-defined species with little intraspecific variability compared to Grimmia s.l. which is composed by sexual less-defined species with higher intraspecific variability. These two different reproduction strategies may imply two different recombination rates.

P1355. A new species of *Exormotheca* (Exormothecaceae, Hepaticae) from China

M. Higuchi[1], **T. Furuki**[2];
[1]Dept. Bot., National Science Museum, Tsukuba, Japan, [2]Dept. Plant Sci., Natural History, Museum and Institute, Chiba, Japan.

A new species of *Exormotheca* (Exormothecaceae, Hepaticae) is reported from China. This is the first record of Exormothecaceae from China and the easternmost locality of the family in Eurasia. The field research organized by the National Science Museum, Tokyo, was made in the southwestern Sichuan Province, China, in cooperation with the Kunming Institute of Botany in 1996. During the field survey in the area of Mt. Singuniangshan unique marchantioid plants were found. The thallus has strongly elevated air chambers coupled with simple air pores and cubical carpocephala of archegoniophores, which are characteristic of the family Exomorthecaceae. The family consists of three genera, *Aitchisoniella*, *Stephensoniella* and *Exormotheca*, of which *Aitchisoniella* and *Stephensoniella* are monotypic and endemic to the western Himalayas. Sichuan plants are a member of *Exormotheca* because of having chlorophyllous filaments in air chambers, and are distinct from other species of the genus by short septa of air chambers, rounded ventral scales with entire margin, ciliate appendages and presence of oil-cells. Sichuan plants may also belong to Sect. *Corbierella*.

P1356. Moss flora in the greater area of Belgrade

S. Grdovic;
Faculty of Veterinary Medicine, University of Belgrade, Belgrade, Serbia and Montenegro.

The research of the moss flora in the greater area of Belgrade included large greens in fifteen localities: the Danube quay, Rušanj, the Sava quay, Avala, the forest of Bojcinska, Kanarevo brdo, Surcin, Banjica, Ada Ciganlija, Zvezdara, Košutnjak, Višnjica, Topcider, Ilicev dunavac, Monastery forest in Rakovica.

The research has proven the existence of 182 moss species which have been classified in 75 genera and 27 families. According to literature (Sabovljevic, 2000) the number of 182 taxons of mosses represents 34% of the moss flora in Serbia.

The research into the moss flora of the greater area of Belgrade has brought to light 8 species that were not previously found in the moss flora in Serbia. They are: *Brachythecium latifolium* Kindb., *Brachythecium campestre* (C. Mull.) B.S.&G., *Brachythecium starkei* (Brid.) B.S.&G., *Ditrichum pusillum* (Hedw.) Hampe, *Fissidens exilis* Hedw., *Rhynchostegiella tennella* (Dicks.) Limpr., *Isopterygyopsis muellerana* (Schimps.) Iwats. and *Tortella fragilis* (Drum.) Limpr.

The research has pointed to a great diversity of moss species and habitats in which they develop.

P1357. Genetic Diversity Of Some Selected Economically Important Philippine *Alliums*

V. A. Panes, M. A. Chan, V. S. Tolentino;
Biology Department, Quezon City, Philippines.

The present study covered interspecific genetic diversity of *Alliums* commonly grown in the Philippines such as *Allium ascalonicum*, *Allium cepa*, *Allium chinense*, *Allium fistulosum*, *Allium odorum* and *Allium sativum*. Eight morphological characters were used such as bulb mass and diameter; number of scales and cloves; diameter, height and mass of cloves; and leaf appearance (either flat or cylindrical) to construct a dendogram. The RAPD analysis yielded 64 loci all of which are polymorphic. The largest genetic distance coefficient is between *A. fistulosum* and *A. sativum* which is 0.693147. The first clade consisted of *A. fistulosum* and *A. chinense*, which had a bootstrap value of 52%. The second clade was composed of *A. ascalonicum* and *A. cepa*, with a bootstrap value of 99%. *A. sativum* was paraphyletic relative to *A. fistulosum* and *A. chinense* with a bootstrap value of 73%. *A. odorum* was divergent relative to the rest of the *Alliums*, with a boostrap value of 100%. The clade of *A. cepa* and *A. ascalonicum* deviated from the clade of *A. fistulosum*, *A. chinense* and *A. sativum*. This study is useful for the selection breeding and species conservation of Philippine *Alliums*.

P1358. Infraspecific variability of the species of the genus Allium L. 1754 (Amaryllidales, Alliaceae) of the southern part of the Pannonian Plains (Serbia and Montenegro)

G. Anackov[1], P. Boza[1], R. Igic[1], B. Bozin[2], D. Vukov[1];
[1]Faculty of natural science, Novi Sad, Serbia and Montenegro, [2]Faculty of Medicine, Novi Sad, Serbia and Montenegro.

Since the determination with standard keys is based upon the morphological characters, the obtained results point to an insufficient number of characters used in infraspecific differentiation, in particular when taxa ranked as varieties and forms were discussed. Determination with standard keys was impracticable in certain cases, despite the fact that certain situations pointed out their belonging to the individual taxa. The analysis of all the morphological characters used in determination of infraspecific Allium taxa of the southern edges of the Pannonian Plains was done to perform adequate and more practical determination. Data were statistically processed using Statistica software for Windows version 5.1. ANOVA and MANOVA tests using taxon as a factor, Principal Componente Analysis (PCA), and Discriminante and Corespondente Analysis were also done. Combinations of characters for infraspecific taxa determination were separated. Cluster analysis showed a similarity between variation of quantitative and qualitative characters.

P1359. Phylogenetic analyses of the genus Crinum (Amaryllidaceae) with emphasis on tropical African species.

E. G. Kwembeya, C. S. Bjorå, B. Stedje, I. Nordal;
University of Oslo, Oslo, Norway.

Fifty species of *Ammocharis*, *Crinum* and *Cybistetes* were sequenced, with *Amaryllis* chosen as outgroup. Two main clades were revealed: All *Ammocharis* taxa, *Crinum baumii* and *Cybistetes longifolia* constituted the first main clade and the rest of the *Crinum* taxa constituted the second. The second main clade is split into three subclades. The first subclade comprises almost only taxa with starshaped flower ("*Stenaster*"). The second subclade includes taxa, all with bellshaped flowers ("*Codonocrinum*") with main distribution in Southern Africa. The third subclade includes "*Codonocrinum*" taxa with tropical distribution. Within this subclade a monophyletic group including the rest of the "*Stenaster*" taxa is situated (those dist. in W. Africa and America). Interestingly a newly discovered species*Crinum binghamii*, found in Zambia, links in a basal position in this W-African to American group. There is accordingly no support for taxonomic recognition of subgeneric delimitation related to flower morphology, but, there are strong geographical and ecological trends in the phylogeny, which will be discussed further.

P1360. Molecular Systematics of The Genus *Goniothalamus* Hook. f. & Thomson

M. Nakkuntod[1], T. Seelanan[1], R. M. K. Saunders[2];
[1]Department of Botany, Faculty of Science, Chulalongkorn University, Bangkok, Thailand, [2]Department of Ecology and Biodiversity, The University of Hong Kong, Hong Kong, China.

The genus *Goniothalamus* Hook. f. & Thomson is one of the largest and most important genera in the Annonaceae. Its members are widespread mainly in South Asia and South East Asia. Many *Goniothalamus* species hold potential as important medicinal resources in Thai traditional medicinal practices, including, for example, the roots of *G. macrophyllus* (Blume) Hook. f. & Thomson. Little is known of the evolution and biogeographical history of this genus. Many morphological characters are ambiguous and reveal little phylogenetically useful information. Molecular systematics, nonetheless, provides tools that can answer these questions. Preliminary results show that the sizes of *rpl*16 intron, *trn*L intron and ITS in all species studied are about the same (i.e., 1,200, 580 and 750 bp, respectively). ITS, however, has the most phylogenetically informative sites, although the size of ITS is shorter than *rpl16* intron. Of all three loci, ITS locus yields the highest number of phylogenetically informative sites, whilst cp markers give few sites. Moreover, DNA fragments from ITS have greater nucleotide substitution than the others.

P1361. Reassessing the generic status of Petalolophus (Annonaceae): evidence for the evolution of a distinct sapromyophilous lineage within Pseuduvaria

Y. C. F. Su[1], J. B. Mols[2], W. Takeuchi[3], P. J. A. Kessler[2], R. M. K. Saunders[1];
[1]University of Hong Kong, Hong Kong, China, [2]Nationaal Herbarium Nederland, Leiden, The Netherlands, [3]Papua New Guinea Forest Research Institute, Lae, Papua New Guinea.

The genus *Petalolophus* (Annonaceae) consists of only one species, *P. megalopus*, and is characterized by large perianth wings that extend abaxially from the midrib of the inner petals. Recently published molecular phylogenetic data suggests that *Petalolophus* is congeneric with *Pseuduvaria*. Morphological and anatomical characteristics of both genera are critically re-examined. *Petalolophus* only differs from *Pseuduvaria* by the autapomorphic possession of perianth wings, indicating that *Petalolophus megalopus* should be transferred to *Pseuduvaria* as "*Pseuduvaria megalopus*". Unlike most Annonaceae, *Pseuduvaria* species are fly-pollinated with inner petals that are apically connivent, forming an open chamber around the reproductive organs. Many *Pseuduvaria* species have light-coloured petals (usually cream or pale yellow), whereas other species are presumably sapromyophilous since they have dark red, purple or brown patches on the petals, and often emit an unpleasant odour. The dark red, convoluted perianth wings of *P. megalopus* are unique in the genus as they clearly mimic carrion, and field observations show that the flowers are visited by flies.

P1362. The genera *Anthericum* and *Chlorophytum* (Anthericaceae), evolution and generic delimitation

C. S. Bjorå[1], G. Hoell[1], B. Stedje[1], I. Nordal[2];
[1]Natural History Museum, University of Oslo, Oslo, Norway, [2]Dept. of Biology, University of Oslo, Oslo, Norway.

Altogether 70 accessions representing 40 species of African and European *Chlorophytum* and *Anthericum* were analysed by sequencing ITS and *trnL-F* spacer and running cladistic analyses with *Leucocrinum* as outgroup. The taxa are grouped in several clades, but the basal topology of the three shows little resolution. However, some clades, obviously with taxonomic sense, were revealed: European *Anthericum* constituted one, and African *Antericum* another monophyletic group. African *Chlorophytum* taxa that up to mid 1990s were referred to *Anthericum* constituted more than one clade. The taxa formerly referred to *Dasystachys* belongs in one clade. All taxa defined by basal chromosome number x=7, including most rain forest taxa, constituted a large, poorly resolved clade. This cladogram indicates that, the genus *Chlorophytum* has transgressed from savanna into rain forest at least twice. Generic delimitation and, also delimitation of some species will be discussed, but more data are needed to conclude.

P1363. The Middle Asia as the greatest diversity center of ephemeroid Umbelliferae(Apiaceae) in the Old World

E. V. Kljukov, I. O. Filatova;
Botanical Garden, Moscow, Russian Federation.

Ephemeroid Umbelliferae are the perennial herbaceous monocarpic or polycarpic plants with tuberous or vertical thickened storage roots. They usually become dormant towards the middle of summer. This plant group is presented in arid areas and is common in the Mediterranean region.

By the recent data, 449 species of Umbelliferae belonging to 109 genera have been recorded in the Middle Asia, including Kazakhstan, Kyrgyzstan, Uzbekistan, Turkmenistan and Tadjikistan. About half of them (196 species from 24 genera) are ephemeroids. Ferula, the largest genus of Umbelliferae in the Middle Asia (96 species), contains ephemeroid species mainly. These plants have vertical or napiform storage roots. The plants belonging to such large genera of Umbelliferae, as Elaeosticta (19 species) and Bunium (17 species) have usually storage roots in the form of globose geophilic tubers.

The largest number of ephemeroid Umbelliferae in the Middle Asia belongs to Apieae tribe. At the same time, such large genera as Bupleurum and Seseli do not contain ephemeroids at all.

P1364. Major clades within Apiaceae subfamilies Saniculoideae and basal Apioideae: Implications for evolution of the woody habit.

C. I. Calviño[1,2], S. R. Downie[1], P. M. Tilney[3], B. van Wyk[3];
[1]University of Illinois at Urbana-Champaign, Urbana, IL, United States, [2]Instituto de Botánica Darwinion, Buenos Aires, Argentina, [3]University of Johannesburg, Auckland Park, South Africa.

The family Apiaceae, as traditionally circumscribed, comprises three subfamilies, with the largest, Apioideae, being the focus of much systematic attention. In this study, we expand results of a previous phylogenetic analysis of chloroplast *rps*16 intron sequences by incorporating additional representation of "core Apiaceae" (Apioideae, Saniculoideae, and the *Azorella* clade) with several woody or herbaceous African umbels, many of which have been postulated to be links between subfamilies Apioideae and Saniculoideae, or to be important lineages in the early evolution of core Apiaceae. Among basal Apioideae, two additional major lineages are inferred (*Annesorhiza* clade; *Lichtensteinia*); tribe Heteromorpheae is expanded. Saniculoideae is maintained as sister to *Steganotaenia* plus *Polemanniopsis*. Core Apiaceae is also expanded to include a fourth major clade (*Hermas*, treated previously as a hydrocotyloid genus). A southern African origin of subfamilies Apioideae and Saniculoideae is postulated, and the placement of herbaceous members at the base of Apioideae suggests, surprisingly, that its ancestor was herbaceous, not woody.

P1365. Architecture and fruit set effects in Chaerophyllum bulbosum (Apiaceae)

K. Reuther, R. Claßen-Bockhoff;
Institut für Spezielle Botanik, Johannes Gutenberg-Universität, 55099 Mainz, Germany.

Most of the European Apiaceae-Apioideae are andromonoecious and show rather constant sex ratios. To test the plasticity in sex expression biennial Chaerophyllum bulbosum was used as a model system and a field trial was carried out in a natural population on the Rhine river banks near Mainz, Germany. The plants bear about 80% (functionally) male flowers in a total of 1000 to 35000 flowers that are produced in white umbels in up to four umbel orders. Treatments were i) control, ii) additional hand-pollinations, iii) exclusion of insects by bagging entire inflorescences and iv) removal of first and second order umbels. Bagged individuals produced both perfect and male flowers. Individuals with removed umbels had significantly more perfect flowers in the umbels of higher branch order and even produced an additional branch order. The results show that andromonoecy in Chaerophyllum bulbosum is an architectural effect which sets the constraints of sexual lability in individual flowers depending on their position and total fruit set.

P1366. Leaf shape variation in *Monstera adansonii* Schott and *M. praetermissa* E.G.Gonç. & Temponi (Araceae) from eastern South America

I. M. Andrade[1], S. J. Mayo[2], D. W. Kirkup[2], C. Van den Berg[1];
[1]Universidade Estadual de Feira de Santana, Feira de Santana, Brazil, [2]Royal Botanic Gardens, Richmond, United Kingdom.

Leaf shape variation was studied in *Monstera adansonii* and *M. praetermissa*. The study is based on over 1500 leaves from 28 field populations in Brazil (Pará, Ceará, Pernambuco, Bahia, Espírito Santo, Rio de Janeiro, São Paulo) and French Guiana. Shapes were compared by multivariate analysis (PCA, CVA) of the Elliptic Fourier coefficients obtained from digitised leaf outlines. Shape/size correlation was studied using principal component scores as shape attributes and correlation between perforation number and leaf blade length was investigated. *M. adansonii* is distinguishable from *M. praetermissa* on leaf blade shape alone, using mature leaves, pre-mature leaves or both together. Many populations were distinguishable within *M. adansonii*, often when geographically close, but the pooled populations did not partition into consistent subgroups. Model-based cluster-analysis resulted in three groups of *M. adansonii* populations, with *M. praetermissa* remaining separate. Shape of pre-mature leaves is just as useful as the mature shape; this result could be useful for conservation field surveys in humid forest islands in Northeast Brazil.

P1367. A Phytogeographic Analysis of Araceae of Cabo Corrientes (Chocó Department, Colombia) and Comparable Lowland Tropical American Floras

M. M. Mora[1,2], R. Bernal[1], T. Croat[3];
[1]Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Bogota, Colombia, [2]University of Puerto Rico, Mayaguez, Puerto Rico, [3]Missouri Botanical Garden, Saint Louis, MO, United States.

We studied the Araceae of the Cabo Corrientes region on the Pacific Coast of Colombia, and compared its aroid flora with those of La Selva (Costa Rica), Barro Colorado Island (Panama), Bajo Calima (Colombia), Río Palenque (Ecuador), and Iquitos (Peru). We found 113 species in 14 genera at Cabo Corrientes; the largest genera were *Anthurium* (38 species), and *Philodendron* (35), which together accounted for 64 percent of the species. Seventy five percent of the species were exclusively epiphytic or hemiepiphytic. Most of the epiphytic species belonged to the genera *Anthurium, Philodendron, Rhodospatha, Syngonium, Monstera,* and *Stenospermation*, the latter three containing exclusively epiphytic or hemiepiphytic species. Five of the wild species are used locally. The flora of Araceae of Cabo Corrientes was most similar to that of La Selva, Barro Colorado Island, and Bajo Calima; similarity with Río Palenque was low. Our findings support Lellinger's view that the Chocó biogeographic region extends to the Nicaragua-Costa Rica border and it is divided into a northern and a southern floras.

P1368. Molecular and morphological systematics of the *Tetraplasandra* group (Araliaceae): floral diversity and implications for pollinator shifts

A. Costello[1], T. J. Motley[2];
[1]The Ross School, East Hampton, NY, United States, [2]The New York Botanical Garden, Bronx, NY, United States.

Tetraplasandra, *Reynoldsia*, and *Munroidendron*, are closely related genera distributed in Samoa, French Polynesia and the Hawaiian archipelago. Maximum parsimony analyses based on ITS, 5S-NTS, AFLPs, and morphology indicate a monophyletic Hawaiian lineage (the *Tetraplasandra* group), a sister-taxon relationship between *Munroidendron* and *R. sandwicensis*, and a polyphyletic *Reynoldsia*. Variation in floral morphology corresponds to phylogenetic relationships within and among the genera. Within *Tetraplasandra*, species with hypogynous flowers (*T. gymnocarpa*, *T. kavaiensis*) cluster together and species (*T. waimeae*, *T. waialealae*) with floral characters suggesting bird pollination cluster together. The differences in floral morphology may be associated with a switch to ornithophily. Field studies confirm native and non-native birds feeding on the blossoms of *T. waimeae* and *T. waialealae*.

P1369. *Helwingia* and other genera at the turn of *Cornales* and *Apiales* (*Araliales*) - evidence that fruit anatomy can provide

E. Y. Yembaturova;
Moscow Agricultural Academy, Moscow, Russian Federation.

The position of some genera in *Cornales* has been questionable. One of them is *Helwingia*, often related to *Araliales* (as monotypic *Helwingiaceae*, or *Helwingiineae* within *Araliales*, or even order *Helwingiales*, close to *Araliales*). Our carpological study revealed new facts to support this treatment, namely: *Helwingia* fruit type and general structural pattern markedly resemble those in most *Araliales* (the number of pyrens in *Helwingia* is reduced to 2-4). Some differences though exist (no secretory reservoirs in *Helwingia* pericarp, different seedcoat structure).

Our research demonstrated that out of *Cornales* representatives, usually related to *Araliales*, *Mastixia* has features of resemblance with *Araliaceae*, showing it as an archaic taxon: mesocarpium secretory ducts, associated with vascular bundles; endocarp structure. Never related to *Araliales*, *Kaliphora* has dimeric half-inferior pyrenarium with literally discrete endocarp (pyrens are not completely fused); slightly ruminated endosperm of *Kaliphora* was never found in any *Cornales*, whereas reported for *Araliales*.

P1370. Molecular phylogenetics of the palm genus Chamaedorea

M. M. Thomas[1], N. C. Garwood[1,2], W. J. Baker[3], S. Henderson[1], D. R. Hodel[4], S. J. Russell[1], **R. M. Bateman**[1];
[1]Natural History Museum, London, United Kingdom, [2]Southern Illinois University, Carbondale, IL, United States, [3]Royal Botanic Gardens, Kew, United Kingdom, [4]University of California, Davis, CA, United States.

We conducted the first molecular phylogenetic analysis of Chamaedorea (Arecaceae: Ceroxyloideae: Hyophorbeae), the largest neotropical genus of palms. The 100+ species of Chamaedorea have not been analyzed cladistically, nor has the monophyly of the genus previously been tested. The prevalent current taxonomy of Chamaedorea recognizes eight subgenera (Hodel 1992), all based on floral characters. Sequence data from the low-copy nuclear genes PRK and RPB2 were analyzed, and Chamaedorea was found to be monophyletic with strong support. Three of the smaller subgenera are well supported by the molecular data. However, at least two of the subgenera are non-monophyletic including the two largest, Chamaedorea and Chamaedoropsis, which are distinguished from each other by the degree of connation in the staminate petals. Many of the well-supported clades resolved by these gene regions are unsupported by existing morphological evidence and define groups never before proposed within Chamaedorea. Two large clades are identified that would benefit from further study, as they contain morphologically diverse and interesting species.

P1371. A Phylogeny of the Palm Tribe Hyophorbeae Based on Plastid DNA sequences

A. Cuenca[1], C. B. Asmussen[2];
[1]Institute of Ecology. Botanical Section. The Royal Veterinary and Agricultura University, Frederiksberg C., Denmark, [2]Institute of Ecology. Botanical Section. The Royal Veterinary and Agricultura University, Frederiksberg, Denmark.

In this work we conducted the first phylogenetical analysis of the tribe Hyophorbeae (Arecaceae), using molecular data from 4.5 kb of coding and noncoding plastid DNA (*mat*K, *rps*16 intron, *ndh*F and *trn*D-*trn*T). The tribe Hyophorbeae is a monophyletic group including more than 115 species. The tribe has a disjunc distribution with four genera in Central and South America and one genus on the Mascarene Islands. The placement of this tribe within the palm family has been controversial, but the tribe is now firmly placed in subfamily Arecoideae. However, the relationships of Hyophorbeae with other groups of the subfamily are still unclear.

In our analyses all five genera in Hyophorbeae are resolved as monophyletic with high support, however, the relationships among the genera are not clear. The monotypic genus *Wendlandiella* from South America and the genus *Hyophorbe* from the Mascarene Islands form a monophyletic group sister to the remaining three genera. Despite the general difficulty to get resolution at low taxonomical level in palms using plastid DNA, we were able to resolve some of the species level relationships, especially within the largest genus *Chamaedorea*.

P1372. The Micromorphology of leaf in Aristolochia (Aristolochiaceae) genus from Guerrero, México.

B. González-Hidalgo, S. Espinosa-Matias, R. M. Foseca-Juárez;
Facultad de Ciencias, México, D.F., Mexico.

On basis of reproductive structures the genus *Aristolochia* has been partitioned in two subsections *Hexandrae* and *Pentandrae*. The aim of this proyect is to describe the micromorphological characteristics founds in the leafs of 21 species of *Aristolochia* genus inhabiliting in Guerrero state, México. The methodological approach involues leaf fragments of 1 x 1 cm from under and upper surfases, these samples were trated with a thin cover of gold in a Denton Vacuum Desk II Cold Sputter. The samples were observed with a SEM Joel JSM-5310LV. It was found that the main types of trichomes are: Straights, uncinated and the combination of these uncinate and straight in the same leaf; there were monocellulars and pluricellulars trichomes with a composition of two to nine cells.

Almost all the species under study have uncinated and straight tricomas except *Aristolochia veraguensis* of *A. inflata* that only have uncinated trichomes with two or three cells. Finally it was found that the pubescence isn't usefull as charasteristic for identify species in the genus *Aristolochia* at leaf not in all the cases, but in some of them.

P1373. Microsporogenesis of *Thitonia diversifolia* (Hemsl.) Gray (Asteraceae-Heliantheae)

N. C. Alcorcés, A. C. Lárez, J. C. Mayz, J. R. Méndez;
Universidad de Oriente, Maturín, estado Monagas, Venezuela.

Tithonia is an American genus of the Asteraceae family, currently constituted by 40 species and infraspecific taxa; in Venezuela, only *Tithonia diversifolia* (Hemsl.) Gray and *T. rotundifolia* (Mill.) S. F. Blake, have been reported. *T. diversifolia* is used in medicine, as green manure, and in weed control. Little is known about its cytology. The study was made with inflorescences collected from different localities in Monagas state, Venezuela, with anthers of early flower buds, fixed in absolute alcohol-acetic acid (3:1) and coloured with acetic orcein (2%). In this species, the microsporogenesis was observed to be simultaneous. Abnormal meiosis divisions were also observed, with lagged chromosomes in metafase I and anaphase I, and asynchronic chromosomes in metafase II. The pollen grains were 26.5µm long, triporate type and muricate sculpture, 64% of them without spermatic nuclei. These irregularities may be responsible for the low percentage of pollen fertility found.

P1374. Local adaptations of rare species Aster amellus L. (Asteraceae)

J. Raabová[1], Z. Münzbergová[2];
[1]Department od Botany, Faculty of Science, Prague, Czech Republic,
[2]Department of Botany, Faculty of Science, Prague, Czech Republic.

Many recent studies showed negative effects of lower population size on plant fitness. One possibility to increase population size is to transfer individuals from other populations. While this approach has many advantages, it can also have negative effects in case of strong local adaptation. Several previous studies showed local adaptations in species over large geographical scales. Nothing is, however, known about local adaptations of nearby populations, over which the transfers are most likely to be done.

We study local adaptations among populations of self-incompatible perennial species of dry grasslands. We selected three populations in two different regions in central part of the Czech Republic and carried out transplant experiments both within and between regions. This enabled us to estimate the degree of local adaptations at two spatial scales. We also analysed allozyme variation of these populations and abiotic conditions and vegetation composition of their localities. Thus, we could test whether genetic and environmental differences of the populations correlate with the degree of local adaptation.

P1375. *Argyranthemum* Webb ex Schultz Bip. (Asteraceae: Anthemideae). Morphological and Reproductive Biodiversity Micromarkers in an Endemic Macaronesian Genus

M. Olangua-Corral, R. Febles, J. Pérez de Paz;
Jardín Botánico Canario, Las Palmas de Gran Canaria, Canary Islands.

The reproductive systems of plant species are considered to be a determinating cause of biodiversity at natural population level, where the reproductive characteristics control the reproductive success of crosses and biodiversity configuration, both genetic and morphological.

Floral organization has been the principal basis of taxonomy and systematics to the extent that systematics and reproductive biology have been closely allied throughout botanical history because of the implications for both of reproductive characters through time and space. Their integration principally at infrageneric levels is indispensable and has high potential value.

This study centres on 9 taxa from Gran Canaria of genus *Argyranthemum* which is made up through adaptive radiation of 24 species and 15 subspecies. The objective is to estimate and understand biodiversity within an island through the detection of morphological reproductive micromarkers and genetic diversity, the inter-intrapopulation structure and its correlation with interpopulational geographical distances. At the same time, the autoincompatibility and therefore the xenogamy of the genus is confirmed

P1376. Anatomic characteristics of vegetative organs of the Balkan endemic species Aster albanicus Deg.

E. Hoxha[1], B. Mustafa[1], F. Rexhepi[2];
[1]Faculty of Natural Sciences, University of Prishtina, Albania, [2]Faculty of Natural Sciences, Unifersity of Prishtina, Albania.

Abstract. Morphological and anatomic characteristics besides genetic basis represent the real reflection of their adaptability against ecological factors of environment where they are realizing its own life. In this direction we approached to the research of vegetative anatomic organs building on endemic species of Kosova and Albania Aster albanicus Deg., extended in Koznik (Kosova) and Divjakë (Albania).

The preparation of materials for research of anatomic building of root,stalk and leaves has been done under the standard methodology of paraffining and the usage of shipping microtome.

The researches show that there do exist the clear differentiation in anatomic building of leaves (palisade tissue, sponger, number of stomas and nervous density) individuals from Koznik and Divjaka.

On basis of analyzed measuring can be concluded that the Aster albanicus Deg., type belongs to plant group with mesomorph characteristics but presenting the kseromorph characteristics too, especially at individual of Aster albanicus in Koznik taking into consideration the conditions of locality kserotoms where are spread out.

P1377. Biogeographic Patterns and Evolution in the Asteraceae of the Páramos

M. O. Dillon;
The Field Museum, Chicago, IL, United States.

Páramos or high-elevation floristic communities (>3000 m) occur in Costa Rica, Panama, Venezuela, Colombia, Ecuador, and extreme northern Peru and contain 101 families and ~3214 species of flowering plants. Asteraceae is the largest family with 113 genera & ~ 973 species (30%) including Senecioneae (277 spp), Astereae (208 spp), Heliantheae (192 spp), Eupatorieae (98 spp), Gnaphalieae (77 spp), Mutisieae (32 spp), Lactuceae (30 spp), Liabeae (25 spp), & Barnadesieae (11 spp). Senecioneae is most diverse (23%), followed by Astereae (13%), and Heliantheae (13%). Westoniella and Jessea, are restricted to Costa Rica and Panama, and 15 genera do not reach northern Peru, e.g., Espeletia. Ascidiogyne, Chersodoma, Helogyne, Novenia, Mniodes, & Paranephelius lack species N of 4°-6° S latitude. Baccharis, Diplostephium, Ferreyrella, Jalcophila, Loricaria, Luciliocline, Lucilia, Senecio, Werneria, & Xenophyllum are throughout the Andes. Phylogenetic studies in Paranephelius (Liabeae) (7 species, of which 5 are in N Peru) utilizing ITS sequence data suggest that Paranephelius is monophyletic, and with Pseudonoseris constitute the Paranepheliinae.

P1378. Evolution by Reticulation of the *Acrolophus* subgroup (*Centaurea* L., Compositae) in the occidental Mediterranean. Origin and diversification of the section *Wilkommia* Blanca

V. N. Suárez-Santiago[1], M. J. Salinas[1], A. T. Romero[1], N. García-Jacas[2], C. Ruiz-Rejón[1], G. Blanca[1];
[1]University of Granada, Granada, Spain, [2]Instituto Botánico de Barcelona, Barcelona, Spain.

Section *Willkommia* Blanca (genus *Centaurea* L., Compositae) is a group of morphologically very similar taxa which is endemic of the middle east of the Iberian Peninsula and northwest of Africa. According to Heywood (1960) and Blanca (1981) its diversification was by a schizoendemic process from an ancestral singameon. Sistematically it is included in the *Jacea* group, *Acrolophus* subgroup, together the sections *Acrolophus* (Cass.) DC. and *Phalolepis* (Cass.) DC.

Comparative analysis of the ITS and 3´ETS regions of the nrDNA reveals the presence of three different ribotypes in the *Acrolophus* subgroup: *Willkommia*, *Acrolophus-Phalolepis* and *Simulans*. These ribotypes show a clear geographic structuration which doesn´t correspond with the Systematic of this subgroup. We explain this conflict among the structuration of the genetic diversity and the morphological evidences by a reticulate evolution model of the occidental Mediterranean taxa.

We also postulate the hybrid origin of the *Willkommia* ribotype and the occurrence of the ancestor of the *Willkommia* section asociated to the hybridization process which originated the ribotype.

P1379. ITS phylogeny of the genus *Centaurea*: the *Jacea* group

T. Uysal[1], **K. Y. Romashchenko**[2], V. N. Suarez Santiago[3], K. Ertugrul[1], A. Susanna[2], N. Garcia-Jacas[2];
[1]Selcuk University, Konya, Turkey, [2]Institut Botanic de Barcelona, Barcelona, Spain, [3]University of Granada, Granada, Spain.

The new delineation of the genus *Centaurea*, now circumscribed for the major part to the large group of species with *Jacea* pollen type, is the reason for a new molecular study of this group with the aim of verifying the sectional classification and the relationships between sections. We have analyzed the ITS sequences, which we had used in a preliminary study, on an extended sample of the group, and we have compared the resulting molecular phylogeny with present sectional classification. Our results confirm that there is a narrow correlation between molecular data and geographic distribution. We have unraveled unsuspected close relationships between some sections, and we have cleared up the position of some species previously not classified in any section. Finally, a large polytomy and the anomalous placement of some taxa in a complicate group of sections from the Eastern Mediterranean region strongly suggest that reticulation has played an important role in the evolution of this group.

P1380. Genus *Centaurea* L. (Asteraceae) in Georgia

L. D. Jinjolia;
Institute of Botany of the Georgian Academy of Sciences, Tbilisi, Georgia.

The Centaurea genus, which comprises approximately five hundred species, is mainly distributed in the countries of Mediterranean, also in Central and East Europe and Near East. About a hundred and ten species were found in the Caucasus.

The specific composition of the genus was specified for Georgia, the system of the genus was elaborated on the level of subspecies based on geomorphologic, polynogical, and anatomic carpological methods.

The representatives of Georgian flora are grouped into eleven subspecies. Reasoning from the concept of polytypical species, twenty-five species are named for the flora of Georgia.

The nature of some species` endemism, as well as small local populations of limestone ecotopes (in the Western Caucasus), could be assumed as a basis for establishing the conservation status category of the species, meeting the requirements of the International Union for the Conservation of Nature (IUCN) and providing reserves for the conservation of the given species and protected territories.

P1381. The Tribe Anthemideae Cass. (Asteraceae) in the Caucasus

N. Khanjyan;
Institute of Botany of the National Academy of Sciences of the Republic of Armenia, Yerevan, Armenia.

A critical revision of the tribe Anthemideae during more than 25 years has specified its taxonomical composition in the Caucasus. The study was carried out by morphological-geographical method and the use of carpological-anatomical data.

On the basis of studying huge herbarium material (LE, ERE, TBI, BAK, MHA, G, E, P, K, B, FL etc.), type specimens, authentics and photocopies of types, personal herbarium collections and observations in nature during numerous field surveys it was revealed that the Anthemideae in the Caucasus is represented by 9 genera and 97 species. The Anthemideae composition in the Caucasus is as follows: Anthemis L. - 16 species, Achillea L. - 14, Anacyclus L. - 1, Artemisia L. - 22, Leucanthemum Mill. - 1, Matricaria L. - 3, Othanthus Hoffmgg. et Link - 1, Tanacetum L. - 29, Tripleurospermum Sch.Bip. - 10.

Nomenclature, typification, geographical distribution, endemism, altitude and ecological conditions as well as practical significance of species were clarified. 11 rare species were revealed out of which 9 species are narrow endemics and 2 - considered extinct.

P1382. Biosystematic studies in the genus *Senecio* (Asteraceae)

S. Sundara Rajan[1], V. Ankalabasappa[2];
[1]137(MIG), Bangalore, India, [2]The Oxford Educational Institution, Bangalore, India.

The genus ***Senecio, a*** member of Asteraceae includes over 1500 species. The global distribution of ***Senecio*** indicates its ancient origin. The present investigation involves 12 species of ***Senecio*** and discusses their interrelationship from the point of view of flavonoid spot pattern on the chromatogram. On morphological grounds, taxa studied fall into four groups. This grouping of species is assessed in terms of numerical systematics based on flavonoid data. The parameters are paired affinity index, matching coefficient, negative correlation and biochemical distance. Findings from these support the grouping of the species on morphological grounds. Two other statistical parameters - Group affinity (GA) value, and Isolation value (IV) are used to study the intrageneric relationship of the species. Low GA and high IV indicate one of the possibilities- a) The genus is highly plastic and under selection pressure there is a maximum diversity within a short period. b) The genus may be ancient and during evolution, the genome has undergone numerous changes leading to diversity in characters. It is concluded that ***Senecio*** is ancient in origin and its species are diversified.

P1383. Comparison of ribosomal DNA site patterns on somatic chromosomes in ten *Aster* species and two allied genera (Asteraceae)

G. Kokubugata[1,2], Y. Saito[2,1], M. Ogawa[3], K. Kondo[4], **T. Konishi**[1];
[1]National Science Museum, Tokyo, Ibaraki, Japan, [2]Ibaraki University, Ibaraki, Japan, [3]Tokushima Prefectural Museum, Tokushima, Japan, [4]Hiroshima University, Hiroshima, Japan.

Somatic chromosomes of ten *Aster* species and two putative-allied genera of *Erigeron* (*E. thunbergii*) and *Solidago* (*S. virgaurea*) in Japan were investigated by the aceto-orcein staining method and the fluorescent *in situ* hybridization (FISH) method using 45S ribosomal DNA (rDNA) probes. The ten *Aster* species, *E. thunbergii* and *S. virgaurea* commonly showed the chromosome number of $2n = 18$. In karyotype, *A. asa-grayi*, *A. miyagii* and *A. spathulifolius* classified to the section *Pseudocalimeris* showed similar karyotype to each other, while *A. komonoensis*, *A. rugulosus*, *A. savatieri* and *A. scaber* classified to the section *Teretiachenium* did not show consistent karyotype. In FISH, the ten *Aster* species and *S. virgaurea* exhibited an rDNA site at the secondary constriction of two chromosomes. *Erigeron thunbergii* exhibited an rDNA site at the secondary constriction and whole satellite of two chromosomes. The rDNA distribution patterns of the *Aster* ten species were more similar to that of *Solidago* than that of *Erigeron*.

P1384. A study of achene slime in several taxa of *Artemisia* (Asteraceae, Anthemideae)

A. Kreitschitz[1], J. Vallès[2];
[1]Institute of Plant Biology, University of Wroclaw, Wroclaw, Poland, [2]Laboratori de Botànica, Facultat de Farmàcia, Universitat de Barcelona, Barcelona, Spain.

Artemisia is one of the largest genera in the Asteraceae, with ca. 500 taxa, from perennial shrubs to annual herbs. It is basically distributed in the Holarctic region and often dominant in deserts, semi-deserts and steppes. It propagates mainly by achenes, characterized by the presence of slime, clearly visible after hydration. We examined the distribution of the slime cells on the achene surface, the slime structure and its formation in connection to plant life form and habitat. The *Artemisia* slime belongs to the cellulose type and consists of pectins and cellulose. Our results reveal the pattern of slime cell distribution, which differs between taxa. A large slime amount, rapidly formed on the achene surface, is typical of plants living in dry habitats and of annual species. The slime facilitates germination and fruit adhesion to the ground or to animals. Thus, it may play an important role in the distribution and expansion of *Artemisia* taxa, being an adaptive feature to dry habitats.

P1385. Genus *Artemisia* L. (Asteraceae) in Georgia

D. I. Mtskhvetadze;
Institute of Botany of the Georgian Academy of Sciences, Tbilisi, Georgia.

A genus *Artemisia* L. spread in Georgia is one of the critical and complex genera of the family *Asteraceae*, which is due to its systematic structure and geographic distribution.

In Georgia the genus *Artemisia* L. includes species, which participate in various vegetation formations and are connected with various belts. They are distributed up to 3000 m above sea level (from the lower mountain belt to the subalpine and alpine ones). Species of the genus occur on dry stony slopes, rocky and skeleton ecotopes, roadsides, croplands as weeds. Some species are edificators of the semi-desert vegetation.

12 species of the genus *Artemisia* L. spread in Georgia are arranged in 3 subgenera on the basis of the shape and structure of the vegetative and generative organs.

Subgenus I: *Artemisia* - 1. *A. vulgaris,* 2. *A. chamaemelifolia,* 3. *A. armeniaca,* 4. *A. annua,* 5. *A. caucasica,* 6. *A. splendens,* 7. *A. austriaca,* 8. *A. absinthium,* 9. *A. incana*

Subgenus II: *Dracunculoides* - 10. *A. marchalliana = A. campestris,* 11. *A. scoparia*

Subgenus III: *Seriphidium* - 12. *A. lerchiana = A. fragrans*

P1386. A study of the taxa *Scorzonera* L. and *Podospermum* D.C. (Asteraceae) in Italy using cytogenetical and molecular tools (sequencing of ribosomal ITS and ETS regions).

G. Tucci[1], **M. O. Winfield**[2], I. De Dominicis[3], P. Salimbeni[1], G. D'Amato[3];
[1]D.A.B.A.C. Università della Tuscia, 01100 Viterbo, Viterbo, Italy, [2]Scottish Crop Research Institute, Invergowrie, Dundee, Scotland, Dundee, United Kingdom, [3]Dip. Biologia Vegetale, Univ. "La Sapienza", 00185 Roma, Roma, Italy.

Morphological differences between the two taxa *Scorzonera* L. (of which there are thought to be 12 species in Italy) and *Podospermum* D.C. (3 species in Italy) are quite small - leaves in the latter are pinnate rather than lanceolate or spatolate, and the base of the achene is concave rather than straight. As a consequence, there has been some debate about their taxonomic status; should *Podospermum* be considered a distinct species or as a subgenera of *Scorzonera*? In addition, some of the relationships among species of *Scorzonera* are not entirely clear. The aim of this study was to analyse all 15 species found in Italy using both cytogenetic and molecular tools (ribosomal ITS and ETS sequences) in order to help clarify these relationships. Results are consistent with an interpretation that places both taxa into one genus. All species, except *S. hirsuta* and *S. villosa* having only 12 chromosomes, were 2n = 14. *S. hirsuta* and *S. villosa* were also the most distinct molecularly, and formed a well supported distinct group. The 3 species of Podospermum clustered with the other species of Scorzonera, being most closely related to *S. aristata* and *S. humilis*.

P1387. Tetraploid and octoploid cytotypes in *Senecio jacobaea* (*Asteraceae*) in the Pannonian Basin and Carpathians

I. Hodálová[1], V. Grulich[2];
[1]Institute of Botany, Slovak Academy of Sciences, Bratislava, Slovakia, [2]Department of Botany, Masaryk University, Brno, Czech Republic.

Populations of *Senecio jacobaea* L. subsp. *jacobaea* in the Panonian Basin and in the Carpathians were studied using karyological and morphological approach. Two different ploidy levels were revealed by flow cytometric analyses in the area studied: tetraploids and octoploids. Tetraploids (distributed commonly throughout Europe) have been found as widespread both in Pannonia and in the Carpathians. Octoploids have been found only in Pannonia and in adjacent mountains of the West Carpathians. In the sympatrical zone of both cytotypes (Pannonia and adjacent parts of the West Carpathians) mixed populations with both tetraploid and octoploid individuals have been identified. Results of the morphometric analyses showed that the ranges of the morphological characters (number of tubular florets, length of tubular florets, length of involucral bracts, number of involucral bracts, length of ray florets, indumentum of outer achenes) of both cytotypes broadly overlap. It was not possible to distinguish the cytotypes reliably by any quantitative character or by their combination.

P1388. Genetic diversity and differentiation in the diploid populations of Dendranthema zawadskii and its related species (Asteraceae)

J. S. Kim, H. Azuma, H. Tobe;
Department of Botany, Graduate School of Science, Kyoto University, Kyoto, Japan.

Although *Dendranthema zawadskii* and its related species have relatively clear taxonomic criteria, their phylogenetic relationships have not been understood well because of the lack of diploid individuals for molecular investigation. However, we could collect diploid individuals of two species (*D. zawadskii* and *D. indicum*) from Korea, and conduct molecular phylogenetic and allozyme analyses to see relationships among the diploid populations of *D. zawadskii*, *D. indicum* and *D. boreale* that are distributed in East Asia. The cpDNA trees showed that populations of the same species did not form a single clade in any species; in other words, any clade was composed of populations of different species. We found even that populations of different species had the same haplotype. Also, the dendrogram obtained by allozyme data generated three major clusters, each of which was composed of populations of different species. Therefore, morphological species concept was not supported. Molecular evidence rather suggests that hybridization have frequently occurred among the populations of the different species of *Dendranthema*.

P1389. The system of the genus *Senecio* L. and *Tephroseris* (Reichenb.) Reichenb. of the flora of Georgia

K. Gagua;
Institute of Botany, Tbilisi, Georgia.

Species of *Senecio* L., a genus characteristic to the flora of Georgia, are presented by considerable components of mountain and high-mountain florocenotypes. The genus *Senecio* L. has been studied in complex. On the basis of macro-morphological and micro-morphological (pollen morphology and seed coat anatomy) characteristics, circumscriptions of the genus are established for Georgia's flora. Genus *Senecio* sensu stricto is limited. *Tephroseris* (Reichenb.) Reichenb. is considered as independent genus. Genera *Pojarkovia*, *Iranecio*, *Caucasalia*. are considered as synonyms for the genus *Senecio*. In the genus circumscription new sections and subsections [Gen. *Senecio* - Sect. *Ologanthi*: Subsect. *Albidiflori* (Gagnidze) Gagnidze et Gagua, Subsect. *Platiphylli* (Gagnidze) Ganidze et Gagua; Sect. *Mediterranei* Gagnidze et Gaguas, Sect. *Scitophylli* (Gagnidze) Gagnidze et Gagua; Gen. *Tephroseris* - Sect. *Cladobotrytes* (Gagnidze) Gagnidze et Gagua; Sect. *Primulifolii* Gagnidze et Gagua] are described, a new nomenclature combination is provided.

P1390. The evolution of B-class genes in diploid and allotetraploid *Tragopogon*

J. Koh[1], M. Yoo[1], P. S. Soltis[2,3], D. E. Soltis[1,3];
[1]Department of Botany, Gainesville, FL, United States, [2]Florida Museum of Natural History, Gainesville, FL, United States, [3]The Genetics Institute, Gainesville, FL, United States.

Tragopogon mirus Ownbey and *T. miscellus* Ownbey are recent allotetraploids (2n = 4x = 24) that formed repeatedly during the past 80 years following the introduction of three diploids (*T. dubius* Scop., *T. pratensis* L., and *T. porrifolius* L.) from Europe into eastern Washington and Idaho, USA. Despite the frequency of polyploidy in plants, little is known about the expression and fate of genes duplicated by polyploidization. We examined homologs of the B-class floral regulators *APETALA3* (*AP3*) and *PISTILLATA* (*PI*) in these tetraploids and their diploid parents. Comparative expression studies examined the contribution of the *PI* homologues of the parental species to the two allopolyploids. *T. miscellus* has two different copies of *PI* homologues. The nucleotide sequences from *T. dubius*, *T. mirus*, and *T. porrifolius* were identical, except for differences in the 3'-untranslated region.

P1391. Taxonomic study of Filago L. (Asteraceae: *Gnaphalieae*) in Iran

N. Akhundzadeh, F. Ghahremaninejad;
Teacher Training University of Tehran (University of tarbiat-Moaallem), Tehran, Islamic Republic of Iran.

Filago is classified in the tribe *Gnaphalieae* (Asteraceae). The tribe *Gnaphalieae* is one of the largest in the family, with more than 180 genera and 2000 species. Filago contains 35 species in north temperate areas, 12 in Iranica area, and 9 species in Iran. *Filago* is divided to three subgenera: Subgen. *Filago,* Subgen *Oglifa*, and Subgen. *Evax.* All the subgenera have some species in Iran. Only subgenus *Evax* has sterile hermaphrodite flowers in the middle part of the capitules; the number of the bracts in subgenus *Filago* is more than the subgeneus *Oglifa*.

In this study all the Iranian species taxonomically were deeply studied. For them morphological characteristics were determined. Identification key is prepared for the Iranian species based on many studied specimens from TARI, FAR, IRAN, TUH, and B herbaria.

Between many collected Iranian plants, one specimen is new to science. The specimen is collected from West Iran (Azarbayjan and Kordestan Provinces). It is closely related to *F. arvensis.*

P1392. Towards an understanding of the trigger plant flora (*Stylidium*) of South West Australia

J. A. Wege;
Western Australian Herbarium, Perth, Australia.

With over 250 taxa, the trigger plant genus *Stylidium* (Stylidiaceae) is amongst the most abundant and diversified genera in Australia; however, this group has received significantly less attention than the iconic Australian genera *Eucalyptus*, *Acacia* and *Grevillea*. Whilst several accounts of *Stylidium* were published in the 19th and early 20th centuries by botanists in Europe, no formal revision of the genus has been undertaken by a botanist based in Australia. Substantial progress has recently been made toward such a treatment for the *Flora of Australia*. This research has focused on taxa from South West Australia: a region internationally recognised for its biodiversity, and a major centre of *Stylidium* diversification. Twenty-five new species have been identified, many of which are geographically restricted and of conservation concern. Field studies have been pivotal to this research since many taxonomically informative characters are difficult, if not impossible, to discern on herbarium specimens. The location and interpretation of historical type material and the correct application of early botanical names remains a major research challenge.

P1393. Morphological variation of *Lactuca serriola* populations from some European countries

I. Dole alová, A. Lebeda, E. KŚstková, A. Novotná;
Palacký University, Faculty of Science, Department of Botany,
lechtitelŢ 11, 783 71 Olomouc, Czech Republic.

Because of a great importance of *L. serriola* in commercial lettuce breeding, the best attention has been paid to effective germplasm management of this species in last decades. Fifty *L. serriola* populations collected in four European countries were cultivated in a greenhouse under controlled conditions and morphologically characterised following the descriptor list of wild *Lactuca* spp. germplasm. As for leaf morphology only *L. serriola* f. *serriola* was recorded in the Czech Republic (100% of plants), 91% of plants originated from Germany were determined as form *serriola* as well. Populations collected in the Netherlands consisted of plants determined as form *integrifolia* in 54.4% of individuals while in populations collected in the United Kingdom it was 98% of plants. Results concerning the other morphological and developmental characteristics obtained during the study are discussed. Funded by projects: EU GENE-MINE (Contract No.QLK5-2000-00722) and MSM 6198959215.

P1394. Betula, Corylus and Alnus airborne pollen in Zagreb, Croatia

R. Peternel[1], **B. Mitiĺ** [2], J. Ļulig[1], I. Hrga[1], P. Hercog[1];
[1]Zagreb Institute of Public Health, Zagreb, Croatia, [2]Faculty of Natural Sciences, Zagreb, Croatia.

The aim of this study was to build up a picture of the influence of meteorological conditions on the start and duration of Betulaceae pollen season and pollen concentrations during three years (2002-2004) in the atmosphere of Zagreb, Croatia. A 7-day VPPS 2000 Hirst volumetric spore trap was used for pollen sampling. The highest annual pollen concentration of all three genera (Alnus, Corylus and Betula) was recorded in 2002 (3,883 pg/m^3, 11,106 pg/m^3 and 14,448 pg/m^3), followed by a decline in 2003, and rise again in 2004. The highly favorable weather conditions in 2002 during the period preceding the pollination of alder, hazel and birch (January) resulted in earlier flowering time of these plants and thus earlier occurrence of their pollen in the air. In all three years, pollination peaks were recorded on the days characterized by temperature above 0 ºC and no or minimal precipitation.

The results of the present study provide useful data for allergologists to reach accurate diagnoses, and timely information on airborne pollen types and concentrations for individuals with pollen hypersensitivity.

P1395. Factors influencing sexual expression in the fern *Woodwardia radicans*

L. de Soto, L. G. Quintanilla, M. Méndez;
Universidad Rey Juan Carlos, Móstoles - Madrid, Spain.

The gametophytes of homosporous ferns are potentially bisexual. However, depending on growing conditions, gametophytes can develop into male, female or dichogamous. In some species, like *Woodwardia radicans*, asexual gametophytes become male in the presence of female and bisexual ones because of the effect of pheromones (i.e. antheridiogens).

Sexual expression is size-dependent in flowering plants and also likely in homosporous ferns, although studies are scarce. In *W. radicans*, male gametophytes are smaller than female and bisexual gametophytes, but the factors affecting size and sexual expression are poorly known. We experimentally manipulated density of individuals, and light and nutrient availability in order to study the resulting sexual expression. Our aim was to find out (1) whether poor growing conditions, independently of antheridiogen, induce maleness, (2) whether a threshold size exists for the change from male to female sexual expression and (3) whether that threshold size is flexible or fixed.

P1396. On the taxonomy of Brachytheciaceae (Musci) in China

Y. F. Wang, D. C. Zhai;
School of Life Science, East China Normal University, Shanghai, China.

The present paper studies the taxonomy of Chinese moss family Brachytheciaceae. The studies are based on field studies, type specimens and collections in Chinese and other herbaria. The research results shows there are eithty species of the Brachytheciaceae, belonging to the eleven genera in China. These genera and species number for each genus are as follows: *Camptothecium* (2 species); *Tomenthypnum* (1 species); *Homalothecium* (2 species); *Palamocladium* (2 species); *Brachythecium* (43 species); *Bryhnia* (5 species); *Cirriphyllum* (2 species); *Myuroclada* (1 species); *Eurhynchium* (11 species); *Rhynchostegium* (9 species) and *Rhynchostegiella* (2 species). Keys to genera in the family and species for each genus based on some important gametophyte and sporophyte characters are also provided together with illustrations and geographical distribution for all Chinese species.

P1397. Morphological- Reproductive Biodiversity Micromarkers in the Canarian Endemic Genus *Parolinia* Webb (Brassicaceae).

O. Fernández-Palacios, J. Pérez de Paz, R. Febles;
Jardín Botánico Canario, Las Palmas de Gran Canaria, Spain.

The reproductive systems of plant species are considered to be a determinating cause of biodiversity at natural population level, where the reproductive characteristics control the reproductive success of crosses, gene flow and biodiversity configuration, both genetic and morphological.

Floral organization has been the principal basis of taxonomy and systematics to the extent that systematics and reproductive biology have been closely allied throughout botanical history because of the implications for both of reproductive characters through time and space. Their integration principally at infrageneric levels is indispensable and has high potential value. The objective of this study is to estimate and understand biodiversity through the detection of morphological-reproductive micromarkers , their intra- and inter-populational structure and correlation of genetic, morphological and geographic distances in *Parolinia*, a diploid, exclusively woody Canarian endemic genus (Matthioleae-Brassicaceae) made up of seven similar narrowly distributed species with a similar ecological habitat.

P1398. Natural selection on flower shape and the evolution of zygomorphy in *Erysimum mediohispanicum* (Brassicaceae)

J. M. Gomez[1], F. Perfectti[2], J. P. Martinez Camacho[2];
[1]Dpto de Biología Animal y Ecología, Universidad de Granada, Granada, Spain, [2]Dpto de Genética, Universidad de Granada, Granada, Spain.

Paleontological and phylogenetic studies have shown that floral bilateral symmetry (zygomorphy) has evolved independently in several plant groups from ancestors showing radial symmetry (actinomorphy). This evolutionary change is thought to be a consequence of strong selection exerted by specialized pollinators through increasing pollinator preference and improving pollen transfer efficiency. Most approaches have hitherto focused on unraveling the developmental genetics of flower symmetry, but little is known on the adaptive significance of intraspecific flower symmetry variation in natural conditions. Here we provide the first evidence for natural selection favoring zygomorphy in a wild population of *Erysimum mediohispanicum* (Brassicaceae), a plant showing extensive continuous variation in flower symmetry ranging from actinomorphic to zygomorphic flowers. By using geometric morphometric tools to describe flower shape, we demonstrate that plants bearing bilaterally symmetric flowers were more visited by pollinators and had the highest fitness, measured by the number of seeds surviving to juvenile stages.

P1399. Phylogeny of Burmanniaceae: Preliminary results based on 18S rDNA sequences

V. Merckx[1], P. Schols[1], P. Maas[2], H. Maas-van de Kamer[2], E. Smets[1];
[1]Laboratory of Plant Systematics, B-3001 Leuven, Belgium, [2]Nationaal Herbarium Nederland, Utrecht University Branch, 3584 CS Utrecht, The Netherlands.

Burmanniaceae are a family of about 130 predominantly myco-heterotrophic annual and perennial herbs. They occur in the tropical and subtropical regions of the Old and the New world. Due to the scarcity of material and the strong vegetative reductions of the mycoheterotrophic species, little is known about their relationships and phylogenetic history. We present the first molecular analysis of the Burmanniaceae based on 18S rDNA sequences. Our sampling includes 40 Burmanniaceae taxa covering six of the family's 13 genera. Analyses using maximum parsimony and Bayesian inference show that Burmanniaceae are polyphyletic: The tribe Thismieae is part of Dioscoreaceae sensu lato while all other Burmanniaceae (tribe Burmannieae) are sister to Dioscoreaceae sensu lato. Within Burmannieae the genera *Burmannia* and *Gymnosiphon* are paraphyletic. The achlorophyllous *Burmannia* species are found throughout the tree, suggesting that the loss of chlorophyll independently evolved more than once within this genus.

P1400. How many species are there? Species delimitation analyses in the genus *Discocactus* (Cactaceae)

M. C. Machado[1], D. C. Zappi[2], E. L. Borba[1];
[1]Universidade Estadual de Feira de Santana, Feira de Santana, Brazil, [2]Royal Botanic Gardens Kew, Richmond, United Kingdom.

The taxonomy of the genus *Discocactus* has been controversial, with a five-fold difference in the number of taxa recognized by competing classifications. In order to make taxonomic decisions on the specific and infraspecific rank of taxa occuring in the state of Bahia, Brazil, the variation of 22 quantitative morphological characters was analysed for 337 individuals from 17 populations, covering most of the taxa described for the state. We employed the character-based species delimitation method of Davis & Nixon (PAA - Population Aggregation Analysis) and the tree-based species delimitation method of Wiens & Penkrot. The results were compared with those obtained from multivariate and statistical analysis. The methods employed disagree on the number of distinct taxa to be recognized; however, the disagreement is restricted to the level of inclusiveness achieved. We took a conservative view and recognized only the taxa resolved by all methods: *D. bahiensis*, *D. catingicola* and *D. zehntneri*, the latter with two subspecies, *zehntneri* and *boomianus*.

P1401. Taxonomy and diversity of the African non-leucobryoid Calymperaceae species

S. Orbán;
Bryological Research Group, Eger, Hungary.

In the course of taxonomical revision were established that 49 species occur in Africa and in the neighbouring Madagascar and in the Indian Ocean Islands.The number of species and names which earlier reached more than 180 were reduced with 70 %. The non-leucobryoid Calymperaceae species belong to four Genera in Africa: Syrrhopodon, Chameleion, Mitthyridium and Calymperes. The richest Genera is the Syrrhopodon comprising 28 species which divided into 39 taxons and have 4 Subgenera and 8 Sections. The Genera Chameleion has only one African species - Ch. cryptocarpos, and the Mitthyridium genus have five species. The Genera Calymperes represented in Africa with 15 species which belongig to three subgenera. Examining the world distribution of the 49 African species there is established that 42,8 percent of the species are endemic, 24,5 % are paleotropical, 14,3% are pantropical and 14,3 % of the species are African-American disjunct. The list of taxons, the accepted and synonym names of the species and the African distribution are published here.

P1402. Taxonomic revision of Silene sect. Atocion based on molecular and morphological data

E. Långström, B. Oxelman;
Department of Systematic Botany, Evolutionary Biology Centre, Uppsala, Sweden.

The Caryophyllaceae genus Silene with ca 800 species is hard to diagnose and internal relationships among the species are obscure. Many of the 44 sections recognized by Chowdhuri (1957) in the most recent revision of Silene are evidently non-monphyletic. One example is Silene sect. Atocion Otth, characterized by Chowdhuri primarily on seed morphology, habit and inflorescence type. The subsections Sedoidae and Rubellae have been demonstrated to belong to different parts of the genus, leaving only eight Mediterranean species in sect. Atocion. These species have unclear relations to the rest of Silene and within the group. This project is a taxonomic revision based on morphological data, DNA sequences from the nuclear RPB2 and ITS regions, as well as the chloroplast rps16 region. These data reveal new species delimitations and relationships among the taxa. The pattern of phylogenetic relationships of the taxa and their relationships to the rest of Silene are complex and more data are needed to fully understand the phylogenetic history. A possible explanation to the observed complexity is ancient homoploid hybridization among distantly related diploid lineages.

P1403. The Origin of the Hawaiian endemic Silene species

F. Eggens[1], M. Popp[2,1], M. Nepokroeff[3], W. L. Wagner[4,5], B. Oxelman[1];
[1]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden, [2]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway, [3]Department of Biology, University of South Dakota, Vermillion, SD, United States, [4]National Tropical Botanical Garden, Kalaheo, HI, United States, [5]Department of Botany, Smithsonian Institution, Washington, DC, United States.

Geographically, one could expect an Asian origin for species endemic to the Hawaiian Islands. Despite this, a number of Hawaiian taxa have been shown to have their closest relatives on the American continents. The endemic Hawaiian *Silene* species were placed in a section with two Japanese *Silene* in the latest global revision of the genus. They have been thought to be the result of two colonizations, one for the shrubby species and one for the remaining herbaceous ones. Our results, based on DNA sequences from the plastid genome, ITS, and the nuclear low copy number gene RPB2 strongly indicate a close relationship between the endemic Hawaiian *Silene* and the American species *S. antirrhina*. This taxon is sister to a monophyletic group consisting of the Hawaiian *Silene*, indicating a single colonization event. *S. antirrhina* is a diploid species that is not related to other native American *Silene*, of which the majority are polyploid and belong to at least three other clades. There is no obvious morphological support for the relationship between the Hawaiian *Silene* and *S. antirrhina*.

P1404. Taxonomy of the *Silene ajanensis* lineage and its participation in the formation of Arctic polyploid *Silene*

A. Petri, B. Oxelman;
Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden.

The diploid *Silene ajanensis* lineage has been involved in the formation of both tetraploid and hexaploid Arctic *Silene*. The *S. ajanensis* group comprises about six taxa, distributed in northeast Asia. Traditionally, most of the taxa have been classified in *Lychnis*, based on the presence of five carpels. This condition, however, has evolved several times in *Silene*. We investigate the *S. ajanensis* group in detail, both from a taxonomic standpoint and from multiple gene phylogenies, in order to more fully understand the relationships within this group and its relation to the polyploid taxa. The results will facilitate a more precise hypothesis about timing and geographical location of the allopolyploidization events. Single gene phylogenies from the low copy nuclear RNA polymerase family (RPA2, RPB2, RPD2a, RPD2b) are helpful in resolving this, but also indicate gene duplications independent of allopolyploidization in the *S. ajanensis* lineage. This emphasizes the need to study multiple independent gene phylogenies to discriminate between whole-genome and single gene duplications.

P1405. Reticulate evolution of Heliosperma as inferred by nuclear RNA Polymerase Gene Family and chloroplast DNA sequences

B. Frajman[1,2], P. Erixon[1], B. Oxelman[1];
[1]Department of Systematic Botany, Evolutionary Biology Centre, Uppsala University, Uppsala, Sweden, [2]Biology Department, Biotechnical Faculty, University of Ljubljana, Ljubljana, Slovenia.

Heliosperma Rchb. (= *Ixoca* Rafin., *Silene* L. *s.l. p.p*), tribe *Sileneae* (Caryophyllaceae), includes about 15 to 20 taxa, most of them being endemic to relatively small areas of the Balkan peninsula. In order to infer the phylogenetic position of *Heliosperma* within *Sileneae* and to examine the relationships within the genus, sequences of a 7kb plastid DNA region as well as homologous nuclear intron regions from the second largest subunit of the RNA polymerase gene family (*RPA2, RPB2, RPD2a* and *RPD2b*) were used. The phylogenies support a sister position of *Heliosperma* to *Viscaria* and *Atocion*, all forming a monophyletic group with *Petrocoptis* and *Eudianthe*. Incongruence between the plastid and nuclear data indicate an ancient chloroplast capture or lineage sorting of chloroplast genome within *Heliosperma*. Moreover, a homoploid hybrid origin of *H. alpestre* / *H. macranthum* lineage with the *Petrocoptis* as a paternal lineage is indicated.

P1406. A phylogenetic study of Silene (Caryophyllaceae) endemic to the Canary Islands

M. E. A. Lundberg[1], A. Santos-Guerra[2], J. Francisco-Ortega[3], B. Oxelman[1];
[1]Evolutionary Biology Centre, Uppsala, Sweden, [2]Jardin Botánico, Puerto de la Cruz, Canary Islands, [3]Department of Biological Sciences, Florida International University, FL, United States.

There are seven taxa of Silene (Caryophyllaceae) endemic to the Canary Islands. All of them are red listed and endangered. Taxonomically, they have been considered to belong to the section Siphonomorpha or more precisely in the S. italica group. We have inferred the phylogenetic relationships among the endemic taxa, their taxonomic position within the genus, as well as their probable geographic origin. For this, we analyzed three different DNA sequence regions, the rps16 intron from the chloroplast genome and the nuclear RPA2 and RPB2, both belonging to the low copy number RNA polymerase gene family. The results of the phylogenetic analysis suggest a single origin of the endemic Silene found on the Canary Islands. The nuclear data support a sister-group relation to S. nutans, whereas the plastid sequences support a sistergroup relationship with a larger group of section Siphonomorpha taxa, including S. nutans. A possible explanation to this pattern is introgression from the S. nutans lineage to the ancestor of the Canarian taxa.

P1407. The morphological characterization of the group Dianthus brachyanthus

A. L. Crespí[1], S. Bernardos[2], F. Amich[2], C. P. Fernandes[1], A. S. Castro[1];
[1]Herbarium, Botanical Garden, CETAV, Vila Real, Portugal,
[2]Department of Botany, University of Salamanca, Salamanca, Spain.

Four species of the group *Dianthus brachyanthus* (*D.brachyanthus* subsp. *brachyanthus*, *D.brachyanthus* subsp. *hispanicus*, *D.langeanus* and *D.gredensis*) are morphologically analysed. Thirty characters were selected for 210 specimens with occurrence in the Iberian Peninsula at whole.The morphological characterization through the groups of correlation, deduced from the first three factors obtained in the PCA, is depicted as a very useful tool to describe the phenotypical tendencies. The results obtained for the morphological expression of the individuals are correlated with the distribution of the taxa. Two morphological tendencies are detected, one of them for the occidental taxa and the other for the oriental one. The characters related with the morhphological variation of the flowers are the most discriminant for the four taxa. Based on the results here exposed, new taxonomical combinations are proposed for these species.

P1408. Biogeography of the afroalpine genus Uebelinia Hochst. (Caryophyllaceae) inferred from chloroplast and low-copy nuclear DNA sequences

M. Popp[1], A. Gizaw[1,2], S. Nemomissa[2], C. Brochmann[1];
[1]National Centre for Biosystematics, Natural History Museum, University of Oslo, Oslo, Norway, [2]Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia.

The present-day afroalpine plants, which occur in the scattered high mountains of East Africa and Ethiopia, have their closest relatives in other remote mountains, even in Europe and Asia. Recent molecular studies have shown that the primarily afroalpine/afromontane genus *Uebelinia* Hochst. (Caryophyllaceae) is nested within *Lychnis* L., thus representing a southwards extension of a primarily northern plant group. The most recent revisions of *Uebelinia* recognize eight taxa at the species or subspecies level. The group has a discontinuous distribution with the highest number of taxa in Ethiopia, and it also occurs in the mountains of Kenya, Tanzania, Uganda, Rwanda, Burundi, Zaire, Cameroon, and Nigeria. Several taxa have very narrow distributions within single mountain systems. Here we use non-coding chloroplast DNA sequences and intron sequences from a low-copy nuclear RNA polymerase gene family, possibly also AFLP markers, to study the biogeographic history of *Uebelinia*. We also test the monophyly of *Uebelinia* and infer the phylogenetic relationships within the group.

P1409. The family Commelinaceae in Southern Peninsular India

S. Nampy;
St. Joseph's College, Kozhikode, Kerala, India.

Commelinaceae with about 41 genera and 640 species world over is distributed mostly in the tropical and warm temperate regions. Peninsular India and the foothills of the Himalayas to Thailand and southwestern China are considered as one of the major center of diversity for Commelinaceae. In southern peninsular India the family is represented by 13 genera and 63 species. Among them 17 species are endemic and many are facing serious threat of extinction. The major genera in southern peninsular India are Murdannia (21species), Commelina (17species) and Cyanotis (11species). Belosynapsis, Amischophacelus, Dictyospermum, are represented by 2 species each, while Amischtolype, Callisia, Floscopa, Pollia, Rhoeo, Rhophalephora, Setcresea, Zebrina, are with one species each. Belosynapsis vivipara, B. kewensis, Commelina indehiscence, C. hirsuta, C. tricolor, C. wightii, Dictyospermum ovalifolium and Murdannia fadeniana and M. lanceolata are extremely rare. The family is studied extensively during the past three years. The present paper discusses the diversity, distribution, taxonomy, and endemism of southern peninsular Indian Commelinaceae.

P1410. A Combined Molecular Phylogenetic Analysis of Commelinaceae; Evidence from rbcL, ndhF, and 26S Nuclear Ribosomal Sequences

T. M. Evans[1], C. R. Hardy[2], R. B. Faden[3], **R. F. Bode**[1];
[1]Hope College, Holland, MI, United States, [2]Millersville University, Millersville, PA, United States, [3]Smithsonian Institution, Washington, DC, United States.

Significant progress has been made in recent years toward a comprehensive understanding of phylogenetic relationships within Commelinaceae. Recent developmental and molecular phylogenetic studies have shed light upon the evolution of the family at the generic level or within specific subgroups within the family. These studies, however, have generally included either broad sampling, with low taxon density, or a more intensive focus on a small group of species. In this study, a combined phylogenetic analysis of three molecular data sets (*rbc*L, *ndh*F, and 26S nuclear ribosomal sequences) is presented. Several new genera have been added, including *Pseudoparis*, *Streptolirion*, *Porandra*, *Tricarpelema*, and *Dictyospermum*. Major conclusions of the analysis include: 1) *Cartonema* is sister to the rest of the family, as supported by previous studies; 2) *Palisota* is sister to a clade containing the remainder of tribe Tradescantieae and tribe Commelineae; 3) subtribes Coleotrypinae, Cyanotinae, Streptoliriinae, and possibly Dichorisandrinae are monophyletic; and 4) subtribe Thyrsantheminae is paraphyletic.

P1411. Phylogeny and plastid genome evolution in the parasitic genus Cuscuta (Convolvulaceae)

S. Stefanovic[1], R. G. Olmstead[2];
[1]University of Toronto at Mississauga, Mississauga, ON, Canada,
[2]University of Washington, Seattle, WA, United States.

Previous findings on plastid (pt) genome structural rearrangements in Cuscuta were attributed to its parasitic life style, but without rigorous phylogenetic framework. Long PCR approach was used to sequence nearly entire pt genome from poorly investigated subgenus Grammica in order to determine its size, structure, gene content, and synteny. This pt genome is compared to that of tobacco and corresponding regions from taxa in the other Cuscuta subgenera. When all known pt genome rearrangements in Convolvulaceae are considered in a molecular phylogenetic framework three categories of rearrangements in Cuscuta are revealed: plesiomorphic, autapomorphic, and synapomorphic. Many of the changes in Cuscuta, previously attributed to its parasitic mode of life are better explained either as plesiomorphic conditions within the family, i.e., conditions shared with the rest of the Convolvulaceae, or in most cases, autapomorphies of particular Cuscuta taxa, not shared with the rest of the species in the genus. The synapomorphic rearrangements are most likely to correlate with the parasitic lifestyle, because they represent changes found in Cuscuta exclusively.

P1412. Visual key for taxa identification on genus cupressus

R. Danti, **G. Della Rocca**, P. Raddi;
Istituto per la Protezione delle Piante IPP-CNR, Sesto Fiorentino (Florence), Italy.

Genus *Cupressus* includes species spread in the temperate-warm zones of the northern hemisphere (Mediterranean basin, N-W and central America, Himalayan region and China).

Systematic position of the various taxa within the genus *Cupressus* is not univocal and is frequently reassessed either at species level or subspecies. In the last seventy years a number of taxonomic revisions of the genus have been reported by some Authors. The developed identification keys are all based on morphological characters. Nevertheless morphological characters are greatly affected by a series of anthropogenic factors including, frequently, cuttings and livestock grazing. So, descriptions developed so far are not robust for all the species and, consequently, not always useful too.Identification of the Cypress species in a few instances is difficult and particularly unclear is the systematic position of the Asian species because their native areas are not clearly defined yet. The objective of the present work is to draw up an explanatory visual key for *Cupressus* species based on colour pictures made either in their native areas or on trees of proved origin maintained ex-situ.

P1413. The amino acid composition of seeds in systematics of Cycadales

S. Y. Zolkin;
Main Botanical Garden RAS, Moscow, Russian Federation.

The amino acid composition of seeds of 21 species from 7 genera, belonging to 3 families of Cycadales order, - Cycadaceae, Zamiaceae and Stangeriaceae were investigated. It has been shown that all representatives of this order have a similar amino acid composition. Some genera, such as Dioon and Zamia are very alike in their amino acid composition. Stangeria eriopus from monotypic family Stangeriaceae does not differ significantly in any of the amino acids from all the other representatives of cycads. All the investigared species of Macrozamia have a similar amino acid composition. Lepidozamia differs from Encephalartos and Macrozamia in lower content of phenyl alanine and leucine and in higher content of arginine and alanine. The difference in the content of some of the amino acids, mainly proline and arginine is marked for species of Cycas and Encephalartos. It should be noted that the amino acid composition as a systematic feature can be probably used at the generic level, especially while distinguishing homogeneous genera from heterogeneous one as well as when considering taxonomic problems at the level of tribes, subfamilies and close families.

P1414. Study on the natural classification of the wild species of Chinese woody peony

T. Hong[1], T. Chen[2], M. Liu[3];
[1]Chinese Academy of Forestry, Beijing, China, [2]Fairy Lake Botanical Garden,, Shenzheng, China, [3]Zhejiang Agricultural University, Hangzhou, China.

In 1804 England scientist Henry C. Andrews named and published the first tree peony species “Paeonia suffruticosa Andrews”. Andrews’ original description of Paeonia suffruticosa was based upon a cultivated plant. The plant with very double magenta flowers was planted in England from China.

Hereafter, England Peony expert S. G. Haw and China specialist Hong Deyuan ignored the “type tree” of Andrews’ Paeonia suffruticosa was a cultivar of tree peony. They mistook it as a “species” or so-called “Paeonia suffruticosa Complex”. Thereby, they treated some wild woody peony (very good species!) as the infraspecific taxa of Paeonia suffruticosa Andrews.
