Optimization of Shipyard Space Allocation and Scheduling using Heuristic Algorithm

J-D. Caprace $\,\cdot\,$ C. Petcu $\,\cdot\,$ M.G. Velarde $\,\cdot\,$ P. Rigo

Received: date / Accepted: date

Abstract In this paper we describe the development of a tool that allows planners to efficiently and effectively plan space within valuable areas of a shipyard. Traditionally, space is considered as resource; however, it is difficult to accurately account for and plan its consumption with the current available planning software's. The spatial scheduling tool described in this paper can be used by planners to manually or automatically reserve space within the shipyard for construction of large blocks over the entire erection period of the ship. The software is coupled with a heuristic optimization solver which is inspired by an algorithm used for "3D bin-packing problems". The result is the ability to efficiently generate and compare multiple space alloca-

1 Introduction

1.1 Why space allocation is an issue for shipyards?

The high complexity of ship production, due to the interaction of many different disciplines (hull construction, electricity, fluids, interior fitting, propulsion, etc.) requires an intensive design and a detailed production planning where most of the tasks are carried out in parallel. [1] highlighted that it is necessary to increase the number of simultaneous tasks in order to obtain the best quality, the lowest price, and the shortest manufacturing lead time during the ship production process.

Today, shipyards change their design method in order to increase the number of simultaneous tasks with the use of more structural blocks (modular construction strategy). Traditionally, the majority of the design decisions were taken based on experience and opinion of the designers. These decisions have a strong influence on production costs, but subsequently on the ship's performance during its life.

One of the most significant observations for the last decades concerning shipbuilding is the increase in size of the ships as shown for passenger ships on Fig. 1. In

J-D. Caprace

addition, making a weld in a workshop is much cheaper than doing the same weld in the dry dock (worse access conditions, welding overhead, slower welding process, etc.). The consequence is an increase of the block size and/or the number of blocks while the working surface is almost equal. Moreover, most of the time, it is not possible to enlarge these working surface. It follows that we arise to a space allocation problem.

The assembly of big elements requires necessary available area within the fabrication workshop to perform the production. As the blocks become larger and heavier, production space in the shipyard becomes a constraint. The largest blocks are limited in the space where they can be produced due to the lifting and handling limits. For this reason, it is important to accurately plan the space in these areas to ensure that blocks are moved only when and where necessary, to efficiently use the available space. Unnecessary moves result in non value-added cost to the block. However, due to production constraints and aggressive construction schedules, maximizing the number of blocks in an area may result in unnecessary moves, while minimizing unnecessary moves results in a less efficient use of the space. The limited space available in shipyards, as we can see

on Fig. 2 for the Uljanik shipyard in Pula (Croatia), and the growth in the size of blocks and sections forces the planners to optimize the use of the available surface within the workshops and storage areas.

Fig. 2 Limited working space in Uljanik shipyard island (Pula – Croatia)

1.2 Current practice

Spatial scheduling is still currently being done by small groups of experienced people using tools such as Computer-Aided Design (CAD), PowerPoint, or Excel and schedule information from their planning systems. Although these ad-hoc tools are relatively effective, they are cumbersome and require a significant amount of time to update even for minor schedule changes. In addition, scheduling practices and lessons learned over time are contained within the experts themselves. In addition, this knowledge is lost and must be reacquired by yet another generation of new employees. Providing some innovative solution to capture this knowledge and automate the process with a "smarter tool" would provide a more efficient allocation of the valuable production space in each of the construction areas facilities.

Research related to optimal block allocation scheduling in shipbuilding is not prevalent, even though it is possible to increase the productivity of shipyards and to decrease the building cost of a ship through efficient use of space resources. However, some recent research shows a growing interest of shipyard to improve the space utilization inside workshops.

In Korea, simulation based production scheduling is growing up, which can contribute to improve production scheduling and planning works and evaluate various production scenarios, [3]. To make most use of the

61

simulation, coupling optimization with simulation is expected to be far more effective to improve the planning quality as well as to reduce the efforts in production planning and control, [4] and [5].

To solve the specific problem various heuristic-based algorithms have been developed to optimize the block assignment and space allocation. [6] present a scheduling algorithm using partial enumeration and decomposition to generate a spatial allocation plan. [7] proposed an optimization of block allocation in assembly area, using simulated annealing method, [8] and [9], blocks allocation optimization in the assembly area based on CST (Constraints Satisfaction Technique) and [10] optimized block division planning using genetic algorithm and product model. Similarly, [11], [12] and [13] proposed a semi-automated scheduler to increase the utilization of work area space. Utilizing the similarity of the two-dimensional packing problem, [14] recently present a bottom-left-fill heuristic method for spatial planning of block assemblies.

As presented before, a large spectrum of researches has been conducted to investigate various algorithms for optimal configuration and develop decision support systems for spatial scheduling of dynamic block assembly. However, all the studies deal with a limited number of production constraints which hardly reflect the realistic production situation. For instance, it can be desirable to keep some blocks together during the assembly stage, or place some blocks only in one type of assembly shop, or at the exit gate, or near the ship which are currently erected, etc.

The paper is organized as follows. After a literature review on relevant research work, a systematic framework for look-ahead scheduling mechanism is presented, wherein a heuristic-based algorithm for optimizing the spatial layout of block assemblies is developed. A case study with computational experiment is then presented to demonstrate the proposed approaches.

2 Space allocation issue

2.1 Similarities with other theories

The dynamic allocation of space in the shipyard is an immensely difficult and time-consuming effort. The difficulty in scheduling floor space, or spatial scheduling, arises in the fact that the space allocation for one block significantly affects the availability of floor space to every other block. Scheduling production space to satisfy an erection schedule becomes even more complex when unexpected changes of the schedule occur (e.g., upstream process delays, weather-related delays, or subcontractor timeliness), [11] and [12]. This illustrates a need for a tool that can assist planners in not only generating efficient spatial layouts, but also modifying these plans accordingly with minimal additional effort. Not only is the practice of scheduling space a difficult problem, but also the automatic or semi-automatic scheduling of the space is even more difficult.

The space allocation issue looks like a cutting stock problem. The cutting stock problem is a well understood problem in the shipbuilding industry. Steel processing facilities in almost every shipyard use nesting software to determine the best allocation of steel plate area for cutting out profiles. Having this technology, the allocation of steel plate space is much more efficient and results in reduced steel waste. Solution procedures to the two-dimensional cutting stock problem have and continue to be developed to improve the efficiency and computation time of the plate layout.

This issue can also be considered with the conventional three-dimensional bin packing problem (3D-BPP) where cubes or solid boxes are "packed" into a larger empty container in an effort to maximize the number of boxes in the container; see Fig. 3 and e.g. in [15]. In the shipbuilding context, the working area, platen, or shop floor length, width and height are considered the "X", "Y" and "Z" dimensions of the container and the "t" dimension is the time schedule horizon. The problem is thus more complex than a simple 3D bin-packing problem: there are three geometric dimensions and in addition, the time dimension. In order to simplify the problem, only two geometrical dimensions (floor length and width) are generally considered additionally to the time dimensions. The objective, as defined by the shipyard managers, is thus to maximize the number of building blocks produced in a given surface over a certain time horizon. In the sequel, we refer to this problem as the Space and Time Allocation (STA) problem.

Only few solution procedures have been developed for these types of problems, [8], [17], [18] and [19], and optimal solutions procedures have proved to be NP-hard because of the exponential explosion of the solution space, [20]. I.e. an "optimal solution" for a large application cannot be found within reasonable computing times. Therefore, the user should accept obtaining a "nearly optimum" solution. An efficient tool should make use of modern heuristics to find such results within short computing time. There is one key difference between shipyard spatial scheduling and the conventional "bin-packing" problem. In the bin-packing problem, it is generally assumed that the blocks to be packed are all available at time 0. In the shipbuilding industry, the blocks become available for placement at different times. Also, the general case of the academic problem is not relevant in the practical sense due to the fact that the "real-world" system has significantly more complex constraints than those of the general case. Some of these constraints include preferred locations, spacing between the units, schedule requirements, and so forth.

[21], [22], [15] and [23] are recent contributions which provide brief surveys of the literature on 3D-BPP. Since the problem is hard, most efficient approaches rely on local search metaheuristics for the solution of largescale instances. In particular [22] have proposed a Guided Local Search (GLS) heuristic for 3D-BPP. In their computational experiments, this approach appears to outperform the best available heuristics for 3D-BPP. It also offers a high degree of flexibility in its implementation, so that it can be easily adapted to variants of the problem involving different objective functions and/or additional constraints. Therefore, the algorithm that we have developed for STA explicitly builds with the aid of their work.

2.2 Challenges of space allocation issue

The dynamic allocation of blocks in shipyards is a huge, difficult and time-consuming effort. The difficulty in space allocation arises in the fact that:

 The allocation of space to one block significantly affects the availability of floor space for the other blocks, [11]. Scheduling production space to satisfy

Fig. 3 3D bin-packing problem in a container - [16]

an erection schedule becomes even more complex when unexpected changes of the schedule occur (e.g., upstream process delays, weather-related delays, or subcontractor timeliness).

- The allocation of space in a industrial environment is an issue with different complex production constraints:
 - Block height might be important because, sometimes, blocks have to be moved by a crane bridge above others blocks.
 - Spacing between blocks might be required for safety and accessibility reasons.
 - Spacing below blocks might be required for transportation with skid platforms.
 - Space above blocks might be required for the movement of other blocks.
 - Preferred location for some blocks might be required to allocate blocks close to specific tools or equipments.
 - Etc.

This illustrates the need for a flexible tool that can assist planners in, not only generating optimal spatial layouts, but also modifying day after day these plans according to the variation of the initial schedule (delays, unplanned maintenance, etc.). The next section describes the approach that has been developed to help in the allocation and planning of floor space within the shipyard.

3 Approach

The objective of the tool described in this paper is to increase the utilization of working area, while maintaining production schedules. An innovative approach has been developed in order to include the following features:

- The automatic allocation of activities (blocks, sections, panels, etc.) in the workshops;
- The minimization of the wasted surface;
- Long-term and day-to-day simulations in order to find how a delay impacts the global planning;
- The post-processing of the result in order to allow a fast decision making (floor plan printing, display of working load and working force charts, display of surface utilization charts, etc.).

This tool should thus provide planning proposals, i.e. a location and a starting day for each block. Unfortunately, it may happen that the available surface in the assembly hall is not sufficient to produce the entire set of blocks. The tool should then try to help the user to take the most efficient decision. For simplification reasons, no details will be taken into account regarding the production processes. It is also assumed that blocks have their final shape during the assembling process. We don't take into account the successive assembly stages. In addition, a block is considered to have a parallelepiped shape. Many blocks are indeed almost parallelepipeds and other shapes could be considered using the same optimization technique.

Dealing with simple data is more convenient, and we knew that a decision tool is only efficient if it keeps things easy to use, even if complex methods are used to solve the problem. Indeed, the software would lose part of its power and efficiency if the time needed to prepare the data becomes excessive. In addition, the ability to make changes quickly and to view the impact of those changes in real time provides a tool that will significantly reduce the cost of planning and replanning.

The first phase of the tool development is the development of a Graphical User Interface (GUI) to assist the planner in his tasks. The second phase of the tool development focuses on capturing the knowledge of the planner and using it to implement an automated optimization module. The following sections provide further details on these two phases of the tool development: the GUI and the automated optimization scheduling procedure. Finally we present an industrial case study and a set of conclusions.

4 Required data for optimization

Both the data related to the shipyard's facilities and to the production activities (ship blocks, sections, etc.) are required in order to define the problem.

4.1 Shipyard facilities

The assembly surfaces of a shipyard contains often more than one working area A_k , for $k = 1, 2, \dots, m$ of rectangular shape, such as section assembly halls, block assembly areas, painting halls, outfitting areas, etc. Different activities on the block are processed in these areas. Each working area could contain different preferential zones in order to perform the activity in a specific place of the workshop rather than another. Subsequently, three different level of information should be considered: the workshop, the working area and the preferential zone. The main information required about the shipyard facilities are:

- The available space in the working areas (length L, width W, height H) of the workshop, see Fig. 4;
- The crane capacities (maximum load, height under the hook C);
- The definition of preferential zones q inside the workshop (length, breadth, height, type of work, etc.);
- The position of the gates;
- The industrial calendar (working days for each ship);
- The personal availability over time.

Fig. 4 Working areas and blocks

It is imperative to know the location of the gates in the assembly hall and the crane bridge height. Indeed, it may happen that a particular block cannot be taken out because other high blocks are on its way to the gate and the height of the crane bridge may not be sufficient to pass over them (crane hook constraint). If blocks are too heavy for the crane bridge, they need to be driven out on a skid platform. In this case, no block at all should remain on the way and supports for blocks have to be elevated in order to let the skid platform get under the block.

4.2 Production activities

Basically, the input data of the software may be summarized as a list of n "activities". Each activity represents a certain work to be done on a particular block $j = 1, 2, \dots, n$. Hence, the following information that can be provided by the Enterprise Resource Planing (ERP) system of the shipyard is required:

- Description of the block block identification, ship identification, comments, etc.;
- Prismatic dimensions of each block length l_j , width w_j , height h_j , for $j = 1, 2, \dots, n$ and related spaces allocated to movements around the blocks. Blocks are considered as parallelepipeds. The major reason for this assumption is that this data is very easily

available; it is easier to deal with basic shapes and their representations on a surface are more easily interpretable. This idea does not affect drastically the results since most blocks have indeed a (almost) parallelepiped shape. For accessibility and security reasons, a certain distance may be required between nearby blocks in the assembly hall. Therefore, an extra length, an extra width and an extra height can be considered;

- Position of the block x_j and y_j these parameters are coordinates representing the position of the upper-left corner of block j in the selected area a_j ;
- Processing time t_j Processing time interacts with two aspects: the total amount of workforce needed for each block and the duration of work. At this stage of the planning, a precise processing time cannot be assessed; therefore the processing time has to be estimated. An estimation of the total amount of man-time needed is available, thus the processing time is computed by dividing this man-time by the available number of workers. The workload assessments become more precise over time. In addition to the processing time of an activity, some times may be required to prepare the appropriate surface and build up supports for blocks or to dismantle them. This work has no effect on the start and the end date. Therefore it has to be taken into account separately;
- Date of production of each block In this case, the earliest starting date also called release date r_j is used (earliest date at which production can start because the required parts are available for assembly) and the latest end date also called due date d_j (the date at which the activity of the block has to be delivered). See Fig. 5;
- Starting date $s_j \in \{r_j, \dots, d_j t_j\}$ this parameter indicates the starting date of the assembly of block j;
- Area $a_j \in \{1, 2, \dots, m\}$ this parameter indicates the working area where the block j will be produced. In some cases, the values may be restricted to a subset of the sections, depending on block characteristics.
- Orientation $o_j \in \{0, 1, 2, 3\}$ this parameter indicates the orientation of the block j in the selected area a. Blocks can have 4 orientations turning by 90 degrees.
- Subcontractor possibility $b_j \in \{0, 1\}$ this parameter indicates whether activity j will be produced inside the shipyard $(b_j = 0)$ or whether it will be subcontracted $(b_j = 1)$. During optimization, these blocks will preferentially be selected to be produced

in other workshops if the assembly area is overloaded;

The following optional additional information can be defined by the user to improve the quality of the scheduling solutions:

- Fictitious block $c_j \in \{0, 1\}$ this boolean parameter indicates that a block is dummy. This option gives the possibility to introduce zones temporarily reserved for activities different from block mounting operations (e.g. storing the ship engines on the assembly shop, temporary space required for cranes, etc.). The fictitious blocks are only used to reduce the available space during a definite time window.
- Target date f_j this option allows the user to give a preferential start date for the optimization module. If this date cannot be reached by the optimizer, the trend will be to approach it as best as possible; On one hand, if we put the target date on the early start date, we can perform the space allocation with the "as soon as possible" rule, and on the other hand, if we put the target date on the latest start date, we perform the space allocation with the "as late as possible" rule.
- Group of blocks g_j several blocks can be grouped so that the optimizer will find a position for them as if they are a single unit. The advantage is that we can simulate the impact of the production of blocks nearby similar ones. Thus the optimization module takes into account a group of blocks as a huge block. A snap tool was implemented to link several blocks together;
- Preferential zone q_j This field indicates the zone in which it is preferable to produce the blocks;
- Ship zone p_j This field indicates the zone of the ship to which the blocks belongs. During the optimization we are trying to group the block from the same ship zone together to decrease the movements of the gantry crane;

Fig. 5 Date and duration of an activity

5 The Graphical User Interface (GUI)

The first part of the tool is an interface for the user (usually a planner or construction manager) to interact with the block attributes, schedule information, and the actual placement of the units within a production working area. A color code is used to show the different status of the blocks.

The main frame of the GUI is divided into two windows. One is the spatial view of the workshop (top view of the workshop on a given date) the other is the timeline view (top view of the workshop with a dimension in space and a dimension in time). These two frames interact in order to display the situation of the workshop at different dates by the dragging of the daily line in the time-line view.

5.1 Spatial view of the workshop

This frame (see Fig. 6(a)) simply shows a top overview of the workshop at a selected date. It is possible that certain blocks will appear or disappear, depending on when those blocks were placed and when they are scheduled to be complete.

The user can move blocks (drag and drop) inside space (X and Y) for the day selected. The main blocks attributes like length, width, height, weight and schedule information such as scheduled start date, planned duration, earliest starting date, latest ending date, actual start can be edited in a properties windows.

5.2 Time-line view of the workshop

The time-line frame (see Fig. 6(b)) shows an overview of each working area with an axis for the time (horizontal axis) and another one for a dimension (X or Y - vertical axis). The user can move blocks along the temporal and spatial (X or Y) dimension by a simple drag and drop. However the displacement of the blocks is limited between the earliest start date and the latest end date, see Fig. 5. The vertical line can be placed on a precise day of the time-line and shows the state of all areas at this date.

5.3 Detection of overlaps

The user is also notified of any collisions between overlapping blocks. The tool detects all the collisions and overlaps between the blocks, not only occurring for the present time, but also for the entire planning period.

5.4 Towards the automated planning

While the spatial scheduling tool (GUI) provides a planner with several features to generate efficient spatial plans more rapidly, the actual method of allocating space is not much different than current shipyard practices, where block placement decisions are based on expert-user knowledge. The following section describes a method to automatically allocate and optimize space according to heuristic algorithm. While it is nearly impossible to capture the entire set of rules, constraints, and preferences used to generate a near-optimal spatial layout, the automated scheduler can be used to generate a valid baseline layout, and the end-user can make modifications to this layout using the spatial scheduling tool.

6 Optimization of space allocation

6.1 Optimization variable and objective function

The STA problem consists in orthogonally ordering the n blocks into the m rectangular areas, without overlapping, and so as to respect the time constraints, with the objective to produce the largest possible number of building blocks.

To achieve this, we defined the following decision variables for each block $j = 1, 2, \dots, n$:

- Position of the block x_j and y_j ;
- Starting date of the activity $s_j \in \{r_j, \cdots, d_j t_j\};$
- The block orientation $o_j \in \{0, 1, 2, 3\};$
- The working area $a_j \in \{1, 2, \cdots, m\};$
- Subcontractor possibility $b_i \in \{0, 1\}$.

(a) Spatial view at a given date

(b) Time-line view – where the vertical axis represents spatial X dimension and the horizontal axis the time-line

Fig. 6 Main frame of the space allocation optimization tool

In addition, each variable can be fixed so that the optimization algorithm does not have the opportunity to modify the value. For example, this feature is used to define the daily production situation of the workshop (real block position inside the workshop).

A solution, that is to say an assignment of values to the above variables, is feasible if the individual and the collective constraints are met. We call individual constraints those which bear on one block only, regardless of the other blocks. The individual constraints can be modelled as follow:

- 1. each block must fit within the with of an area a_j : $x_j \ge 0$ and $x_j + [o_j w_j + (1 - o_j)l_j] \le W$;
- 2. each block must fit within the length of an area a_j : $y_j \ge 0$ and $y_j + [o_j l_j + (1 - o_j)w_j] \le L;$
- 3. each block must fit in its time window: $s_j \ge r_j$ and $s_j + t_j \le d_j$

On the other hand, collective constraints deal with the interaction between the positions of different blocks. unless we mention otherwise, the only collective constraint is that the blocks may not overlap.

6.2 Algorithm

As previously mentioned our developments are based on the solutions presented by [22] for the 3D-BPP problem.

6.2.1 General approach

Let X be any solution of the STA problem, that is, any assignment of values to the variables a_j, x_j, y_j, o_j and s_j for $j = 1, 2, \ldots, n$. We implicitly assume that $b_j = 1$ for all j. While trying to find a feasible schedule, our local heuristic search strictly enforces the individual block constraints, meaning that X always satisfies the constraints (1)-(3). On the other hand, we do not enforce the collective constraints, but we measure the extent of their violation and these measures are summed in an auxiliary objective function to be minimized. Without additional real-life collective constraints, the extent of the violations can be measured by the total "volume" $[m^2 \times days]$ of pairwise overlaps between the *n* blocks. Thus, if we denote by $overlaps_{ii}(X)$ the volume of the overlap between blocks i and j, then the auxiliary objective function can be formulated as shown in equation 1.

$$f(X) = \sum_{1 \le i < j \le n} overlap_{ij}(X) \tag{1}$$

Starting from an arbitrary infeasible solution where blocks can overlap, searching for a feasible solution can be achieved by minimizing the function f, since an objective value of zero indicates that all the collective constraints are satisfied, see Fig. 7.

A typical local search procedure starts by moving from the current solution X to another X' in a neighbourhood $\nu(X)$ whenever this move improves the value of the objective function. Slightly adapting the framework of [22], who do not allow rotating the boxes, we define the neighbourhood $\nu(X)$ as the set of all solutions that can be obtained by translating any single block along the coordinate axes or along the time-line, or by a move of the same relative position in another area of the working surface, or by a ± 90 degree rotation of a block around one of its four corners. A neighbour of X is therefore constructed by assigning a new value to exactly one of the variables x_j, y_j, s_j, a_j or o_j . It is clear that this definition allows to move from any solution to any other solution through a sequence of neighbours.

It is well-known that local search procedures may easily get suck in a local minimum of poor quality. Another difficulty with local search procedures is that the neighbourhood of any given solution may be quite large and therefore, exploring the neighbourhood to find an improving move can be very costly in computation time. To deal with the above issues, we rely on the Guided Local Search (GLS) heuristic, and its accompanying neighbourhood reduction scheme called Fast Local Search (FLS).

Fig. 7 Optimization flow of the STA problem – where X^* is the best available solution, X_0 is the initial solution, $f(X^*) = 0$ represents a solution without overlaps, t measures the runtime, T is the runtime limit, GLS is the Guided Local Search

6.2.2 Guided local search

Generally speaking, GLS augments the objective function f of a problem to include a set of penalty terms associated with "undesirable features" of a solution, and it considers the new function h, instead of the original one, for minimization by a local search procedure. This procedure is confined by the penalty terms and focuses attention on promising regions of the search space. Each time the local search procedure gets caught in a local minimum, penalties are modified and the local search procedure is called again to minimize the modified objective function. This general scheme has been adapted to 3D-BPP by [22]. In their precedure, the features of a solution X are the Boolean variables $I_{ii}(X) \in 0, 1$, which indicate whether blocks i and j overlap $I_{ij}(X) = 1$ or not $I_{ij}(X) = 0$. The value of the $overlap_{ij}(X)$ measures the impact of the corresponding feature on the solution X. The number of time an "active" feature has been penalized is denoted by p_{ij} , which is initially zero. Thus, the augmented objective function takes the form shown in equation 2, where λ is a parameter – the only one in this method – that has to be chosen experimentally.

$$h(X) = f(X) + \lambda \sum_{1 \le i < j \le n} p_{ij} I_{ij}(X)$$

=
$$\sum_{1 \le i < j \le n} overlap_{ij}(X) + \lambda \sum_{1 \le i < j \le n} p_{ij} I_{ij}(X)$$

(2)

Intuitively speaking, Guided Local Search (GLS) attempts to penalize the features associated with a large overlap, but which have not been penalized very often in the past. More formally, we define an utility function $\mu_{ij}(X) = overlap_{ij}(X)/(1+p_{ij})$ for each pair of blocks (i, j). At each iteration the procedure adds one unit to the penalty p_{ij} corresponding to the pair of blocks with maximum utility, then calls the local search procedure, see Fig. 8. In a sense, the search procedure forced to set a higher priority on these features. Since features with maximum utility keep changing all the time, this guiding principle prevents GLS from getting stuck in local minima.

The adaptation of the algorithm has been numerically validated and tested for several standard test cases and published in [24] and [25].

6.2.3 Fast local search

The main objective of Fast Local Search (FLS) is to reduce the size of the neighbourhoods explored in the local search phase, by an appropriate selection of moves that are likely to reduce the overlaps with maximum utility.

To describe the FLS, consider any solution X and any variable m among the variables x_j , y_j , s_j , a_j , o_j with $j \in [1, ..., n]$. Informally, FLS selects at random a variable m within a list of activate variables, as long as this list is not empty – active variables are those which are most likely to lead to an improvement of the current solution. The, FLS searches within the domain of m for an improvement of the objective function. If no improvement is found, then the variable m becomes inactive and is removed from the list until the end of the current call of FLS.

More formally, we define $\nu_m(X)$ as the set of all solutions which differ from X only by the value of variable m. The neighbourhood $\nu(X)$ is thus divided into a number of smaller sub-neighbourhoods as shown in equation 3.

$$\nu(X) = \bigcup_{m} \nu_m(X) \tag{3}$$

Each of the sub-neighbourhoods $\nu_m(X)$ can be either active or inactive. Initially, only some sub-neighbourhoods are active. FLS now continuously visits the active subneighbourhoods in random order, see Fig. 9. If there exists a solution X_m within the sub-neighbourhood $\nu_m(X)$

Fig. 8 Optimization flow of the GLS(X,T) – where X is the current solution, X^* is the best available solution, X_0 is the initial solution, t measures the runtime, T is the runtime limit, FLS is the Fast Local Search, p_{ij} is the penalty for all pairs of blocks, (i, j) is a pair of block, and h(X) is defined in equation 2

such that $h(X_m) < h(X)$, then X becomes X_m ; otherwise we suppose that the selected sub-neighbourhood will provide no more significant improvements at this step, and thus it becomes inactive. When there is no active sub-neighbourhoods left, the FLS procedure is terminated and the best solution found is returned to GLS.

Fig. 9 Optimization flow of the FLS(X, (i, j)) – where X is the current solution, (i, j) is a pair of block, *activelist* is the list of the variables associated with the moves applicable to blocks i and j, and to the blocks overlapping either i or j, m^* is the best value of m, i.e. the best move reducing more the objective function, X_m is the solution obtained by setting $m := m^*$ in X, and h(X) is defined in equation 2

The size of the sub-neighbourhoods related to the a_i and the o_i variables is relatively small, therefore FLS is set to test all the neighbours of these sets. On the other hand, using an enumerative method for testing the translations along the x, y, and s-axes would be very time consuming, especially when areas and/or time windows are large. We may observe, however, that only certain coordinates of such neighbourhoods need to be investigated. Indeed, as pointed out by [22], all $overlap_{ij}(x)$ functions (respectively $overlap_{ij}(y)$, $overlap_{ij}(s)$ are piecewise linear functions, and will for that reason always reach their minimum in one of their breakpoints or at the limits of their domains. Thinking of the geometry of the 3D-BPP, we can easily understand that a best packing arises either when the boxes touch each other along their faces, or when they touch the sides of the bins, see Fig 10. As results, FLS only needs to comput the values of f(x) (respectively, f(y), f(s)) for x (respectively, y, s) at breakpoints or extreme values. In fact, there are at most four breakpoints for each overlap function, and only the first and the last are evaluated.

Once all active moves have been deactivated by the FLS, two possibilities remain. If the total objective is null, the process is finished. In the other case all the moves will become inactive, because no more improving moves exist. A local minimum is reached and the FLS iteration is finished. The process starts again at the first step and as those overlaps cannot be solved, they will sometimes be selected as the pair having the maximum utility. When this occurs, moves of these blocks are reactivated and their penalties are increased. So, if we add the penalties to the objective function, the objective function value of the actual solution will enlarge and moves improving the objective function will appear, even if the result will be worse in term of overlap. But now we have left the local optimum and a better solution can be found after several iterations.

6.2.4 Selecting the blocks

In the previous sections, we described a GLS heuristic to find a feasible solution of the STA problem. If GLS works as expected, then it should return a space and time allocation with zero overlap, i.e. a feasible solution, when there is one. In general, however, no such feasible solution may exist for the set of blocks initially included in the instance, and we face the problem of selecting a maximum subset of blocks to be scheduled for assembly. In order to solve this problem we rely on the following assumption telling that if GLS cannot find a feasible solution of STA within a predetermined amount of computation time T, then the heuristic assumption is that the instance is probably infeasible.

A procedure has been developed allowing to add and remove blocks from the current set, see Fig. 11. Thus, assume that, at any iteration of the procedure, X is a solution (feasible or not) involving some subset of

Fig. 10 Illustration of FLS neighbourhood size reduction

blocks. If the solution GLS(X, T) returned by GLS is feasible, then this solution is candidate to be the final optimal solution. So, we record it if it is better than the best incumbent solution X^* , and we try to include an additional block in the set. On the other hand, if GLS(X, T) is not feasible, then a fast post-processing step is performed to produce a feasible solution X': this is achieved by simply removing blocks in a greedy fashion until all overlaps are cancelled. The solution X' is recorded if it is better than the incumbent X^* ; then, we remove an overlapping block from GLS(X, T) and the process is repeated. The procedure is stopped after a predetermined amount of computation time, or by any more sophisticated stopping criterion, and returns the feasible solution X^* involving the largest collection of blocks.

Fig. 11 Optimization flow of the block selection – where X is the current solution, X^* is the best available solution, X' is a feasible solution generated by GLS, X_0 is the initial solution, t measures the runtime, T is the runtime limit for GLS and T_{max} is the global runtime limit of the optimization

6.2.5 Additional constraints

The general case of the academic problem is not relevant in the practical sense due to the fact that the shipbuilding industry has significantly more complex constraints than those of the general case. Various sideconstraints have to be considered in order to increase the practical relevance of the STA model. Fortunately, the GLS framework proved flexible enough to incorporate most of these constraints without too much additional effort. For example, in practice, it may be necessary to restrict or to impose the position of certain blocks, e.g., because these blocks are already in process when the planning process is launched, or because some required handling or production equipment is only available in a particular area, etc. Such individual constraints on blocks are easily handled by the GLS algorithm: forbidden positions and infeasible neighbours are simply not generated during the search. Thus, in practice, the end-user may fix the value or reduce the domain of any variable when using the software. For instance, he may prohibit the rotation of some blocks or/and their translations or/and the working area.

Another industrial constraint that can occur is to allocate the preferential zones q_j defined in section 4.2 for some specific blocks. In other terms, the GLS will allocate the block taking into account a certain priority instead of using a random selection of the blocks. Other priorities can easily be defined taking into account other parameters such as the block weight, the block size or the block complexity.

More complex collective constraints also appeared in the real-life situation. In particular, for the assembly halls, each working area has a single door, and the crane bridge can only carry the blocks up to a certain height C, see Fig. 12. As a result, it may happen that a tall block obstructs the door or stands otherwise in the way, and some blocks may not be delivered in time because there is no feasible passageway to carry them out of the hall. Here again, the GLS approach proved "generic" enough to deal with this issue. For each generated solution X, we added to the objective function h(X) a new penalty term which accounts for exit difficulties as shown in equation 4, where $exit_{ij}(X)$ measures the overlap between block i and the "exit path" for block j.

$$g(X) = h(X) + e(X)$$

= $\sum_{i < j} overlap_{ij}(X) + \lambda \sum_{i < j} p_{ij}I_{ij}(X) + \sum_{i < j} exit_{ij}(X)$
(4)

The exit path for j is restricted by security constraints which impose to use a straight path, and thus it is determined by:

- the longitudinal interval $[x_j, x_j + o_j w_j + (1 o_j)l_j];$
- the transversal interval $[0, y_j + (1 o_j)w_j + o_jl_j]$, as the doors are at position y = 0;
- the vertical interval $[C h_j, C]$, since each block can be carried up to the height of the crane;

- the completion date $s_j + t_j$ of block j;
- the area a_j where block j is produced.

Note that the value of the exit terms could somehow be scaled in relation to the h(X) values, but this did not appear to be useful in our procedure, as the new penalty terms proved sufficient to drive the objective function to zero.

Fig. 12 Illustration of overlaps due to crane movements

Additional collective constraints arise when a family of related blocks have to be produced for a ship. For example, all the blocks that include the emergency boats require similar production equipments, and it is convenient to allocate them to a same zone of the working area. In a similar way, two blocks that are adjacent in the ship structure may need to be produced next to each other in the assembly area, so as to allow a fine positioning of connecting elements such as structural members or piping tracks. An easy way to cope with the latter requirement is to define a super-block that includes the two (or more) adjacent blocks and to replace the individual blocks by this super-block in the data of the problem. With the variable g_i described in section 4.2, several blocks can be grouped so that the GLS will find a position for them as if they are a single unit. This parameter doesn't affect directly the GLS algorithm but increases considerably the end-user flexibility. For the first situation, however, this method is too restrictive, and we preferred instead to define a "distance" constraint. With the variable p_i described in section 4.2, GLS will minimize the relative distance between two blocks in order to reduce the undesired movement of the gantry crane.

Other collective constraints could certainly be included in the model by taking full advantage of the flexibility of the GLS framework.

J-D. Caprace et al.

6.2.6 Robustness

The GLS procedure, always starts from an initial solution X_0 . A drawback of this approach is that the structure of X_0 can confine the GLS to an area of the solution space that can be difficult to escape (especially for small values of λ), and therefore, the search process may not reach the very best solution.

However, in a dynamic industrial setting, this apparent drawback turns out to be an advantage. Indeed, it may be very costly, or practically impossible for the company to frequently readjust the schedules and the allocation of blocks to the working areas. By generating new solutions from previous ones, the GLS procedure actually ensures that the structure of previous solutions can be preserved when the production plans are updated. This is to be contrasted with various methods proposed for rectangle packing problems, which typically rely on construction strategies and for which a slight modification of the data may lead to major perturbations of the solution. As a consequence, it may prove rewarding to run GLS with a relatively small value of λ in the industrial context.

7 Case study

7.1 Presentation

This case study focuses on the assembly shop of an European shipyard where relatively small sections (60 ~ 120 tons) are joined together to form huge blocks (550 ~ 750 tons). Typically, the ship is then erected in the dry dock block-by-block until the ship is finished using a gantry crane.

The modelling of this workshop contains four working areas (see Fig. 13) as well as the dry dock. The "bin" is an additional area where blocks are temporary placed if they are not allocated.

Fig. 13 Layout of the assembly shop considered for the case study $\$

A dataset of 268 blocks have been considered where 61 blocks are fictitious and mainly represent part of the ships in construction in the dry dock, 51 blocks are fixed and represent the actual situation of the working areas and finally 156 blocks should be allocated to solve the STA problem. The surface of the blocks to be allocated is varying between $200m^2$ and $1800m^2$ with an average of $750m^2$. The dimensions of the blocks to be allocated (width and length) are varying between 8.5m and 50mwith an average of 28m. The time period of the dataset is about 1.5 year. The working duration of the blocks is varying between 15 and 68 days with an average of 40 days. This dataset correspond to a highly constrained shipyard STA problem where the space available inside the workshop is quite similar or superior to the sum of the block surface.

7.2 Manual and automatic scheduling

Manual allocation of activities. Manually, the user can drag and drop a non-allocated block from "bin" area into an empty working area. Even if an area seems to be void, another block may have been allocated to this place some days later. The software detects automatically such conflicts: critical blocks will directly change color. A double click on any block shows directly all block attributes. Multi-selection is also available to change the value of any parameters for several blocks.

Allocation of activities with the optimization module. In practice, allocating blocks with the optimization tool ensures that there is no collision. The optimizer tool gives always a feasible solution.

While it is nearly impossible to capture the entire set of rules, constraints, and preferences used by the planner, the optimization module can be used to generate a valid baseline layout, and the end-user can make modifications to this layout using the GUI. The tool of overlapping detection is very powerful in this case of manual adjustment of final optimized solution.

If no feasible solution is found by the optimization algorithm, the user can directly see which blocks lead to problems and then choose an adapted solution. The user can identify the production surface utilization problems that may happen for the actual data (basically the fact that not all blocks can be produced in time). He may for example raise the workforce availability or subcontract some blocks.

Day to day optimization. The difficulty in space allocation, or spatial scheduling, arises in the fact that the allocation of space to one block significantly affects the availability of floor space to the other blocks. Scheduling production space to satisfy an erection schedule becomes even more complex when unexpected changes to the schedule occur (modification of block duration, production delays, etc.).

In order to take into account this constraint, we implemented the possibility to fix the attribute of some blocks so that they cannot be moved by the optimizer. This functionality is useful to define the starting state of the workshop: blocks already in the workshop cannot be moved during the optimization!

Data connection. A link between the current Enterprise Resource Planning (ERP) system of the shipyard and the software was also implemented to update all attributes of blocks before an optimization. When a modification occurs inside the planning (activities duration, block dimensions, production delays, etc.) the latest information are always available for the optimization.

7.3 Results and achievements

A comparison between the manual allocation of activities and the optimization algorithm has been done by a planner of the shipyard. The planner used a simplistic allocation rule such as the allocation of the first block in one corner and processing by rows or by columns. Nevertheless, we considered some additional constraints such as the safety distance between the block or the possibility to rotate the blocks in order to improve the solution.

The main problem during the allocation of the blocks is that the planner does not foresee the scheduling of the blocks along the time. For an optimal allocation of the activities the optimization algorithm is really helpful.

Tab. 1 as well as Fig. 14 show the relative gains between the manual and the automatic allocation of the blocks (optimization algorithm).

We observe in Tab. 1 that the working surfaces are better used (gain of 12.7%) because more blocks have been allocated during the same considered period (137 blocks instead of 118 blocks). In the case of the optimized schedule only 19 blocks have not been allocated while for the manual solution 38 blocks have not been placed. However, the planner should find a solution to allocate the remaining 19 blocks that cannot be produced in time. He may for example raise the workforce availability to reduce the working duration or subcontract some blocks. Furthermore the average utilization of the working areas have been improved as shown in Fig. 14(d). Both of the solution, i.e. the manual scheduling and the automatic scheduling, have been considered feasible by the planner of the shipyard. Nevertheless, he corrected 3% of the position of the blocks for the optimized solution taking into account additional constraints.

Description	Unit	Manual	Optimized	Gair
Surface used	$m^2 \times days$	3593324	4115958	12.7%
Block placed	#	118	137	13.8%
Block not placed	#	38	19	50%

 Table 1 Gain between the manual and the automatic allocation

In addition the scheduling time is drastically reduced (hours instead of days). This is probably the most interesting advantage of the developed tool. The planner considered that the tool can contribute to improve production scheduling works and appreciate particularly that he is now able to evaluate various production scenarios in a short time.

For small problems, when space available inside the workshop is largely superior to the sum of the block surface, computation times are between 30 and 150 seconds for ~ 250 blocks. For more constrained problems, when the space available inside the workshop is quite similar to the sum of the block surface, the time required to find an optimized solution increases from 5 minutes to 1 hour.

Without the tool such planning could take several days. Consequently another advantage of the tool is that different schedules can be tested. For instance, if any production parameter is changed such as the block splitting or the number of ship to produce simultaneously, the impact on the total production time can easily be studied. These kinds of studies were not possible manually.

8 Conclusions

In this paper, we have presented a space and time allocation problem arising in large shipyards, and we have modelled it as a 3-dimensional bin packing problem.

We have demonstrated the main advantages of the GLS to solve the STA problem:

- Good correspondence between results obtained and industrial constraints;
- Low computation time (some minutes);

- Four dimensional problems are solved (three spatial dimensions and one temporal dimension);
- Solution obtained is always feasible;
- If a schedule modification arises and causes an overlap between blocks, the algorithm will be able to solve only locally the issue without modifying the global solution.

The proposed innovative approach allows a more efficient scheduling for the shipyard. The planner can test more alternatives and rapidly modify the scheduling to

(a) Time-line – Manual (b) Time-line – Optimized

(d) Surface utilization in % vs. time

Fig. 14 Comparison of the time-line results between the manual and automatic allocation, where 14(a) and 14(b) present the time-line view where the vertical axis is the spatial X dimension and horizontal axis the time-line and 14(c) and 14(d) present respectively the number of blocks and the surface utilization ratio in function of time

find the best one. But the preparation and verification of data for the simulation remain a major stage to ensure the reliability of the results.

Gains obtained for the shipyard are substantial. The workshop productivity by using the new concept is increased as less time is needed for scheduling and a better space utilization is achieved.

This generic approach allows incorporating various reallife constraints and leads to the successful implementation of a flexible and robust application for the shipbuilding industry, but potentially also for other industries.

9 Future work

The work outlined in this paper presents a new promising method for shipyard spatial scheduling. Nevertheless, several improvements or integrations of new constraints could be performed:

- An extension of the rectangular shapes for workshops and/or blocks to any shapes. However this would require a complete overhaul of the software and his optimization method.
- An implementation of a tool to fit and smooth the workload of the workshop to the workforce available. It could be done during the optimization phase as a multi objective optimization.
- Development of a tool to consider predecessors and successors for the different activities to be allocated.
