HIGHLIGHTS

- Dioxin-like PCBs accounted for over 83% of the total TEQ for all cetaceans
- Negative correlations were found between length and TEQ values in franciscanas.
- PCB concentrations found are among the highest ever reported for cetaceans.

ABSTRACT

Blubber samples from three delphinid species (false killer whale, Guiana and rough-toothed dolphin), as well as liver samples from franciscana dolphins were analyzed for dioxins and related compounds (DRCs). Samples were collected from 35 cetaceans stranded or incidentally captured in a highly industrialized and urbanized area (Southeast and Southern Brazilian regions). Dioxin-like PCBs accounted for over 83% of the total TEQ for all cetaceans. Non-ortho coplanar PCBs, for franciscanas (82%), and mono-ortho PCBs (up to 80%), for delphinids, constituted the groups of highest contribution to total TEQ. Regarding franciscana dolphins, significant negative correlations were found between total length (TL) and three variables, Σ TEQ-DRCs, Σ TEQ-PCDF and Σ TEQ non-ortho PCB. An increasing efficiency of the detoxifying activity with the growth of the animal may be a plausible explanation for these findings. This hypothesis is reinforced by the significant negative correlation found between TL and PCB126/PCB169 concentration ratio. DRC concentrations (ng/g lipids) varied from 36 to 3006, for franciscana dolphins, as well as from 356 to 30,776, for delphinids. The sum of dioxin-like and indicator PCBs varied from 34,662 to 279,407 ng/g lipids, for Guiana dolphins from Rio de Janeiro state, which are among the highest PCB concentrations ever reported for cetaceans. The high concentrations found in our study raise concern not only on the conservation of Brazilian coastal cetaceans, but also on the possibility of human health problem due to consumption of fish from Brazilian estuaries.

1. Introduction

Special concern has been raised since the 1960s about the environmental persistence, bioaccumulative capacity and toxicity of dioxins and related compounds (DRCs), such as polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), as well as non-ortho and mono-ortho polychlorinated biphenyls (dioxin-like PCBs) (Bopp et al., 1991; Cleemann et al., 2000). DRCs constitute a group of polyhalogenated aromatic hydrocarbons that have similarities from the structural, chemical and toxicological point of view (McDonald et al., 1994). These persistent and bioaccumulative contaminants are carcinogenic (Chaloupka et al., 1993; Cleemann et al., 2000), immunosuppressive (Harper et al., 1993), and induce a number of pathological effects related to their endocrine disrupting action in mammals, including reproductive impairment (Schecter et al., 2006). Despite their toxicity, studies on environmental levels of DRCs in Brazil are scarce (de Assunção et al., 2005).

Dioxins are unintentionally-produced contaminants, generated by different processes, including paper bleaching, synthesis of pesticides, herbicides, fungicides and PCBs, as well as burning of wastes and vegetation (Alcock et al., 1999; Cleemann et al., 2000; McDonald et al., 1994; Schecter et al., 2006). Taking the latter activity into consideration, it is interesting to mention that intentional burning of sugar cane crops and forest fires are common in Brazil (Lara et al., 2005; Santilli et al., 2005).

Polychlorinated biphenyls (PCBs) were used in a number of industrial activities, but mainly as dielectric fluids in capacitors and transformers (Alcock et al., 1999). Manufacture, use and commercialization of PCBs have been prohibited in Brazil since the beginning of the 1980s (Azevedo e Silva et al., 2007; Penteadó and Vaz, 2001). However, the same restrictive law allows the functioning of already installed apparatuses up to their complete replacement or substitution of their dielectric fluid (Azevedo e Silva et al., 2007; Penteadó and Vaz, 2001). Industrial and urban developments, at present, spread along the entire Brazilian coast; however, they are particularly concentrated along the Southeastern and Southern Brazilian regions (Saboia, 2000). Therefore, evaluating environmental contamination by DRCs in these two regions constitutes a matter of interest.

Using samples from cetaceans, the present study constitutes the first scientific investigation on DRC levels in marine biota from Brazil. Due to their high level in the food chain, their long life-span, and, for some species, their year-round presence in polluted and relatively small areas, cetaceans are important indicators of environmental contamination (Bjørge, 2001; O'Shea and Tanabe, 2003). In addition to providing information on the pattern and magnitude of DRCs that are reaching the top positions of the marine food webs in Brazil, analyses of cetacean tissues provide valuable data for conservation purposes. The high marine mammal exposure to DRCs in different regions of the globe raises concern about the conservation of the species, as adverse effects on reproductive and immune systems have been demonstrated for these animals (Dietz et al., 1989; Reijnders, 1986). The Brazilian economic growth and the subsequent use and degradation of the coastal zone are a concern for the conservation of small coastal cetaceans. In the present study, samples from four cetacean species (franciscana dolphin, *Pontoporia blainvillei*; Guiana dolphin, *Sotalia guianensis*; rough-toothed dolphin, *Steno bredanensis*; and false killer whale, *Pseudorca crassidens*) were analyzed for DRCs.

Franciscana and Guiana dolphins are small cetaceans that can reach up to 1.5 and 2.0 m, respectively. They occur exclusively in western Atlantic coastal waters of South (franciscana and Guiana dolphins) and Central (Guiana dolphins) America (Cunha et al., 2005; Secchi et al., 2003). Due to their nearshore distribution, these dolphin species are especially vulnerable to the effects of human activities. Rough-toothed dolphins and false killer whales occur in tropical to warm temperate waters all over the world (Baird, 2009; Miyazaki and Perrin, 1994). In Brazil, these species occur predominantly on

the continental shelf (Bisi, 2011; Dorneles et al., 2010, 2008b, 2007a) and rough-toothed dolphins can even be found in shallow coastal waters (Flores and Ximenez, 1997). Rough-toothed dolphins can occasionally reach more than 2.8 m of total length (Jefferson, 2009). Taking into consideration that this continental shelf (CS) delphinid has many prey species in common with estuarine dolphin species, such as the Guiana dolphin (Melo et al., 2010, submitted for publication), the greater size of rough-toothed dolphins means that these CS delphinids have anatomical characteristics that enable them to feed on larger fish, and hence, on prey specimens that had a longer exposure time to pollutants than those consumed by Guiana dolphins. Although it is still controversial whether or not false killer whales feed on other cetacean species, they are known to prey on large and long-lived fish such as tunas and swordfish (Baird et al., 2008). This feature, combined with the hypothesis that organohalogen compounds from bays and estuaries of the Southeastern Brazilian region are transported to the adjacent Atlantic Ocean waters (Dorneles et al., 2010), makes DRC determination in rough-toothed dolphins and false killer whales a matter of great scientific interest.

Because of these reasons, cetaceans were used in the present study as indicators of micropollutant trophic flow, as well as sentinel species for human health. The latter approach is based on the fact that many fish species are consumed by humans in Rio de Janeiro at the size preyed on by the delphinid species analyzed in our study (Melo et al., 2010, submitted for publication). In addition, it is also of great interest to investigate if accumulation of persistent bioaccumulative toxicants can pose an additional threat to these cetacean species.

2. Materials and methods

2.1. Sampling and sample preparation

Liver and blubber samples were obtained by different marine mammal research groups from five Brazilian states (Fig. 1), including the Southeastern [Espírito Santo (ES), Rio de Janeiro (RJ) and São Paulo (SP) states] and the Southern [Santa Catarina (SC) and Rio Grande do Sul (RS) states] regions of the country. They were collected through the necropsy of cetaceans either incidentally captured in fishing operations or stranded on the beaches. Liver samples were collected from franciscana dolphins, comprising fourteen males from Rio Grande do Sul (RS, n = 3), Santa Catarina (SC, n = 2), São Paulo (SP, males, n = 6) and Espírito Santo (ES, n = 3) states, as well as six female franciscana dolphins from São Paulo (SP, females, n = 6) state. Blubber samples were collected in RJ from 15 delphinids, comprising 11 Guiana dolphins (males, n = 7; females, n = 4), three rough-toothed dolphins (males, n = 1; females, n = 2) and one false killer whale (female, n = 1). After dissection, samples were wrapped in aluminum foil and kept frozen (−20 °C) until analyses.

2.2. Analytical procedure—targeted compounds

The following dioxins and furans were targeted for analysis: 2,3,7,8-Tetra CDD; 1,2,3,7,8-Penta CDD; 1,2,3,4,7,8-Hexa CDD; 1,2,3,6,7,8-Hexa CDD; 1,2,3,7,8,9-Hexa CDD; 1,2,3,4,6,7,8-Hepta CDD; Octa CDD (OCDD); 2,3,7,8-Tetra CDF; 1,2,3,7,8-Penta CDF; 2,3,4,7,8-Penta CDF; 1,2,3,4,7,8-Hexa CDF; 1,2,3,6,7,8-Hexa CDF; 1,2,3,7,8,9-Hexa CDF; 2,3,4,6,7,8-Hexa CDF; 1,2,3,4,6,7,8-Hepta CDF; 1,2,3,4,7,8,9-Hepta CDF; Octa CDF (OCDF). Concerning dioxin-like PCBs, the following congeners (IUPAC numbers) were targeted for analysis: 77; 81; 126; 169; 105; 114; 118; 123; 156; 157; 167 and 189. Toxic equivalent (TEQ) concentrations of PCDD/Fs and dioxin-like PCBs were calculated using the World Health Organization (WHO)-2005 toxic equivalency factors (TEF) (van den Berg et al., 2006). Concentrations below detection limits were considered as zero (lower bound TEQ). For blubber samples, in addition to all the mentioned above

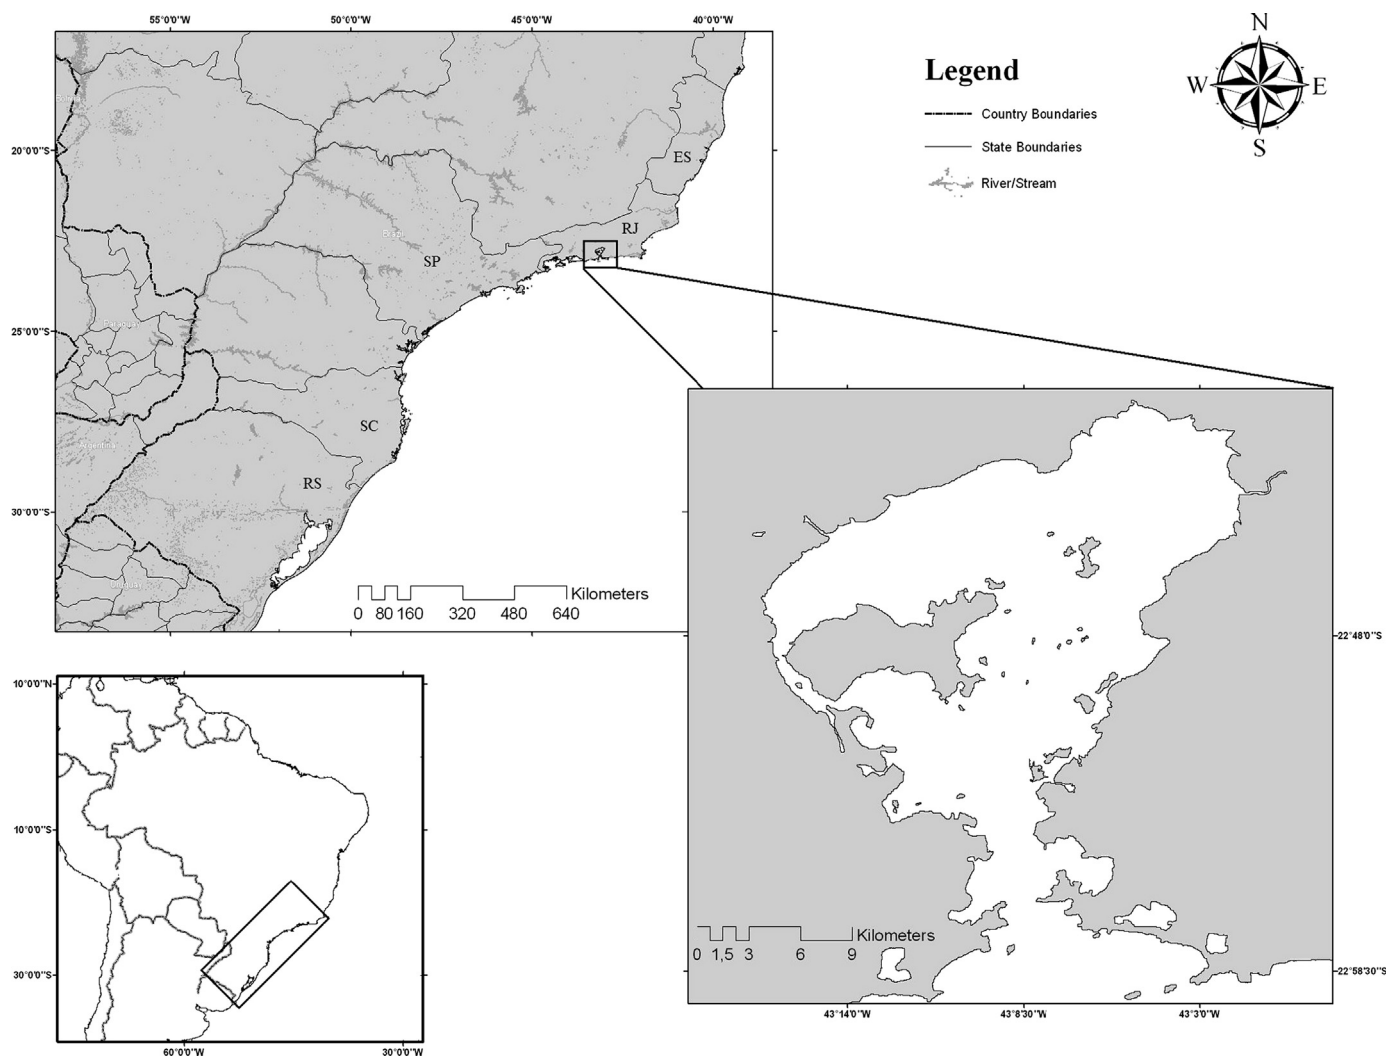

Fig. 1. Brazilian map amplifying Rio Grande do Sul (RS), Santa Catarina (SC), São Paulo (SP), Rio de Janeiro (RJ) and Espírito Santo (ES) states. Guanabara Bay is complementarily amplified.

DRCs, levels of indicator-PCBs (IUPAC numbers: 28, 52, 101, 138, 153, 180) were also measured.

2.3. Analytical procedure—liver sample analysis

The analytical procedure has been detailed elsewhere (Eljarrat et al., 2008). Briefly, samples were fortified with $^{13}\text{C}_{12}$ -labeled PCDD/F and $^{13}\text{C}_{12}$ -labeled PCB quantification standard solutions (Wellington Laboratories Inc., Canada), EPA 1613 LCS and WP-LCS, and extracted using a Dionex ASE100 at the following conditions: hexane, 100 °C, 1500 psi, 90% flush volume and two static cycles (Focant et al., 2001). After extraction, the solvent was removed and, subsequently fat content was determined gravimetrically. Resulting extracts were transferred into a separation funnel and liquid-extracted with concentrated sulphuric acid to remove organic matter. Clean-up stage was performed in an automated purification Power Prep™ System (FMS, Inc., USA) including acidic silica gel and basic alumina columns for mono-ortho PCB purification and an additional carbon column for PCDD/F and coplanar PCB cleanup. Different mixtures of hexane:DCM were used to recover mono-ortho PCBs while retaining interfering compounds. PCDD/Fs and coplanar PCBs were recovered with toluene. The final extracts were concentrated avoiding dryness, spiked with EPA1613-ISS and WP-ISS internal standard solutions (Wellington Laboratories Inc., Canada) and further analyzed by GC–HRMS.

2.4. Analytical procedure—blubber sample analysis

The extraction, purification and measurement methods are described elsewhere (Focant et al., 2001). Briefly, blubber samples were extracted by pressurized liquid extraction (PLE) using a Dionex (Sunnyvale, CA, USA) ASE 200 extractor. Conditions were: 33 ml extraction cells filled approximately 5 g of blubber sample and sodium sulphate, 20 ml of hexane per cycle, 5 min cycle time, two cycles per extraction, pressure of 1500 p.s.i. The fat extracts were dried on sodium sulphate prior to complete solvent evaporation. A solution of hexane/dichloromethane was added to aliquots of about 200–300 mg of extracted lipids. The lipid extracts were then spiked with a mixture containing seventeen ^{13}C -labeled 2,3,7,8-substituted dioxins isomers, 4 coplanar PCBs isomers (EDF-4144, LGC Promochem) and 8 mono-ortho PCB isomers (Campro Scientific WP-LCS). An automated multi-column clean-up was performed on the Power-Prep system (FMS, Waltham, MA, USA). The lipid content was determined gravimetrically. All analyses were performed by GC–HRMS using a MAT95XL high-resolution mass spectrometer (Finnigan, Bremen, Germany) and a Hewlett-Packard (Palo Alto, CA, USA) 6890 series gas chromatograph.

2.5. Statistical treatment

Due to the small sample sizes, non-parametric tests were used for investigating possible correlations between compounds and

biological parameters (*Spearman's correlation test*), as well as for investigating possible differences between species, sexes, and regions, regarding pollutant levels and profiles (*Mann–Whitney U test*). Due to the low number of individuals of some species/groups, only data from franciscana dolphins from SP and Guiana dolphins from RJ were used for statistical evaluation. The Statistica 7.0 Statistical Software System was used for statistical analyses and the level of significance was set at $p \leq 0.05$.

3. Results and discussion

PCDD, PCDF and dioxin-like (non-ortho and mono-ortho) PCB concentrations and TEQ values (pg.g^{-1} , l.w.), as well as percentages to ΣTEQ , in liver or blubber of cetaceans from Southeastern and Southern Brazilian regions, are presented in Table 1.

The use of TEFs to achieve TEQ constitutes an accurate procedure for the assessment of the toxic potential of a complex mixture of pollutants that are capable of triggering Aryl hydrocarbon (Ah) receptor-mediated effects, such as DRCs (Sanderson and Van Den Berg, 1999). Considering that metabolism of DRCs is also mediated by the Ah receptor, as well as that metabolizing rates for xenobiotics may vary according to age (Reijnders, 2003) and gender (Hall, 2002), possible correlations with the total length and possible sex-related differences were investigated not only for DRC concentrations but also for TEQ values.

3.1. Franciscana dolphins

Dioxin-like PCBs accounted for 83–96% of the total TEQs in the hepatic tissues of franciscana dolphins. In this context, non-ortho coplanar PCBs deserve to be highlighted, since the group contributed to 82% of the total TEQs, on average. Among the latter group, PCB-126 was by far the congener of greatest importance. In fact, of the measured DRCs, PCB-126 contributed to the majority of the total TEQ in all franciscana dolphins (mean 78%, SD 11%). However, PCB-118 occurred in the highest concentrations, which varied from 19.7 to 563.9 ng/g (l.w.). PCDDs and PCDFs accounted for, on average, 10% of the total TEQs. The predominant PCDD/F congener found in the livers of franciscana dolphins was OCDD, with concentrations ranging between 32 and 1093 pg/g (l.w.). Concentrations of PCDDs were greater than those of PCDFs in all individuals. However, regarding the TEQ values (TEQ pg/g l.w.), levels were in general higher for PCDFs. Among furans, 2,3,4,7,8-PeCDF provided the highest contribution to total TEQ.

It is important to keep in mind that while analyzing franciscana dolphins from RS, SC, SP and ES, individuals from three different management areas are being considered. It has been proposed that franciscana should be split into four stocks for management purposes, three of which occur in Brazilian waters (Secchi et al., 2003). Each stock inhabits discrete areas named Franciscana Management Areas (FMA): FMA I, including coastal waters of ES and RJ states; FMA II, covering SP to SC states; and FMA III, comprising the coastal waters of RS state and Uruguay (Secchi et al., 2003). A recent study from our research team (Lailson-Brito et al., 2011) has shown that different ecological franciscana dolphin populations could exhibit remarkably distinct organochlorine compound bioaccumulation profiles, characterized by different $\Sigma\text{DDT}/\Sigma\text{PCB}$ ratios, even within the same management area (FMA II). However, in our study there was no distinction among areas. Instead, there was great variation among individuals (Fig. 2).

According to Ballschmiter and Wittlinger (1991), the environmental levels of many organohalogen compounds in Northern and Southern Hemispheres are a consequence of emissions within each half of the planet independently. As DRCs are pollutants of urban/industrial origin, it is worth mentioning that SP houses a human population of approximately 40 million people (Rudge et al., 2011). In addition, the metropolitan area of São Paulo city constitutes the most industrialized center of Latin America (Saldiva et al., 1994). In this context, it becomes interesting to compare the organochlorine compound profiles between franciscana dolphins from SP state and air samples from São Paulo City (de Assunção et al., 2005). Considering the PCDF profiles specifically (Fig. 2), for all individuals from SP state, with the exception of BP136, a higher contribution of PeCDF to ΣPCDF in dolphins than in air could be observed. The contribution of PeCDF in dolphin liver samples (excluding BP136 from the analysis) varied from 25.3 to 65.5% (50.8 ± 11.7 , Mean \pm SD), while in air samples from São Paulo City (de Assunção et al., 2005) a percentage of 12.5 could be observed. A possible explanation for this lies in the selective biomagnification of 2,3,4,7,8-PeCDF reported in literature (Rolff et al., 1993).

For investigating possible gender-related differences on DRC bioaccumulation by franciscana dolphins from SP state, comparisons between sexes were performed regarding ΣPCDD , ΣPCDF , $\Sigma\text{TEQ-PCDD}$, $\Sigma\text{TEQ-PCDF}$, $\Sigma\text{non-ortho PCB}$, $\Sigma\text{ortho PCB}$, $\Sigma\text{TEQ non-ortho PCB}$, $\Sigma\text{TEQ ortho PCB}$, $\Sigma\text{DL-PCB}$, $\Sigma\text{TEQ-DRCs}$, as well as the percent contribution to total TEQ (% to $\Sigma\text{TEQ-DRCs}$) of $\Sigma\text{TEQ-PCDD}$, $\Sigma\text{TEQ-PCDF}$, $\Sigma\text{TEQ non-ortho PCB}$ and $\Sigma\text{TEQ ortho PCB}$. No significant differences were observed.

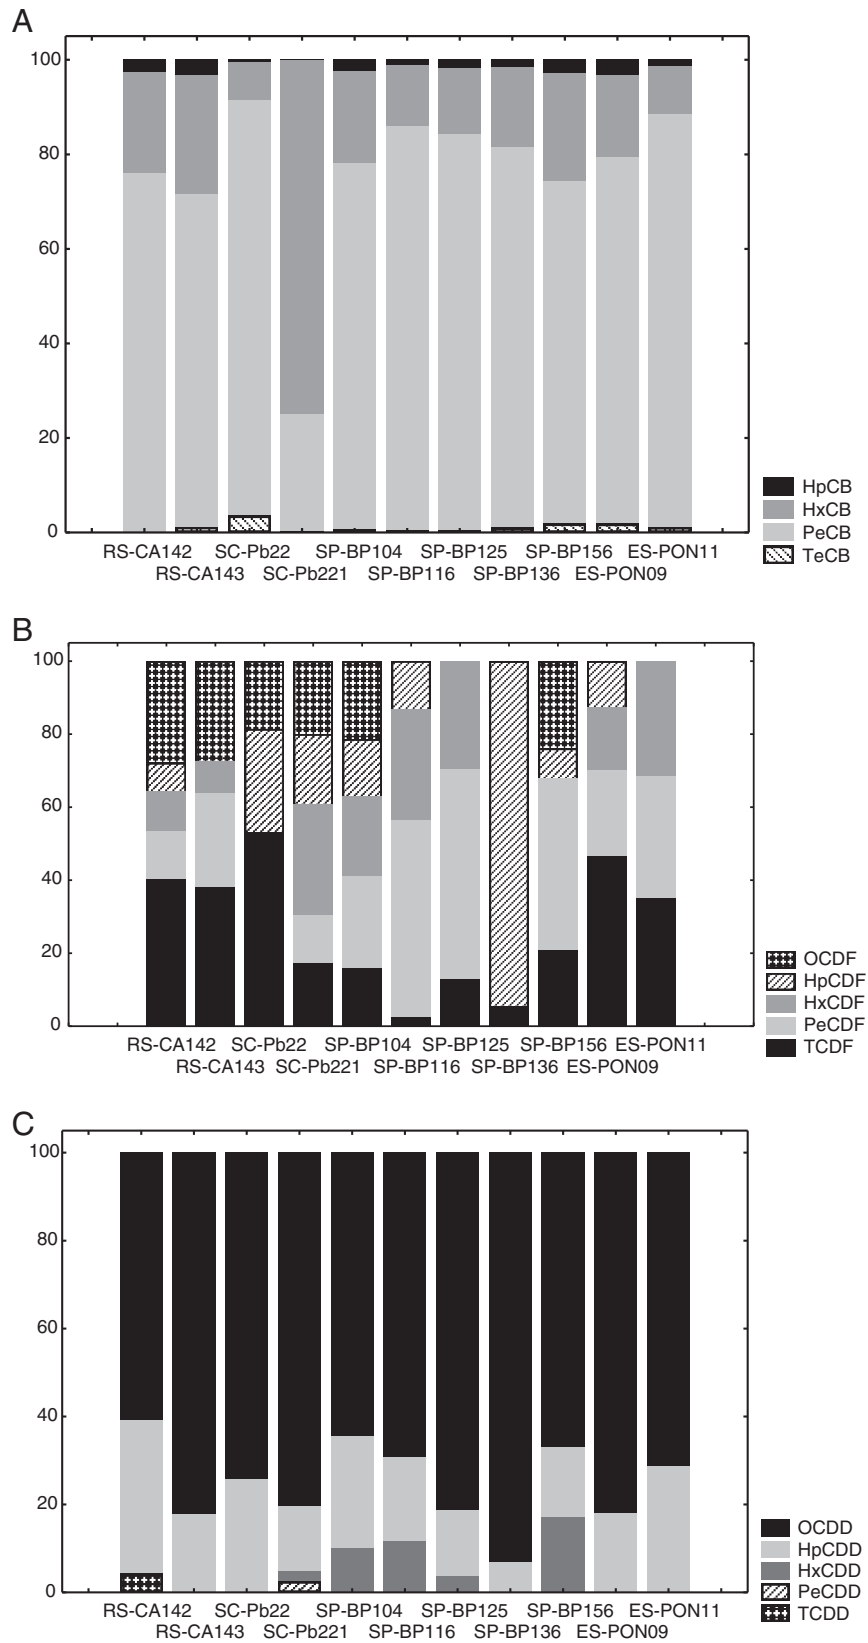

Fig. 2. Relative contribution of PCBs (Fig. 2-A), PCDFs (Fig. 2-B) and PCDDs (Fig. 2-C) grouped by the number of chlorine atoms in the molecule (e.g. tetra-chlorinated biphenyls, TeCB; penta-chlorinated dibenzofurans, PeCDF; and hexa-chlorinated dibenzodioxins, HxCDD) to Σ PCB (Fig. 2-A), Σ PCDF (Fig. 2-B) and Σ PCDD (Fig. 2-C), in liver samples of male franciscana dolphins from the Brazilian states of Rio Grande do Sul (RS), Santa Catarina (SC), São Paulo (SP) and Espírito Santo (ES). The figure exposes the individual codes of each dolphin (e.g. CA142, CA143, Pb22 and etc.), which are preceded by the identification of the Brazilian state (RS, SC, SP, ES).

DRC levels in male mammals generally increase with age (O'Shea and Tanabe, 2003); however, a different accumulation pattern is commonly observed for females. This difference is a consequence of the elimination of pollutants through placental and lactational transfer to offspring. In general, concentrations of organohalogen compounds also increase through life in females, but this occurs up to the start of the reproduction, after which the levels reach a plateau or even decrease with age (Dorneles et al., 2010; O'Shea and Tanabe, 2003; Thron et al., 2004). Considering that no significant sex-related differences were observed, as well as that reproduction had not started for immature females, groups constituted of all individuals and composed of males and immature females were also used in statistical treatment scenarios.

For investigating possible correlations between DRC concentrations or TEQ values and total length of franciscana dolphins from SP state, tests were performed in three different scenarios, i.e., regarding only males, males and immature females and all individuals. The pollutant-related variables investigated were Σ PCDD, Σ PCDF, Σ TEQ-PCDD, Σ TEQ-PCDF, Σ non-ortho PCB, Σ ortho PCB, Σ TEQ non-ortho PCB, Σ TEQ ortho PCB, Σ DL-PCB, as well as Σ TEQ-DRCs. No significant correlation was found for DRC concentrations; however, correlations were observed for TEQ values. Significant negative correlations were found between total length and three TEQ-related variables, i.e., Σ TEQ-DRCs, Σ TEQ-PCDF and Σ TEQ non-ortho PCB, in three different scenarios: considering all individuals (males and females) ($p = 0.025$, $R_s = -0.69$; $p = 0.005$, $R_s = -0.81$; and $p = 0.019$, $R_s = -0.69$; for Σ TEQ-DRCs, Σ TEQ-PCDF and Σ TEQ non-ortho PCB, respectively); considering the group formed by males and immature females ($p = 0.01$, $R_s = -0.83$; for Σ TEQ-DRCs and Σ TEQ-PCDF; as well as $p = 0.005$, $R_s = -0.83$, for Σ TEQ non-ortho PCB); and considering only males ($p = 0.014$, $R_s = -0.95$; $p = 0.015$, $R_s = -0.95$; and $p = 0.011$, $R_s = -0.96$; for Σ TEQ-DRCs, Σ TEQ-PCDF and Σ TEQ non-ortho PCB, respectively).

As cited above, TEQ values result from the concentrations of the different DRCs as well as from the ability of each compound to induce the Ah-receptor mediated response. Therefore, the fact that correlations with total length were found for TEQ values rather than for concentrations, associated with the fact that they constituted negative correlations, suggests these findings result from chemically-induced developmental disruption. As mentioned, inhibition of growth and development is among the effects attributed to exposure to DRCs (Sanderson and Van Den Berg, 1999). However, an increasing efficiency of the detoxifying activity with the growth of the animal may be a plausible explanation as well (Reijnders, 2003). The concentration ratios between PCB-77 and PCB-169, as well as between PCB-126 and PCB-169, have been used for evaluating enzyme induction and detoxifying activity (Corsolini et al., 2000; Storelli and Marcotrigiano, 2003). Such use is based on the fact that PCB-169 is the most stable coplanar congener (Corsolini et al., 2000). The PCB77/PCB169 and the PCB126/PCB169 concentration ratios of the franciscana dolphins from the present study averaged 29.1 and 7.4, respectively. Therefore, possible correlations between these ratios and total length values of franciscana dolphins from SP were investigated in the same three scenarios mentioned above. A significant negative correlation was found between total length and PCB126/PCB169 concentration ratio for the group formed by males and immature females ($p = 0.036$, $R_s = 0.7$). The same correlation was not found for the other groups (only males and all individuals) possibly due to the small sample size of the male group, as well as due to the increased number of females in the group composed by all franciscanas. As cited, there are gender-related differences in the metabolizing rates for xenobiotics (Hall, 2002). Nevertheless, this finding reinforces the hypothesis of increasing efficiency of the detoxifying activity with the growth of the animal.

The DRC levels verified in the present study constitute a matter of concern for the conservation of the species. The hepatic PCDD and

PCDF concentrations of franciscana dolphins are high when compared to cetaceans from different regions of the globe (Table 2). In addition, three franciscana dolphins (two males from SP and SC, and 1 female from SP) exhibited Σ TEQ concentrations within the range of threshold levels for TEQs in livers of aquatic mammals that are capable of eliciting physiological effects (160 to 1400 $\mu\text{g}\cdot\text{g}^{-1}$, l.w.) (Kannan et al., 2000). Contamination with pollutants that have been shown to be risk factors for cancer, immune deficiency and reproductive abnormalities (Schecter et al., 2006) constitutes a matter of concern for all species. However, this is especially important for species facing population decreases due to other man-made causes, which enhances the apprehension over this dolphin, as franciscana is the cetacean species most impacted by fisheries in the southwestern Atlantic (Secchi et al., 2003).

3.2. Guiana dolphins

Dioxin-like PCBs accounted for over 98.8% of the total TEQ for all Guiana dolphins from RJ. For this cetacean population, mono-ortho PCBs constituted the group of highest contribution, which varied from 49 to 80% to the total TEQ. PCB-118 was the compound of greatest importance among mono-ortho PCB congeners, with an average contribution of 34% to the total TEQ. This penta-PCB was also the compound with the highest concentrations in the adipose tissue, which varied from 2.81 to 11.5 $\mu\text{g}/\text{g}$ (l.w.). PCDDs and PCDFs accounted for less than 1.2% of the total TEQ in all Guiana dolphins. The predominant PCDD/F congeners found in blubber of Guiana dolphins were OctaCDD (mean \pm SD; 19.4 ± 29.0 $\mu\text{g}/\text{g}$ lipids) and 1,2,3,4,7,8-HexaCDF (6.7 ± 5.4 $\mu\text{g}/\text{g}$ lipids). Regarding the TEQ values (TEQ $\mu\text{g}/\text{g}$ l.w.), 1,2,3,7,8-PentaCDD provided the highest contribution among PCDD/Fs when the average of all Guiana dolphins was considered. However, this penta-chlorinated dibenzo-*p*-dioxin was not the PCDD/F of greatest contribution to total TEQ for six individuals (two males and the four females).

For investigating possible correlations between DRC concentrations or TEQ values and total length of Guiana dolphins from RJ, tests were performed in two different scenarios, i.e., regarding only males and all individuals. The pollutant-related variables investigated were Σ PCDD, Σ PCDF, Σ TEQ-PCDD, Σ TEQ-PCDF, Σ non-ortho PCB, Σ ortho PCB, Σ TEQ non-ortho PCB, Σ TEQ ortho PCB, Σ DL-PCB, as well as Σ TEQ DL-PCB. No significant correlations were found for DRC concentrations or TEQ values.

For investigating possible gender-related differences on DRC bioaccumulation by Guiana dolphins from RJ, comparisons between sexes were performed regarding Σ PCDD, Σ PCDF, Σ TEQ-PCDD, Σ TEQ-PCDF, Σ non-ortho PCB, Σ ortho PCB, Σ TEQ non-ortho PCB, Σ TEQ ortho PCB, Σ DL-PCB and Σ TEQ DL-PCB. Significantly higher Σ TEQ-PCDD levels were verified in males than in females ($p = 0.02$). Higher persistent bioaccumulative toxicant concentrations in male than in female mammals have been legitimately attributed to the mother-to-calf transfer (O'Shea and Tanabe, 2003). However, the fact that significant differences between sexes were found for TEQ values rather than for concentrations suggests gender-related peculiarities in DRC metabolizing capabilities play an important role in this process. As mentioned above, males and females metabolize DRCs at different rates (Hall, 2002).

3.3. Rough-toothed dolphins

On average, dioxin-like PCBs accounted for 93% of the total TEQ for rough-toothed dolphins from RJ. For this species, the contribution of mono-ortho PCBs to the total TEQ varied from 26 to 72%, and the contribution of non-ortho PCBs was between 14 and 69%. PCB-118 and PCB-126 were the compounds of highest contribution among mono-ortho and non-ortho coplanar PCB congeners, with contribution percentages to the total TEQ that varied from 13 to 43% as well

Table 2

Mean Σ PCDD and Σ PCDF concentrations (pg/g, l.w.) in blubber (B) and liver (L), with standard deviation (\pm SD), number of individuals of each species/area of sampling of cetaceans from all over the world.

PS, present study.

as from 2.3 to 59%. PCB-118 was the compound of highest concentration, which varied from 174 to 11,822 ng/g (l.w.). Concentrations of PCB-126 varied from 189 to 1940 pg/g lipids. The summed contribution of PCDDs and PCDFs to the total TEQ in rough-toothed dolphins varied from 1.6 to 13.9%. A different pattern was found in Guiana dolphins, for which the contribution of these compound classes was very low. An extremely wide concentration range was observed for the predominant PCDD/F congeners found in blubber of rough-toothed dolphins, since OctaCDD and 1,2,3,4,7,8-HexaCDF levels varied from 6.5 to 713, as well as from 0.4 to 1026 pg/g lipids. This organochlorine compound (OC) accumulation pattern, in which extremely high concentrations are found in only a few individuals, has been reported for marine mammals (Hall, 2002). Actually, extremely wide concentration ranges could be found for organohalogen compounds in marine mammals (Dietz et al., 2004; Hall, 2002; Sonne et al., 2008, 2004, 2006b, 2005, 2006c), even reaching a 70-fold variation (Sonne, 2010).

In fact, the Σ PCDD (747 pg/g lipids) and Σ PCDF (1313 pg/g lipids) concentrations found in blubber of a female rough-toothed dolphin are among the highest ever reported for marine mammals (Table 2). Finding high concentrations of persistent accumulative toxicants in this dolphin population is not surprising. Rough-toothed dolphins from RJ feed on top-predator fish (Bisi et al., 2012; Melo et al., 2010), thus they are more likely to take in high amounts of contaminants that have accumulated in the bodies of the prey.

3.4. False killer whales

Concentrations and percent contribution of PCB-118, PCB-126, OctaCDD and 1,2,3,4,7,8-HexaCDF lie within the range mentioned for rough-toothed dolphins, with the exception of the PCB-126 concentration, which was higher for the false killer whale (2179 pg/g lipids). It is important to note that, as there was only one individual, the pollutant levels and profiles may not be representative of the population. Despite this, the Σ PCDD and Σ PCDF concentrations found in our study compare favorably with data for false killer whales from North America (Jarman et al., 1996) (Table 2).

3.5. A serious PCB problem

Comparing DRC concentrations in franciscana dolphins from SP with levels of the same compounds in Guiana dolphins from RJ is a difficult task, since contaminant determination was performed in liver and blubber, respectively. Evaluating the body distribution of lipophilic organohalogen compounds in cetaceans, Watanabe et al. (1999) and Ramu et al. (2005) observed that, in general, the highest levels are found in blubber, even considering lipid normalized concentrations. However, different body distribution patterns are observed for compounds of the same chemical class (Kunisue et al., 2008). An investigation that dealt with DRC concentrations in raccoon dogs from Japan showed that the HxCB-157 ratio in liver/adipose tissue presented values close to 1.0 (Kunisue et al., 2006). To the authors' knowledge, this approach has not been applied to cetaceans yet. Although species-specific differences in toxicokinetics of DRCs may exist, the latter cited investigation turned HxCB-157 into the most suitable compound for comparison between liver and adipose tissue concentrations. Therefore, statistical comparison between the HxCB-157 concentrations of franciscana dolphins and Guiana dolphins was performed, limiting it to male dolphins from SP and RJ, respectively. The HxCB-157 concentrations found in Guiana dolphins were significantly higher than those found in franciscana dolphins ($p = 0.003$). Since both data sets presented normal distribution, the mean values were used as a reference and it could be observed that HxCB-157 levels of Guiana dolphins were supposedly 75 times those of franciscana dolphins. Even considering two dolphin species, this should be done with caution due to possible species-specific differences in metabolism. However, it was the most appropriate among the available tools for comparing the exposure to PCBs between both odontocete species/populations. Nonetheless, this finding suggests that Guiana dolphins from RJ are more exposed to PCBs than franciscana dolphins from SP.

PCB levels found in Guiana dolphins in the present study are among the highest ever reported for cetaceans. For instance, these concentrations were in the range reported by Kuehl et al. (1991) and Berggren et al. (1999) in blubber samples from bottlenose,

common and white-sided dolphins from the U.S. Atlantic Coast (Kuehl et al., 1991), as well as from male harbor porpoises from the Baltic Sea, the Kattegat–Skagerrak Seas and the West Coast of Norway (Berggren et al., 1999). In the study performed by Kuehl et al. (1991), the total PCB concentrations varied from 17.4 to 195 µg/g lipid, and in the investigation conducted by Berggren et al. (1999), the levels varied between 2.2 and 78 µg/g lipid (sum of CB52, CB101, CB118, CB138, CB153 and CB180). The concentration range reported by Kuehl et al. (1991) comprises the sum of one hundred PCB congeners, much more than the 18 PCB congeners determined in the present study. In Kuehl et al. (1991) and Berggren et al. (1999), cetaceans were collected from 1978 to 1990. During the 1970s and 1980s, the manufacturing of PCBs was terminated in most industrialized nations. This implies further that the animals analyzed by Kuehl et al. (1991) and Berggren et al. (1999) lived not only in a highly polluted area but also in a period of elevated environmental contamination by PCBs. The sample set analyzed by Kuehl et al. (1991) included bottlenose dolphins obtained after an unusual mortality event. Although the impact of these immunosuppressive compounds (Sonne et al., 2006a) is not fully known, their role as causative agents in that mass mortality was considered by the authors (Kuehl et al., 1991), which emphasizes the toxicological importance of the concentrations found in Guiana dolphins from RJ. Among cetaceans species, the highest concentrations of biomagnifying pollutants are usually found in killer whales, due to their predation on organisms that occupy high trophic positions, such as sharks, seals and other cetaceans (O'Shea and Tanabe, 2003). Therefore, the magnitude of the delphinid exposure to PCBs in RJ waters can be exemplified with the fact that concentrations found in these dolphins are comparable to the levels verified in killer whales from Alaska (Ylitalo et al., 2001).

Interestingly, 10 out of the 11 Guiana dolphins analyzed in the present study were found in Guanabara Bay, which may explain the extremely high PCB concentrations found. Guanabara Bay is the most anthropogenically disturbed area along the Brazilian coast (Dorneles et al., 2008b). The estuary is bordered by more than 14,000 industries and four cities (Wasserman et al., 2006) with a population of more than 10 million people (Jablonski et al., 2006; Kjerfve et al., 1997). Despite the anthropogenic pressure, the small Guiana dolphin population exhibits habitat fidelity to Guanabara Bay, since the same individuals are found year-round in this site (Azevedo et al., 2004), where feeding-related activities predominate (Azevedo et al., 2007). In addition to the expected contamination by PCBs from a highly urbanized and industrialized area, some activities in Rio de Janeiro amplify the apprehension. Eleven thousand liters of Aroclor were stolen from an abandoned building in Rio de Janeiro City in September 2005 (ALERJ, 2005). This raises suspicion on the existence of an illegal market and usage of PCBs in Brazil, which is a serious reason for concern in terms of environmental pollution.

The Brazilian economic growth and the consequent use and degradation of the coastal zone are a threat to the conservation of coastal cetaceans. A large set of construction works is planned for the establishment of harbors, shipyards and industries on Brazilian coastal bays and their drainage basins. Many of these estuaries have been suffering from a large series of different types of pressure, as well as they have been going through broad dredging and even submarine demolishing. Some Brazilian bays seem to be on the same degradation path once followed by Guanabara Bay, which harbors a residual Guiana dolphin population assessed to be around 40 individuals only (Azevedo et al., submitted for publication). Environmental contamination by DRCs constitutes one additional obstacle for these marine mammals to reach their natural longevity and reproduce at a physiologically normal rate. The concerns generated by the DRC contamination are amplified when it is taken into account that these cetaceans are exposed to other persistent bioaccumulative toxicants (PBTs) that have been shown to be endocrine disruptors, tumor promoters and immunosuppressors as well (Schecter et al., 2006;

Simonyte et al., 2006; Sonne et al., 2006a; Whalen et al., 1999). The high exposure of cetaceans from Brazil to cadmium (Dorneles et al., 2007a, 2007b), mercury (Lailson-Brito et al., 2012a), organochlorine pesticides (Lailson-Brito et al., 2011, 2010, 2012b), as well as to organotin (Dorneles et al., 2008b), perfluoroalkyl (Dorneles et al., 2008a) and organobrominated (Alonso et al., 2012; Dorneles et al., 2010) compounds has already been reported. Therefore, the possibility of synergistic effects among these PBTs should not be ruled out.

The data generated by the present study raises apprehension on the possibility of human health problem due to consumption of fish from Brazilian estuaries. This apprehension is augmented when it is considered that many fish species are consumed by humans in Rio de Janeiro at the size preyed on by Guiana dolphins from Guanabara Bay (Melo et al., submitted for publication). Therefore, risk assessment studies on human exposure to PCBs through consumption of fish from Guanabara Bay are of fundamental importance.

Conflict of interest

The authors state that there is no conflict of interest.

Acknowledgments

This work was supported by the Ministry of Education of Brazil—CAPES (“Ciências do Mar”—Proc. 23038.051661/2009–18, as well as fellowship to M.B. Alonso, “Sandwich Programme”—PDEE), by the Brazilian Research Council—CNPq and by Rio de Janeiro State Government Research Agency—FAPERJ (“Pensa Rio” Program). This study was also supported by a scientific cooperation established between CNPq and F.R.S.—FNRS (Proc. 490471/2010–2 CNPq). The Yaqu Pacha Foundation is acknowledged for its financial support to research projects that allowed cetacean carcass recovery. Dr. Lailson-Brito is a researcher of “Prociência” Program—FAPERJ/UERJ. Dr. Azevedo has a research grant from CNPq (grant No. 304826/2008–1). Since Dr. Torres is partially funded by Grant 1D43TW00640 from the Fogarty International Center of the National Institute of Health, this institution is also acknowledged. Dr. Torres is also a Research Fellow of CNPq and FAPERJ. Krishna Das is a F.R.S.—FNRS research associate.
