International Scientific Conference

ABSTRACT BOOK

7-10 July 2015 • Paris, France

This Abstract book is based on a compilation of all abstracts selected for oral and poster presentations, as of 15 May 2015.

Due to the inability of some authors to attend, some of those works will therefore not be presented during the conference.

OUR UNDER
COMMON CLIMATE
FUTURE CHANGE

Welcome to the Conference

Welcome to Paris, welcome to 'Our Common Future under Climate Change'!

On behalf of the High Level Board, the Organizing Committee and the Scientific Committee, it is our pleasure to welcome you to Paris to the largest forum for the scientific community to come together ahead of COP21, hosted by France in December 2015 ("Paris Climat 2015").

Building on the results of the IPCC 5th Assessment Report (AR5), this four-day conference will address key issues concerning climate change in the broader context of global change. It will offer an opportunity to discuss solutions for both mitigation and adaptation issues. The Conference also aims to contribute to a science-society dialogue, notably thanks to specific sessions with stakeholders during the event and through nearly 80 accredited side events taking place all around the world from June 1st to July 15th.

When putting together this event over the past months, we were greatly encouraged by the huge interest from the global scientific community, with more than 400 parallel sessions and 2200 abstracts submitted, eventually leading to the organization of 140 parallel sessions.

Strong support was also received from many public French, European and international institutions and organizations, allowing us to invite many keynote speakers and fund the participation of more than 120 young researchers from developing countries. Let us warmly thank all those who made this possible.

The International Scientific Committee deserves warm thanks for designing plenary and large parallel sessions as well as supervising the call for contributions and the call for sessions, as well as the merging process of more than 400 parallel sessions into 140 parallel sessions. The Organizing Committee did its best to ensure that the overall organization for the conference was relevant to the objectives and scope. The High Level Board raised the funds, engaged the scientific community to contribute and accredited side events. The Conference Secretariat worked hard to make this event happening. The Communication Advisory Board was instrumental in launching and framing our communication activities on different media. We are very grateful to all.

We very much hope that you will enjoy your stay in Paris and benefit from exciting scientific

interactions, contributing to the future scientific agenda. We also hope that the conference will facilitate, encourage and develop connections between scientists and stakeholders, allowing to draw new avenues in the research agenda engaging the scientific community to elaborate, asses and monitor solutions to tackle climate change together with other major global challenges, including sustainable development goals.

L1.1 - Climate variability and change over the last millennia: Paleoclimate information and climate simulations

K-L1.1-01

Model-data comparison over the last millennium: progress, uncertainties and challenges

F. Gondalez Rouco (1)
(1) Instituto de Geociencias, Madrid, Spain

Present day climate variability and change, including recent anthropogenic warming, poses questions that cannot be answered based solely upon instrumental records. The last two millennia (L2k), and specifically the last millennium (LM), are immediate temporal intervals that involve climate processes similar to nowadays. The last 2k and LM have the potential to expand our understanding of climate variability from inter-annual and decadal to multi-centennial timescales, place a wider context for current warming and explore internally induced and externally forced responses of the climate system. Knowledge about proxy-based climate reconstructions, paleoclimate model simulations and estimations of external radiative forcing emerge then as key elements to gain insights about the relative roles of internal versus forced variability.

Comparisons of last millennium simulations and reconstructions constitute opportunities for learning about pre-instrumental climate variability beyond the lessons that climate simulations or reconstruction efforts can offer by themselves. Model-data comparisons provide insight about the relative roles of internal variability and external natural or anthropogenic induced changes and the processes involved. The relatively short ranges of external forcing variability within the last 2k/LM nevertheless make these comparisons challenging and further complicated by the large uncertainties that affect both reconstructions and model simulations (Masson-Delmotte et al. 2013).

This work reports on the progress of about a decade of efforts in L2k/LM model-data comparison and discusses how model-data comparison exercises focused on the last millennium can improve our understanding of decadal to multi-centennial climate variability as well as contribute to our knowledge of present and future climate and/or associated projection uncertainties. For this purpose, the available continental, hemispherical and global L2k/LM temperature reconstructions, an ensemble of simulations including both Paleoclimate Modelling Intercomparison Project Phase III / Coupled Model Intercomparison Project Phase 5 (PMIP3/CMIP5; Taylor et al 2012) and non-PMIP3 model experiments, as well as the external forcing configurations applied (Schmidt et al 2012) are analysed. In addition, for each simulation considered, a total external forcing (TEF), including all individual forcing factors, is estimated as a simple approach to compare the total radiative forcing applied to each experiment (Fernández-Donado et al., 2013).

At hemispherical and global scales, simulations and reconstructions broadly agree on the major temperature changes and suggest, despite the important influence of the internal variability, an overall linear response to external forcing above multidecadal timescales. The rate of temperature response to LM changes in TEF is quantified as a metric of the transient climate response during the LM (LMTCR) and its distribution from the model and reconstructed ensembles are compared to other estimates of climate sensitivity and transient climate response. LMTCR also allows to frame a simple quantitative comparison between simulations and reconstructions where discrepant behaviors can be singled out. The uncertainties in reconstructions and model experiments that impact our understanding of simulated and reconstruction responses at these spatial scales are also discussed.

At regional/continental scales we focus on the assessment of PMIP3/CMIP5 experiments and temperature reconstructions developed within the PAGES 2k project (PAGES 2k consortium 2013) and their responses to forcing and report on their consistency across regions and timescales. Inter-regional behavior is more homogeneous in the simulated than in the reconstructed climates. Agreement between simulations and reconstructions is higher for Northern Hemisphere regions whilst models disagree more with the reconstructions in the Southern Hemisphere.

Variability of the North Atlantic Oscillation during the past millennium

V. Masson-Delmotte (1) ; P. Ortega (2) ; F. Lehner (3) ; D. Swingedouw (4) ; CC. Raible (5) ; M. Casado (6) ; P. Yiou (7)
(1) IPSL, Paris; (2) 1LSCE/IPSL, UMR 8212 (CEA-CNRS-UVSQ), CEA Saclay , Gif-sur-Yvette, France; (3) University of Bern, , Climate and environmental physics, physics institute,, Bern, Switzerland; (4) Universite de Bordeaux, UMR CNRS 5805 EPOC, Pessac, France; (5) University of Bern, Climate and environmental physics, physics institute, Bern, Switzerland; (6) 1LSCE/IPSL, UMR 8212 (CEA-CNRS-UVSQ), CEA Saclay, Gif-sur-Yvette, France; (7) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France

The North Atlantic Oscillation (NAO) is the dominant mode of winter atmospheric circulation variability in the Northern Hemisphere. This atmospheric mode is characterized by a changing dipole of sea-level pressure between the Azores and Iceland, and has widespread impacts on temperature, precipitation, storm tracks and therefore on strategic sectors such as insurance, renewable energy production, crop yields and water management.

Recent developments of dynamical methods offer promising advances for seasonal NAO predictions. However, assessing potential predictability at multi-annual time scales requires a documentation of past NAO low-frequency variability. A recent bi-proxy NAO reconstruction spanning the last millennium suggests that long-lasting positive NAO conditions were established during medieval times, explaining the particularly warm conditions over Europe; however, this result is still debated. Here, we present a new annually-resolved NAO reconstruction for the last millennium based on an initial selection of 48 proxy records distributed around the Atlantic Ocean and surrounding continents and built through an ensemble of multivariate regressions. This approach has been validated in perfect model analyses, using climate simulations as physically consistent surrogates of the real world. The analysis makes evident that the multi-proxy reconstruction outperforms the bi-proxy index.

The final reconstruction shows no persistent positive NAO during the medieval period, but suggests that positive phases were dominant during the thirteenth and fourteenth

centuries. It also reveals that a positive NAO emerges two years after strong volcanic eruptions, consistent with results obtained from models and satellite observations for the Mt Pinatubo eruption in the Philippines.

K-L1.1-03

European summer hydroclimate variability during the last millennium

H. Linderholm (1) ; K. Seftigen (2) ; E. Cook (3) ; D. Chen (4) ; T. Ou (4)
(1) University of Göteborg, Institute of geography, Göteborg, Sweden; (2) Swiss Federal Research Institute WSL, Birmensdorf, Switzerland; (3) Columbia University, Lamont-doherty earth observatory, Columbia, United States of America; (4) Gothenburg University, Department of earth sciences, Gothenburg, Sweden

Associated with global warming, changes in extreme weather and climate events have been observed in Europe, including increased frequencies of heat waves as well as the frequency or intensity of heavy precipitation events. In a future warmer world, it is likely that the risk of hydroclimatological extremes will increase. Extreme hydroclimate events, such as droughts and floods, can have significant impacts on society, e.g. by affecting food availability, water quality, health, energy, infrastructure etc., but also on ecosystems. It is apparent that climate variability and change already pose a challenge to Europe's economic sectors, production systems, and ecosystems. Increased drought frequency will significantly affect natural and human systems, and compared to other hazards, hey can persist for long periods and affect large areas. Floods, associated with heavy precipitation events, can pose threats to human life and property, and also affect water quality, e.g. by spreading pollutants and fertilizers.

Clearly, society must prepare for an intensification of hydroclimate extremes in the future. However, major uncertainties and knowledge gaps still exist in understanding and modeling hydroclimate, making it difficult to quantify future changes and their impacts on systems and sectors. A prerequisite to mitigate extreme hydroclimatological events is good understanding of their spatiotemporal characteristics as well as the mechanisms generating such events. However, the lack of instrumental observations limits the period of spatial analysis to the recent century, making it difficult to fully understand natural hydroclimate variability.

Tree rings can provide annually resolved environmental and climate information and are widely used as proxies of past climatic events, such as drought or floods. The wide geographical distribution of tree-ring chronologies, compared to most other high-resolution climate proxies, provides a potential to infer past climate change on large spatial scales. Recently, past hydroclimate variability has been reconstructed from networks of moisture-sensitive tree-ring chronologies in North America and Monsoon. These reconstructions have not only provided valuable information of past hydroclimatic characteristics, but they have also contributed essential background data for increasing the understanding of the underlying mechanisms of past drought variability.

This presentation will focus on a new reconstruction of summer hydroclimate variability in Fennoscandia during the last millennium. Using tree-ring data from a dense network, a point-by-point multiple nested regression approach was used to reconstruct June through August average Standardized Precipitation Evapotranspiration Index (SPEI) with a spatial resolution of 0.5°x 0.5°. We will show that the data provides highly useful information of regional natural hydroclimate variability in time and space in a long-term context, making it possible to assess the impact of global warming on hydroclimate in Fennoscandia. It also allows for identification of historical extreme hydrological events, including severity, duration and magnitude. Moreover, we will discuss potential drivers of hydroclimate regional drought variability on different time scales. Finally, we will take a broader, European, look on summer hydroclimate variability during the last 1000 years.

K-L1.1-04

Atmospheric carbon dioxide tracks climate and land carbon changes during the past millennium

T. K. Bauska (1)
(1) University of Cambridge, Department of earth sciences, Cambridge, United Kingdom

The land carbon reservoir is predicted to turn into a net source of carbon to the atmosphere if global warming continues unabated. Multi-decadal, global-scale observations needed to test this predication are difficult adding uncertainties to projections of atmospheric CO2 and climate. Ice core records of the last millennium document atmospheric CO2 variations on multi-decadal to centennial timescales but attempts to constrain the underlying drivers of atmospheric CO2 using the stable isotopic composition of atmospheric carbon dioxide (δ13C-CO2) have been limited by the precision and temporal resolution of existing data. This spurred discussion on the magnitude of climate-carbon feedbacks and emissions from past anthropogenic land use change .

We developed a new high-resolution, high-precision ice core record of δ13C-CO2 and use it to show that terrestrial organic carbon likely controlled multi-decadal scale atmospheric CO2 variability from 760-1850 C.E. Our results put strong limits on the net source of land carbon to the atmosphere prior to the Industrial period. If significant long-term carbon emissions came from pre-industrial anthropogenic land-use changes, they must have been offset by some natural 13C depleted land sink, plausibly peatlands. On multi-decadal timescales, carbon cycle changes appear to covary with reconstructed regional climate changes, consistent with climate as an important driver of land carbon storage on these time scales.

Our new observations present a challenging benchmark for models attempting to simulate the climate and carbon cycle of the past in order to understand the projections for the future. However, reducing the uncertainties in past temperature reconstructions and developing stronger constraints on pre-Industrial anthropogenic emissions are likely needed to provide further insight into climate-carbon cycle interactions.

L1.2 - Climate Change and Land Systems: Impacts and Feedbacks

K-L1.2-01

Climate change and land systems: Impacts and feedbacks related to drought

S. Seneviratne (1)
(1) ETH, Zurich, Institute for atmospheric and climate science, Zurich, Switzerland

Land systems have numerous two-way interactions with the climate system. While they are often strongly affected by climate variability and changes, in particular in relation to droughts and hot extremes, they also impact climate through direct forcing and feedbacks. In particular, the modulation of soil water dynamics by ecosystems is an important factor affecting itself the evolution of droughts and heatwaves in several regions. In addition, human management, e.g. through changes in surface properties associated with agriculture practice, also affects these interactions. This presentation will provide a brief overview of the underlying mechanisms, including insights from new research, and will introduce the main topics addressed in this session.

K-L1.2-02

Climate and the water-energy-food nexus

C. Dalin (1)
(1) LSE, Grantham research institute,, London, United Kingdom

Water, energy and food are essential for human well-being, and socio-economic development. Global projections indicate that demand for these resources will increase significantly over the next decades, under the pressure of population growth, economic development, urbanisation, diversifying diets, cultural and technological changes, and climate change (Hoff 2011). Annual and seasonal climate variability, as well as climate change, strongly affect all components of the water-energy-food nexus, adding to the challenge of using resources sustainably across sectors. While uncertainties remain high, climate models project decreases in annual precipitation in many developing countries, e.g. by as much as 20% in southern Africa by 2080. These changes would propagate into reduced water availability and crop yields, which, combined with projected population growth, reinforces the need for planners to collaborate across sectors and account for climate variability and change. Recognition of spatial and sectoral interdependencies in the nexus should inform policies, institutions, and investments for enhancing water, energy, and food security, and thus support sustainable development in climate-sensitive environments. This presentation will highlight the importance of recognising these linkages, and identify spatial and topical hotspots in current nexus research.

K-L1.2-03

Revising the planetary boundary for freshwater use

D. Gerten (1)
(1) Potsdam Institute for Climate Impact Research, Potsdam, Germany

Nine intertwined 'planetary boundaries' demarcate the multidimensional 'safe' space for key earth system processes. Leaving this safe space due to the environmental imprint of collective human activities, Earth may be moved out of its Holocene status which up to now enabled the development of a human society of several billion people. While the concept and quantitative basis of planetary boundaries has recently undergone a comprehensive update (Steffen et al., Science, 2015), some boundaries still require a more robust quantification, especially in terms of upscaling regional patterns to the planetary scale and in terms of boundary interactions. Moreover, comprehensive assessments of development pathways for civil society under the constraint of planetary boundaries are still lacking.

This talk shows ways to improve the definition and assessment of the planetary boundary for human freshwater use, which is challenging as the regional pattern of water availabilities and limitations and the tight interactions with land cover and use are to be considered. The core approach is to account, spatially explicitly, for the environmental flow requirements of riverine ecosystems, which define local limitations to human water use and serve as a basis for a geographically explicit 'bottom-up' estimation of the planetary boundary. A pilot assessment – based on high-resolution simulations with a dynamic global vegetation and water balance model – indicates that the value of the planetary boundary may be lower than suggested earlier. Different estimation methods to assess environmental flows suggest a value between 1,100 and 4,500 km3 consumptive water use per year (original estimate from Rockström et al., Nature 2009: 4,000 km3 per year). Thus, humanity's current consumptive water use (at least ~1,600 km3 per year), let alone water withdrawal (~3,600 km3/year), already exceeds the lower end of this range that reflects stringent environmental policies. Moreover, local tolerance limits of water use are already exceeded in many places, such as in parts of southern Europe, southern Asia, the Near and Middle East, and in the western US. Building on these results, the presentation elaborates on how the definition and quantification of the freshwater boundary can be further improved, for example by including "green" water, by specifying linkages with other planetary boundaries (such as the one for land-system change), and by water ethical considerations. Initial estimates of the potential of improved on-farm water management to increase crop production while staying within the planetary boundaries for freshwater use and land-system change are also presented.

K-L1.2-04

Land use changes and their impacts on climate

J. Pongratz (1)
(1) Max-Planck Institute for Meteorology, Hamburg, Germany

About three quarters of the ice-free land surface have undergone some form of land use change: about one quarter has undergone a change in land cover, in particular deforestation for agricultural expansion; on another one half the vegetation cover has been kept but is managed, as happens e.g. in forestry. This land cover change and land management affects climate through multiple pathways. The political focus mostly lies on land use change as contributor to the human-induced rise in atmospheric CO2 and thus global warming. The local-scale climate, more relevant for adaptation, can show strong effects due to biogeophysical effects such as changes in water and heat fluxes.

Land use change (mostly restricted to land cover change) has therefore entered into most Earth system models (ESMs) used to project climate change. With the Coupled Model Intercomparison Project 5 (CMIP5) land use change has for the first time been considered in the climate simulations underlying the IPCC assessment report. However, the spread across model results for both carbon cycle and biogeophysical aspects has been found to be substantial. This initiated a range of studies that aim at understanding the reasons why estimates differ so much. These findings can be arranged along a chain of uncertainties from uncertain land use datasets, differences in their implementation in ESMs, to various definitions of land-use-induced carbon fluxes in models. This talk will discuss these sources of model spread and ways forward to reduce the uncertainties.

Understanding the sources of uncertainty is particularly important now: Recent observational studies suggest that land management can have effects on climate that are of similar strength as those of land cover change, yet occur on much larger area. The ESM community is therefore moving beyond land cover change towards land management for a more complete representation of the human impact on climate.

K-L1.2-05

Terrestrial carbon cycle feedbacks in the climate system

L. Mercado (1)
(1) University of Exeter, Exeter, United Kingdom

Terrestrial ecosystems take up around a quarter of the human CO2 emissions from fossil fuel burning, land use and land cover changes each year (Le Quéré et al., 2015), mitigating climate change for the present day. Can we rely on this carbon sink in the future?

Terrestrial ecosystems store a vast quantity of carbon in biomass and soils and their storage capacity depends on environmental conditions. Elevated CO2 is known to act as a fertilizer, stimulating plant production, and a changing climate (e.g. temperature and precipitation) will alter the lifetime of carbon in plants and soils. For example, the seminal work by Cox et al., (2000) suggested that future climate warming will lead to a release of carbon from terrestrial ecosystems, through temperature-enhanced soil decomposition, and highlighted the vulnerability of tropical forests to climate change. This represents a positive climate carbon cycle feedback, whereby an initial warming leads to a terrestrial release of CO2, which in turn leads to further warming.

Subsequently much research has focused on the role of terrestrial ecosystems and their feedbacks in the Earth system. Here we review the current state-of-the-knowledge drawing from the latest synthesis in the IPCC AR5 WG1 report, and our research at the University of Exeter, Met Office Hadley Centre and Centre of Ecology and Hydrology, UK. In particular, we present the effect of aerosols, implications of plant acclimation to temperature,

and the resilience of tropical forests on the future development of the land carbon sink (Mercado et al., 2009, Booth et al., 2012, Huntingford et al., 2013). I will highlight the key uncertainties in our understanding of climate- terrestrial carbon cycle feedbacks, and present recent work on emerging constraints on climate carbon cycle feedbacks (Cox et al., 2013, Wenzel et al 2014).

K-L1.2-06

Global impacts of climate change on terrestrial biodiversity and ecosystem service supply

W. Cramer (1)
(1) CNRS, Imbe, Aix-en-Provence, France

Impacts of recent climate change have been observed and attributed worldwide. Many of these affect land ecosystems, their function and the diversity of organisms in them. Scenarios of future warming, changes in rainfall patterns, and sea-level rise all indicate significant impacts on biodiversity in natural and managed landscapes, despite uncertainties regarding spatial patterns and confounding drivers such as land use and land management change, and urbanisation. While biodiversity loss may be considered a major impact of climate change in its own right, concerns are growing that the supply of essential services to humanity, where these depend on intact ecosystems, is also at risk. For certain key ecosystem services, such as climate regulation, food and timber production, water purification and others, the global nature of possible losses has been considered widely (also by the IPCC), but other ecosystem services are less easily quantified. I will summarise the state of knowledge for more comprehensive assessments of future global biodiversity loss and changes in ecosystem service provisioning, and thereby indicate the need for interaction between assessments of risks made by the IPCC and the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES).

L1.3 – Climate Change and Ocean Systems: Introduction and Background

K-L1.3-01

Climate Change and Ocean Systems: Introduction and Background

JP. Gattuso (1)
(1) CNRS and Université Pierre et Marie Curie, Laboratoire d'Océanographie de Villefranche, Villefranche-sur-mer, France

The ocean moderates climate change at the cost of profound alterations of its physics, chemistry, ecology, and services. However, despite the ocean's critical role in global ecosystem processes and services, international climate negotiations have only minimally touched on ocean impacts. Any new climate regime that fails to minimize ocean impacts will be incomplete and inadequate. This session, as well as session «2207: Ocean Change: Understanding and projecting the impacts of warming and acidification on natural and human systems» on Wednesday afternoon will provide an integrated and updated perspective on the changes, risks and projections for both natural and human systems. This will facilitate the construction of key messages for the COP21 negotiation process on the Ocean and associated issues.

K-L1.3-02

Challenges to ocean life and associated human interests: IPCC assessments and beyond

HO. Pörtner (1)
(1) Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

Oceans cover more than 70% of the planet and their biota create half the oxygen humankind uses to breathe and burn fossil fuels. Oceans cover about 11 % of the global population's demand for animal protein. Climate change causes oceans to warm and stratify, and sea level to rise, as well as Arctic summer sea ice to shrink. Ocean warming accounts for more than 90% of the energy accumulated in the climate system. Warming causes oceans to lose oxygen overall and during an expansion of hypoxic water layers. Concomitantly, the accumulation of anthropogenic CO2 in ocean surface waters disturbs water chemistry and causes acidification. These climate drivers alter ocean ecosystems and the services they provide. They frequently relocate and reduce marine biological resources on which human societies depend, affecting economic benefits, livelihoods, food availability and public health particularly for coastal communities. The recent IPCC assessment report (AR5) as well as the Structured Expert Dialogue have comprehensively considered impacts, vulnerability, adaptation options and projected climate risks for the oceans and their services to humankind. Ocean warming has caused geographical shifts in the distribution of marine species, associated with changes in the species composition and function of ecosystems. Recent meta-analyses indicate that ambient temperature and hypoxia extremes in some regions are already close to permanent tolerance limits of marine animals and plants indicating a risk of expanding water bodies void of higher marine life. Empirical observations together with mechanism-based knowledge of organism and ecosystem vulnerabilities support the detection of climate impacts in the field and their attribution to climate change. They also support more accurate, higher confidence projections of climate change impacts in the oceans, as well as of associated risk such as of ocean acidification effects on key animal phyla and their economic value. Such assessments of risks were recently developed further by the Oceans 2015 initiative. Warming-induced shifts in ocean productivity and species distribution, including of exploited fish and invertebrates, and declines in their body size are projected to result in reductions of fisheries productivity, especially at lower latitudes. In contrast, fisheries at high latitudes may benefit from increased abundance and diversity of commercially valuable species. Evidence is increasing that anthropogenic ocean acidification is affecting organisms, ecosystems and associated human interests (particularly bivalve fisheries and aquaculture) in areas with and without a natural background of elevated CO2 concentrations. Hypoxic areas that exclude active pelagic fishes such as tuna and their fisheries are expanding. Impacts thus go beyond those of simply warming and include effects of acidification and deoxygenation. These combined effects of the three climate drivers will lead organisms to reach long-term tolerance limits even earlier than with temperature changing alone, enhancing sensitivity through dynamic shifts of thermal limits. For example, recent modeling emphasizes that combined warming and oxygen loss constrain metabolic scope of key species and thereby habitat and biogeographical distribution across wider ocean areas than previously thought. Through effects on performance at the levels of reproduction, behaviour and growth, marine life forms including those that are economically relevant, are thus threatened by climate drivers changing individually and even more so by their additive or synergistic effects. Together with shifts in ocean circulation and productivity the resulting dynamic changes in thermal bioenvelopes have major implications for the ranges of geographical distribution of marine species, their competitive and trophic interactions, population dynamics and community compositions. Such integrative view is also being developed for paleo-observations of climate change effects. It should also be included in modeled projections of ecosystem change, which will inform social-ecological models projecting effects on fisheries and aquaculture. Assessments of risks of ocean warming, deoxygenation, and acidification to ecosystem services have generally concluded that human communities and artisanal fishermen at low latitudes often have the lowest capacity to adapt to losses in natural resources, for example by replacement with alternative foods. Substantial challenges remain to anticipate the ecosystem-wide impacts of the combined drivers of warming, deoxygenation, and acidification, and the ensuing alterations of ecosystem services for human communities. Finally, the projections of climate change impacts in the oceans and along coasts, including sea level rise, and the associated risks and scopes for adaptation,

need to be considered when setting the long-term global goals (LTGG) of climate change mitigation. As an example, the long-term risks of sea-level rise, Arctic sea ice loss and combined impacts of ocean warming and acidification on key groups of corals, bivalves and other calcifiers, that have high economic value in tourism, coastal protection and fisheries, strongly support setting the LTGG to but not above 1.5°C global warming above preindustrial values.

K-L1.3-03

Oceans of Concern

E. Poloczanska (1)
(1) CSIRO, Ocean and atmosphere flagship, Brisbane, Australia

Climate change and ocean acidification will reorganize food webs and alter ecosystem function, with attendant impacts on human communities and activities. The impacts of climate change have been detected across all oceans; changes to ocean have altered the timing of plankton blooms and migratory patterns and spawning in fish and invertebrates, over recent decades. Shifts in species distributions to higher latitudes are a commonly reported response of marine fishes and invertebrates to warming oceans. Differences in rates of change with climate change amongst species and populations imply that marine ecosystems may be substantially reorganized at regional scales. Indeed, at a global scale a strong warming signal is already evident in fish catches, with an increasing dominance of warm-water species found in catches coastal and shelf areas. Modelling approaches project a global redistribution of marine biodiversity this century with regional differences driven by species invasions and local extinctions. The emergence of novel assemblages of species with no past or contemporary analogues will consequently require new strategies for managing coastal areas and fisheries. Large changes in species composition are projected in both polar and tropical oceans with increases in species richness at high latitudes. High local extinctions are projected in equatorial oceans, particularly in the central Indo-Pacific, as species are eliminated with warming. The different futures emerge for tropical biodiversity by 2050s under high and low emission scenarios with widespread species losses and declines in species richness around the equator, particularly in the central Indo-Pacific, if global temperatures exceed the 2°C limit. Further, under the medium to high emission scenarios, ocean acidification poses substantial risks to marine ecosystems, particularly coral reefs and polar ecosystems. Climate change is a risk food resources, coastal livelihoods, and industries dependent on the Ocean, adding to the threats of over-fishing and other non-climate stressors, and the likelihood of exceeding adaptation limits increases with greater rates and magnitude of climate change.

L1.4 - Climate change and health - Risks and Responses

K-L1.4-01

A holistic approach to assessing the risks of climate change

D. King (1)
(1) Foreign and Commonwealth Office, London, United Kingdom

Sir David King will present a new approach to assessing the risks of climate change, designed to inform governments' decision-making on how to prioritise the objective of reducing the risks of climate change relative to other national objectives. At the core of this is a different way of interrogating the science: instead of projecting 'most likely' climatic changes and then describing the impacts of those, this approach asks first what it is that we might wish to avoid, and then considers its likelihood as a function of time under different scenarios. This assessment of the science is complemented by assessments of the relative difficulty of achieving different global emissions pathways, and of the systemic risks of climate change to the global economy and international security. When combined with a recognition of the essentially subjective nature of any valuation of future events, this approach can give governments a clearer and more holistic assessment of the risk that climate change poses to their national interests.

K-L1.4-02

2015 Lancet Commission on Health and Climate Change: Emergency actions to protect human health

W. Nick (1)
(1) Lancet Commission On Health And Climate Change, London, United Kingdom

In 2009, the UCL-Lancet Commission on Managing the Health Effects of Climate Change called climate change "the biggest global health threat of the 21st century". Five years on, a new multidisciplinary, international Commission has formed to map out a comprehensive response to climate change, in order to ensure the highest attainable standards of health for populations worldwide. The Commission represents a collaboration between over 80 European and Chinese climate scientists and geographers, social and environmental scientists, biodiversity experts, engineers and energy policy experts, economists, political scientists and public policy experts, and health professionals – all seeking a response to climate change which is designed to protect and promote human health. Nick Watts will present the key messages and recommendations from the Commission's work.

K-L1.4-03

Climate change, co-benefits and the global public health agenda

N. Maria (1)
(1) World Health Organization, Geneva, Switzerland

Dr Neira will address the implications of the evidence presented for the wider public health agenda, and in making a positive contribution to the preparations for the UNFCCC CoP21 in Paris in December. This will include outlining how evidence is now being translated into a support programme to build health system resilience to climate change, focussing on the most vulnerable countries. It will also focus particularly on the opportunities for large, local health cobenefits of climate change mitigation policies, particularly in reducing the over seven million annual deaths that WHO estimates are attributable to air pollution.

L1.5 – Climate variability, change and vulnerability in the Pacific, Indian and Southern Oceans

K-L1.5-01

ENSO and the Tropical Pacific in a Changing Climate

M. Mcphaden (1)
(1) NOAA/PMEL, Seattle, United States of America

The El Niño/Southern Oscillation (ENSO) cycle represents the strongest year to year fluctuation of the climate system on the planet. El Niño, the warm phase of ENSO, and La Niña, the cold phase of ENSO, arise through coupled ocean–atmosphere interactions in the tropical Pacific mediated by positive feedbacks between surface wind and sea surface temperature variations. Warm and cold ENSO episodes lead to global shifts in patterns of weather variability that cause droughts, floods, heat waves and other extreme events around the world. ENSO-related natural disasters have significant consequences for society in terms of lives lost, property damage and economic vitality. Understanding how ENSO may change in the future as a result of anthropogenic greenhouse gas forcing is therefore a compelling question that has challenged the scientific community. This presentation will review our current understanding of ENSO dynamics, predictability, and societal impacts. It will also assess current efforts to understand how ENSO may change in the future based on analyses of the instrumental record, CMIP models, and paleo data.

K-L1.5-02

Indian Ocean interannual to decadal variability in the context of climate change

J. Vialard (1) ; W. Han (2) ; M. Lengaigne (3) ; A. Nidheesh, (4) ; V. Parvathi, (4) ; I. Suresh, (4)
(1) IRD, LOCEAN, Paris, France; (2) University of Colorado, Boulder, United States of America; (3) UPMC, Paris, France; (4) National Institute of Oceanography, Goa, India

In the sixties, the Indian Ocean was the focus of the oceanographer's international community due to its dynamic response to monsoons. In the eighties, this focus shifted entirely to the neighbouring Pacific, berth of the El Niño Southern Oscillation (ENSO), most powerful interannual climate mode on earth. It is only at the turn of the century that the Indian Ocean came back into fashion with the discovery of its own intrinsic interannual climate variability (the Indian Ocean Dipole) and the development of a basin-wide observing network. After reviewing interannual variability of the Indian Ocean, I will turn to the natural decadal climate variability, which has comparatively been much less described in this basin than in the Pacific and Atlantic Oceans. I will in particular question if this decadal variability purely arises from the neighbouring Pacific or if an intrinsic variability also exists in the Indian Ocean. The climate change signal will finally be discussed in the Indian Ocean. We will show, on the particular example of anoxic events along the west coast of India, how long-term trends and shorter-term variability can cause extreme events with important societal consequences.

K-L1.5-03

21st century projections for the Pacific region

S. Power (1) ; M. Collins (2) ; K. Hennessy (3) ; E. Guilyardi (4)
(1) Bureau of Meteorology, Cawcr, Melbourne, Australia; (2) Exeter University, Exeter, United Kingdom; (3) SCIRO, Dickson, Australia; (4) LOCEAN/IPSL, UPMC case 100, Paris, France

Here we will examine the latest scientific information available on projections for climate in the Pacific, and what this means for developing island states in the region. Particular attention will be paid to changes in surface temperature, winds, rainfall, El Nino, tropical cyclones, and ocean acidification, for different scenarios of future greenhouse gas emissions. The continuing importance of decadal climate variability for the region will also be highlighted. This presentation will draw upon the latest IPCC report and more recent research, including research conducted in the Pacific Australia Climate Change Science and Adaptation Planning Project.

K-L1.5-04

Southern Ocean in a changing climate

A. Thompson (1)
(1) Caltech , Los Angeles, United States of America

Recent Southern Ocean studies have suggested a slowdown of ocean carbon sequestration, an acidification of the water-masses, an overall warming and freshening in the vicinity of Antarctica, and drastic changes in sea-ice and ice-shelf distributions. Observed changes are profound: the warming rate is faster than the global average, and occurs in the deepest layers of the ocean, therefore isolating the climate signal for decades to millennia ; ice-shelves are melting, which accelerates the discharge of the ice sheet via the ice streams, and has a direct and major impact on the global sea level rise. These important changes are directly related to the large-scale circulation of the Southern Ocean and the associated biogeochemistry. This talk aims at summarizing our current understanding of how the large-scale circulation of the Southern Ocean works, how it impacts the carbon cycle, and how interactions with the Antarctic cryosphere influence it.

O-L1.5-01

Future changes in the South Pacific convergence zone and its tropical cyclones using regional dynamical downscaling

M. Lengaigne (1) ; M. Bador (2) ; C. Menkes (3) ; J. Lefèvre (4) ; N. Jourdain (5) ; S. Jullien (6) ; P. Marchesiello (7) ; S. Thibaut (8) ; L. Terray (9)
(1) UPMC, Paris, France; (2) CERFACS, Climate Modelling and Global Change team, Toulouse, France, France; (3) IRD, LOCEAN, Noumea, New Caledonia; (4) IRD, Legos, Noumea, New Caledonia; (5) CNRS, Lgge, grenoble, France; (6) UPMC, Locean, Paris, France; (7) IRD, Legos, Toulouse, France; (8) CNRS, Legos, Toulouse, France; (9) CERFACS/CNRS, Sciences de l'Univers au CERFACS, URA1875, Toulouse, France

The South Pacific Convergence Zone (SPCZ) is the largest convective area of the Southern Hemisphere and has been recognized as a hot spot for climate variability (CLIVAR, 2012) as its functioning is poorly understood. Regionally, the SPCZ is the main source of rainfall in a vast majority of the Southern Pacific Island nations and the strong precipitation gradients related to the SPCZ make local hydrological conditions very sensitive to small displacement of this rain belt. The interannual variability of the SPCZ location is related to the El Niño/Southern Oscillation. El Niño events tend to occur accordingly with a northeastward displacement of the SPCZ, and La Niña events tend to occur with a southwestward displacement of the SPCZ. During strong El Niño events, the SPCZ undergoes an extreme swing by up to ten degrees of latitude toward the equator and collapses to a more zonally oriented structure. The SPCZ location not only strongly constrains the hydrological cycle but is also the breeding ground of tropical cyclones (TCs) in the South Pacific, as it combines all the large-scale atmospheric conditions that favor the genesis of TCs. Current climate models poorly reproduce the key characteristics of the SPCZ, leading to large uncertainties in the potential evolution of the South Pacific TC activity. Hence, assessing the SPCZ and its tropical cyclones in the future climate remains a challenge.

Here, we use a dynamical downscaling approach. Using results from an ensemble of 14 CMIP3 climate models under the SRES-A2 greenhouse gas scenario, we force a regional configuration of the WRF atmospheric model. The configuration uses a two-way nesting approach to increase the spatial resolution from 1° to 1/3° in the SPCZ region. We first perform a control simulation forced by the NCEP2 reanalysis over the past 30 years, and a future

simulation based on an anomaly method (e.g. Zhao et al. 2009), where we add the mean 21st century regional SST warming pattern and atmospheric change along lateral boundaries to the NCEP2 fields.

Results show an accurate representation of the SPCZ location, its north-south displacements in response to El Niño/Southern Oscillation, as well as a correct TC distribution in the region. The future simulation indicates an increase of the precipitation within the SPCZ and the equatorial region, and a decrease northeast of the SPCZ mean location, in good agreement with climate models. The mean SPCZ location under future conditions presents a southward shift in its eastern part, and generally an increased variability of its interannual geographical position. We also find more frequent strong El Niño events in the future, with zonally oriented SPCZ. We explore the respective role of increased greenhouse gases in the domain versus the role of lateral boundaries. Large-scale conditions from lateral boundaries induce a significant (-20%) decrease of cyclones frequencies in the region. However, greenhouse gases locally counter this decrease. Overall, we do not find any significant change of cyclone frequencies in the Southwest Pacific in a warmer climate, in contrast with most recent studies, which find a decrease of cyclogenesis (-6% to -34% according to references gathered in Knutson et al. 2010).

The Climate-Development 'Conflict': Asking the right questions

N. Rao (1)
(1) IIASA, Energy, Laxenburg, Austria

There is both confusion and concern regarding the impact of poverty eradication on climate change. Some equate poverty eradication with coal use, particularly in India and China; others assume consumption from people rising out of poverty would be highly material-intensive. What if all the world's poor had refrigerators? What implications does economic development have for stabilizing climate change at 2 degrees C? Conjectures abound, but scientific research so far offers few real answers to these questions. This is in part because we haven't been asking the right questions. What stands between poverty eradication and greenhouse gas emissions is the nature of developing countries' development pathways, income distribution, patterns of energy use, technological development, and different scenarios of global cooperation on climate change mitigation. There is much yet to be learned about the interaction of these drivers. New approaches to quantifying human development and energy use shows that there have been many low-carbon development pathways in the past, and that meeting basic needs may be less carbon intensive than growth in affluence. Current trends in India reveal an exponential growth in low-carbon resources, even among the poor. While basic development aspirations cannot be thwarted, their impact on climate change is by no means outside the realm of influence by both national and international policy.

L2.2 - New pledges (INDCs) for 2025/2030: Are they reinforcing development and consistent with a 2 oC pathway?

K-L2.2-01

INDCs and development objectives

N.Dubash (1)

Abstract not communicated

K-L2.2-02

What science tells us about the emission levels for a 2oC pathway

P. Ciais (1) ; T. Gasser (2) ; P. Friedlingstein (3) ; GP. Peters (4) ; J. Rogelj (5)
(1) IPSL, Lsce, Gif sur Yvette, France; (2) LSCE, Gif-sur-Yvette, France; (3) University of Exeter, Exeter, United Kingdom; (4) Center for International Climate and Environmental Research, Oslo, Norway; (5) IIASA, Laxenburg, Austria

Limiting global warming to below 2°C above pre-industrial levels will require sustained and important efforts to reduce anthropogenic emissions of greenhouse gas emissions and to enhance and maintain sinks of carbon dioxide in the land-use sector. Fossil fuel CO2 emissions have continued to grow at an average rate of 2.5% per year over the past decade. Even at today's annual emission levels, the cumulative CO2 emission quota in line with staying below 2°C would be exhausted in less than 30 years. We will examine how pledges of largest emitting countries to reduce emissions, or maintain sinks in the land-use sector are consistent with a trajectory enabling not to breach the international agreed 2°C temperature limit. In particular, we examine how forest carbon sinks in the US, Canada, Russia, China and the EU, as well as reduced deforestation in tropical countries, can help efforts to attenuate near-term climate change. A specific attention will also be given to the contribution of nations to historical radiative forcing and climate change, including long-lived greenhouse gases and short-lived forcers such as CH4 and aerosols, of which the latter can have a climate cooling or warming effect.

K-L2.2-03

Assessment of intended nationally determined contributions to a 2015 international climate agreement

M. Den Elzen (1) ; N. Höhne (2)
(1) PBL Netherlands Environmental Assessment Agency, Department of Climate, Air and Energy, Bilthoven, Netherlands; (2) New Climate Institute, Cologne, Germany

One of the most fundamental questions in the preparation of a new international climate agreement is whether countries' proposals to reduce greenhouse gas emissions after 2020 are equally ambitious compared to their peers. Methodologies to rate countries' climate action often rate different things and therefore come to different conclusions (Surminski and Williamson, 2014).

From the variety of methods that have been applied in the past to rate the ambition of countries climate action proposals, we distinguish two main strands, which are described here as black and white for illustration, acknowledging that they overlap in practice. Both relate to the principle of common but differentiated responsibilities and respective capabilities:

- Moral obligation: From this viewpoint, countries have a moral obligation to reduce their emissions. This moral obligation can be measured in a simple way, e.g. for developed countries as the sustained emission reduction

effort since 1990 (a commonly used base year) or more sophisticated using a variety of equity principles, so called "effort sharing" calculations (including the IPCC AR5 equity database (Clarke et al., 2014; Höhne et al., 2014)). This strand relates to the "differentiated" element of the agreed principle.

- Technical necessity: The starting point of this viewpoint is whether the proposal is in line with what is technically necessary from now on, irrespective of the moral obligation. This could be judged by whether the countries' proposal is in line with its contribution in globally cost effective model pathways (according to scenarios such as those included in the IPCC AR5 scenario database (Clarke et al., 2014) and model comparison studies, like LIMITS (Tavoni et al., 2015)), leverages all mitigation potential, or covers all policies that the country's peers undertake. This strand relates more the "common" element of the agreed principle.

The two strands may lead to fundamentally different outcomes. A developing country for example may have limited moral obligation, but significantly more mitigation potential, as developing countries are characterized by higher energy and carbon intensities, have rapidly rising baseline emissions and a high share of new infrastructure (Clarke et al., 2014). For a developed country it may be the other way around, it may have a very high moral obligation, but may have technical difficulty to reduce domestic emissions in the same order of magnitude without retiring old infrastructure before the end of its life ("carbon lock in" or "stranded assets").

The methods are applied illustratively to the recent post-2020 climate proposals by the USA, China and the EU. The results differ substantially per method, which confirms that a comprehensive ambition assessment is necessary to provide the full picture.

Integrating development and climate policy in South Africa

T. Caetano (1)
(1) University of Cape Town, Energy Research Centre, Cape Town, South Africa

South Africa's approach to its INDC will very likely be framed by development and climate. The formal process of consultation by government has yet to take place, but we know that the National Development Plan (NDP) is as important as South Africa's climate policy. Some research we have undertaken at the Energy Research Centre (ERC) illustrates the challenges of seeking a substantial reduction in poverty, inequality and emissions.

The key question facing the mitigation community in South Africa is the pace with which the country can decarbonize the energy sector, which currently accounts for majority of total emissions, without undermining development imperatives – the NDP places reduction of poverty and inequality at the top of a list of multiple priorities.

The current structure of the South African economy has resulted in sub-optimal environmental (high carbon intensity) and social (high Gini-coefficient and low HDI) outcomes. High levels of poverty and inequality are likely to be exacerbated substantially by climate change impacts in the future, while a reliance on energy- and capital-intensive, and low-labour-absorbing sectors means that even with a sophisticated tax and redistribution system, there are simply too few employed and skilled citizens in the economy to drive improvements in living standards and key socio-economic indicators for majority of the population. Inclusive growth is a necessary condition for attaining better socio-economic outcomes in the future, but the type of growth that South Africa has experienced in the past few decades has not been sufficient.

A key question then is the extent to which a structural change in the economy can meet both mitigation and development objectives. Growth in sectors that are labour-intensive, absorb low- and un-skilled workers and are low carbon need to be incentivized if South Africa is going to move forward with climate compatible growth and development.

The domestic policy system is characterized, however, by lock-in and path dependency. While consultations on the INDC are ongoing, ERC research suggests that what is crucial is an understanding of how a just transition over the next decades from an inequitable and carbon intensive economy to a more equitable and low carbon economy can be achieved. South Africa's national climate policy, as indicated in 2009, is that its emissions will follow a 'peak, plateau and decline' trajectory to 2050. The NDP includes an environmental chapter that talks to "an equitable transition to a low-carbon economy", yet this remains to be fully integrated with chapters on economy, employment and infrastructure. ERC research has provided initial analysis on what would be required, either with a more skilled work force or possibly a different structure of the economy, to move toward a successful integration of development and climate policy.

K-L2.2-05

The economic and competitiveness dimensions of the Draft Chilean INDC

A. Rudnick (1)
(1) MAPS Programme, Latin America, Santiago, Chile

Chile's national contribution to mitigation is based on a commitment to reducing greenhouse gases for the post-2020 period. It is based on the sectorial analyses and the mitigation scenarios developed in 2013-2014 with MAPS Chile (Phase 2), the results of the National Greenhouse Gas Inventory, and additional information provided by the Ministries of Environment, Energy, Agriculture and the Treasury.

Chile aims to reduce its greenhouse gas emissions while decreasing poverty and inequality as well as continue advancing toward sustainable, competitive, inclusive and low-carbon development. To confront these challenges successfully, the country should direct all its efforts to decoupling economic growth from greenhouse gas emissions.

Draft Intended Nationally Determined Contribution on Mitigation

Chile analyzed a subset of three forms of contribution for the whole economy, namely: i) carbon intensity target, ii) a deviation below business as usual scenario specified ex ante, and iii) trajectories. From a review of existing literature and considering the national experience with the Copenhagen pledge, Chile has chosen to report its contribution for the post-2020 period in the form of emissions intensity. Chile's contribution will allow the country to reach high levels of economy-wide mitigation. Methodologically, it takes two components into account: a) a carbon intensity target, expressed in greenhouse gas emissions per unit of economic development (GDP) which includes all sectors where mitigation is possible in Chile except for forestry; and b) a separate target for forestry. t

The draft INDC was submitted to a national consultation process, were two options of carbon intensity target were consulted.

Option A: Chile is committed to reducing its CO2eq emissions per GDP unit by 30-35% below their 2007 levels by 2025. Chile is also committed to reducing its CO2eq

emissions per GDP unit by 40-45% below their 2007 levels by 2030.

Option B: Chile is committed to reducing its CO2eq emissions per GDP unit by 25-30% below their 2007 levels by 2025. Chile is also committed to reducing its CO2eq emissions per GDP unit by 35-40% below their 2007 levels by 2030.

Figure 1:Upper value of Option A expressed in emissions (excluding LULUCF) per unit of GDP

Source: Draft INDC. Government of Chile. 2015.

In addition, for the forestry sector Chile has proposed restoring about 100,000 hectares of degraded land (forestation) with its own resources investing an estimated US$250 million, reaching an area of at least 100,000 hectares of managed native forest by 2035.

National perspective

Chile already has concrete and ambitious goals and policies, and has consistent energy policies to move towards a clean, safe, sustainable matrix (Law on renewable energy, energy efficiency targets, carbon tax). Emission mitigation is seen as an opportunity to low-carbon development with multiple benefits such as job creation, improved population health, competitiveness and others.

The mitigation scenarios considered for the draft INDC were modeled through a dynamic stochastic general equilibrium model (in Phase 2 of MAPS-Chile) for two macroeconomic variables: increase in the value of GDP and increased employment. The values presented in the table below correspond to percentage deviations from the baseline from 2013 to 2030. The three scenarios represent the mitigation range included in Option A and Option B of the draft INDC.

Table 1: Macro economic effects of mitigation options

Scenario	GDP	Employment	CO_2eq Emissions
	2030	2030	2030
80/20 (Lower value of Option B)	1,2%	0,0%	-18,8%
Medio (Upper value of Option B and lower value of Option A)	6,7%	5,5%	-23,4%
Alto (Upper value of Option A)	7,4%	6,3%	-26,2%

Source: MAPS Chile results (Phase 2).

According to the GDP growth rate, the population projections, and the mitigation measures and policy choices considered in the three mitigation scenarios, the macroeconomic modeling results indicate that high mitigation scenario is not only the most ambitious in terms of emission reduction, but also verifies the largest increases in GDP and employment levels to 2030.

L2.3 - Climatic Variability and the Social and Human Dimensions of Vulnerability

K-L2.3-01

Extremes of climate variability and impacts on society: The drought and water crisis of 2014-15 in Southeastern Brazil

J. Marengo (1)
(1) CEMADEN, San Paolo, Brazil

Deficient rainy season during the austral summers of 2013-14 and 2014-15 over most of southeastern Brazil affected the São Paulo Metropolitan Area (SPMA)-South America's largest metropolis, home to 20 million people and where 10% of Brazilians live and a third of GDP is produced. Together with high temperatures throughout 2014 and up to January 2015 and a subsequent increase in water demand, the persistent lack of rainfall determined a drought situation, impacting on the use of water for human consumption, hydropower, as well as water for agriculture, creating an acute "water crisis" situation. In the last 60 years, some extreme dry events have impacted Southeastern Brazil, including the 1953-54 episode and the 2000-2001 as the most intense. Here we intend to assess how extraordinary the recent extreme drought that started in summer of 2013, persisted throughout 2014 and continued up to January 2015 was, and to analyze some of the main factors contributing to it.

The hydropower reservoirs—which account for around 70% of the country's entire hydroelectric power generation- and the rivers feeding the Cantareira reservoir system, which provides almost half of the city of São Paulo's water, were almost dry by the end of 2014.The severe drought of the summer 2014-2015 was associated with a wide, intense and very persistent high-pressure area placed from surface to the upper troposphere. The anticyclonic system that dominates the atmospheric circulation over eastern South America extended from the sea level to the upper troposphere inhibiting the distinctive seasonal convective activity. This anticyclone lasted 45 days, extremely rare in terms of duration and never previously recorded for that region.

The region of Cantareira region experienced the most severe drought during the summer of 2014, and this year corresponds to the warmest year in the region since 1962. Other drought years, as in 1971 and 2001 were also among the six warmest years during that period. Therefore, the worse water crisis in Sao Paulo during the warmest year during the last 52 years is a relevant example of climate change risk due to rising temperatures due to anthropogenic influences.

However, origins of the current water crisis go beyond the rainfall deficiency, to include an array of interconnected factors: the city's surging population growth in the 20th century; a chronically leaky system that spills vast amounts of water before it can reach homes; and the destruction of surrounding forests and wetlands that have historically soaked up rain and released it slowly into reservoirs. Rainfall over the Cantareira system has been decreasing during the last decades and the levels in 2014 were the lowest since 1940. Longer-term planning by regional governments has fallen short, and many residents are already enduring sporadic water cutoffs, some going days without it. SABESP, the state utility company has reduced its extraction from the reservoir by a third, cut its pump pressure at night, and offered discounts to customers who reduce their consumption. Some parts of the city are relying on water trucks to maintain their supply.

Managing multifunctionnality for Climate Smart Landscapes

C. Mbow (1)
(1) Institut des Science de l'Environnement, Faculté des sciences et techniques, Dakar-Senegal, Senegal

This presentation addresses the importance of managing trade-offs for sustainability in the face of climate change and how in particular the integrated landscape approach could be the one way to achieve many climate change related objectives. The presentation suggests a analytics for harnessing the climate smart landscape approach to the emerging climate challenges using some examples of practices that are suited to different contexts. From the historical footprints of the co-evolution between policy and science in the aim of achieving integrated solutions to climate/environmental crisis, we suggest some avenues on how to use landscape management principles in the design and the implementation of multiple goals; and what are the key barriers.

K-L2.3-03

Exploring the human dimension of urban resilience: perspectives from the Pacific region

D. Mcevoy (1)
(1) RMIT University, Melbourne, Australia

Cities in the Pacific region, which in many instances are already vulnerable to a range of natural hazard and weather-related events, will be faced by a multitude of resilience challenges in the future as a consequence of the interactions between a changing climate and rapid urbanization processes. These challenges are further complicated in the Pacific by land tenure arrangements, with tensions between municipal and customary land ownership often commonplace. Drawing from ongoing research activity as part of UN-Habitat's Cities and Climate Change Initiative, the presentation will explore the human dimension of climate vulnerability in the capital cities of Honiara (Solomon Islands) and Port Vila (Vanuatu). Both these case studies have been affected by recent weather-related disasters as evidenced by the Honiara floods in 2014 and the impact of Cyclone Pam on Port Vila in 2015. Discussion of the human dimension of urban resilience will not only address the current and future hazard component but also how changing levels of exposure, sensitivity and adaptive capacity will affect the resilience of the urban system (and its component parts). Lessons learnt from this analysis have the potential to positively influence the development of adaptation pathways and the enhancement of local resilience strengthening activity.

L2.4 - Early Warning for Thresholds and Tipping Points in the Earth System

K-L2.4-01

Early warning of climate tipping points

T. Lenton (1)
(1) university of exeter, exeter, United Kingdom

A 'tipping point' occurs when a small change in forcing triggers a strongly non-linear response in the internal dynamics of a system, qualitatively changing its future state. Large-scale 'tipping elements' have been identified in the Earth's climate system that may pass a tipping point under human-induced global change this century. At the smaller scale of ecosystems, some tipping points have already been observed, and more are anticipated in future. Our capacity to forecast such abrupt, non-linear changes has historically been poor. However, much excitement has recently been generated by the theory that some approaching tipping points carry generic early warning signals. I will critically examine the prospects for gaining early warning of approaching tipping points. Promising methods are based on detecting 'critical slowing down' in the rate a system recovers from small perturbations, and on accompanying changes in the statistical distribution of its behaviour. I will show examples of early warning signals in paleo-data approaching past abrupt climate changes, and in models being gradually forced past physical climate tipping points. I will also discuss the conditions under which the methods fail. Finally, I will show an example of pronounced slowing down in observational climate data, for North Pacific sea surface temperatures, and explore the implications for well-known marine ecosystem 'regime shifts'.

K-L2.4-02

Are there tipping points in terrestrial ecosystems?

M. Hirota (1)
(1) Federal University of Santa Catarina , Santa Catarina, Brazil

Terrestrial ecosystems have been undergoing unprecedented climate and human-induced disturbances, which are likely to push these systems towards changes in their physiognomies, structure, and functioning. It has been hypothesized that these new configurations may be alternative regimes of systems comprising vegetation-climate-disturbance interactions. Thus, one way of explaining the dynamics of ecosystems in transition may be the theory of multi-stability and concepts such as resilience, hysteresis and tipping points. However, whether such multiple regimes indeed exist in climate-vegetation-disturbance systems and whether we can identify and quantify tipping points of such systems still remain largely unclear due to various reasons such as the role of heterogeneity and multi-scale processes in amplifying or dampening hysteresis and environmental change. This highlights the need to inter- multidisciplinary teams, which investigate such questions and help addressing management practices and preserving ecosystem services for future adaptation policies.

K-L2.4-03

Approaching Tipping Points: context, anticipation and community-based monitoring

M. Nuttall (1)
(1) University of Alberta, Department of anthropology, Alberta, Canada

From the Arctic to the topics, Prairie and steppeland environments to high mountain areas, deltaic regions and low-lying ecosystems, people are observing and experiencing significant environmental shifts. However, it does not necessarily follow that they think about climate change as the most pressing issue affecting their lives. In this presentation, I discuss some aspects of how to understand the consequences of climate change, as well as identifying tipping points and thresholds, in a broader context. Rapid social, economic and demographic change, resource management and resource development, quota systems, trade barriers and conservation policies, among many things, have significant implications for human security and livelihoods. In many cases, climate change merely magnifies existing societal, political, economic, legal, institutional and other challenges that people experience in their everyday lives. In the far north of Greenland, for example, while the thinning sea ice and melting glaciers are perceived as troubling and worrying, local people see economic opportunities for their communities in the form of emerging halibut fisheries. Yet, although dramatic changes in climate require people to respond in particular ways, transformations in global markets that affect small-scale fisheries often have greater consequences. And while the disappearance of sea ice and glacial retreat may indicate approaching tipping points, irreversible social, cultural and economic change was precipitated in the 1980s by environmentalist opposition to seal hunting, while the prospect of oil development and mining mean different kinds of tipping points in the near future. As they reflect on a changing climate, local people do so from the position of living through considerable social and economic transformation that may have nothing to do with environmental change.

In this presentation, I consider the above and then focus on two things. First, building on earlier work on tipping points and anticipatory knowledge, I consider anticipation; how people think about the world around them, how they orient themselves and live toward the future, and how they create and enact change within a world that is also undergoing a constant process of becoming and being remade. I discuss how a focus on anticipation in local settings would give us a greater understanding of a diversity of approaches to precaution, pre-emption and preparedness. Given the

challenges (as well as opportunities) that climate change brings to environment and society, understanding how anticipation is inherent in everyday life and implicit in social relations and cultural practices, and how aspects of those relations and practices can emerge from anticipation, is a way to understand successful local strategies of adaptation, the nature of resilience and how people prepare themselves for uncertain futures. Second, I discuss some anthropological methods and prospects for identifying and gaining early warning of tipping points through reflection on collaborative and participatory-based community research. By way of example, I draw on an interdisciplinary project in the High Arctic environment of northern Greenland (the EU-funded ICE-ARC project) which is working with communities to help them prepare for and negotiate change in the future. Central to this project is community-based monitoring, a process that not only seeks to identify early warnings of tipping points, but something that builds local research capacity and puts in place a local observing system. This will help improve climate predictions for understanding the impacts of climate change on marine ecosystems and Arctic societies and enable communities to build capacity towards ensuring sustainable livelihoods.

K-L2.4-04

Can we avoid the next tipping in Antarctica?

R. Winkelmann (1)
(1) PIK Potsdam, -, Germany

Sea-level rise is a given consequence of anthropogenic climate change. How much and how fast it is going to rise will depend critically on the future evolution of the Antarctic Ice Sheet which stores water equivalent to more than 50 meters of global sea-level rise. Most of West Antarctica's marine ice sheet lies on an inland-sloping bed and is thereby prone to an instability mechanism, the so-called marine ice sheet instability. Recent observations suggest that the grounding line has probably already transgressed into the unstable regime in part of the West Antarctic Ice Sheet due to warm water intrusion into the shelf cavities. Similar topographic configurations are found in large parts of the East Antarctic Ice Sheet which holds marine ice equivalent to 19 meters of global sea-level rise, more than five times as much as West Antarctica. For Wilkes basin in East Antarctica, it has been shown that removing a specific coastal ice volume, a so-called ice plug, can destabilize the entire basin, leading to self-sustained ice discharge and long-term sea-level rise of several meters. Here, we will explore the regions which might be subject to the marine ice-sheet instability, the processes potentially triggering it, and the consequences and implications for future sea-level rise.

K-L2.4-05

Effects of climate change and other driver of global changes on biodiversity

C. Bellard (1)
(1) Université Paris Sud, Paris, France

Current threats have greatly accelerated the rate at which extinctions occur. Climate change is expected to become one of the most important threat in the future (Bellard et al. 2012). In general, multiple threats, such as habitat destruction, invasive species, overexploitation, and climate change lead to an increase in species extinction risk. The combined impacts of multiple threats are also diminishing the capacity of natural systems to cope with the effects of these changes. Yet, over the past decade most studies have assessed the future spatial distribution of these threats individually. This approach can be ineffective and ecologically misleading, because cumulative effect of different threats are not considered. Most of the conservation measures that are based on such studies consider a subset of threats, which may be of little benefit if other threats remain unaddressed. In addition, the combined impacts of different threats might be larger than the cumulative effect of each threat on biodiversity. Because little is known about the possible existence of interacting effects, quantifying the magnitude of potential synergies should become a priority.

Here, we propose to use two case studies at a global scale: biodiversity hotspot (Bellard et al. 2014), and USA to illustrate the need to consider multiple interactions between climate change and other threats. For instance, we will examine the effect of climate change including sea level rise and land use changes on biodiversity hotspot. We will discuss congruence between threats, species vulnerability and protected areas through the biodiversity hotspot. We will also discuss the potential impact of future interaction of climate change, land use changes, and invasive species for 196 endemic species across USA (Bellard et al., submitted). To this aim, we took into account the spatial distribution of biodiversity vulnerable to these threats. In particular, we found high cumulative threat values (>2 threats) aggregated over the eastern part of the USA, with lower values in the central and western parts. Cumulative impact analyses also suggested that the return on investments for conservation purposes may be low when high cumulative threat areas with low species diversity require protection from many threats (e.g., Minnesota, Wisconsin, Michigan, Iowa states). These analyses provide a useful means of identifying where conservation measures and monitoring programs that should consider multiple threats should be implemented in the future. Ultimately, we will further discuss why manager should consider multiple threats to mitigate the future effect of climate change.

L2.5 - Food and water security under climate change

K-L2.5-01

Future landscapes of food supply and demand and implications for emissions

JF. Soussana (1)
(1) Inra, Paris, France

Climate change and the rise in atmospheric CO2 will reorganize food systems and alter agricultural productivity, with impacts on food security, land use and greenhouse gas emissions. Food security is still an issue for about 795 million undernourished people, mostly located in the least developed countries of the planet. The agriculture sector is already affected by climate change, with significant global negative impacts on wheat and maize yields being observed over the last decades. The global food systems would be severely threatened under high end global warming scenarios. The agriculture, forestry and land use sector contributes to 24% of global anthropogenic greenhouse gas (GHG) emissions, with livestock alone estimated to contribute about 14.5% of total human induced emissions when a supply chain approach is considered. Globally, GHG emissions from agriculture could be reduced by 20-30% if less efficient producers would adopt the best practices of their peers, in the same production system and region. Technologies and practices that help reduce emissions exist but are not yet widely used. Those that improve efficiency and plant and animal health also have productivity co-benefits. In addition, the agriculture sector could benefit from carbon offset programs that represent potential additional income. Climate change matters to the agriculture sector. Direct impacts on production range from extreme climatic events, droughts and floods, to thermal stress and reduced yields. A large proportion of low income farmers are highly exposed to climate change. Forward-looking scenarios of plausible agricultural sector developments were developed

based on the new IPCC scenario framework. The results in terms of agricultural market developments, land and water use, and GHG emissions going until 2050 highlight the role that demand driven and supply driven changes in the sector could play both for greenhouse gas mitigation and for adaptation to climate change.

K-L2.5-02

Past and future weather-induced risk in crop production

J. Elliott (1)
(1) University of Chicago, Chicago, United States of America

The global food system has seen increased volatility in recent years, with spiking food prices blamed for civil unrest on several continents. Rising prices for global commodity products like soy, meat and palm are increasingly driving deforestation around the globe, and with agriculture increasingly interconnected to global food and energy markets, weather-related risk and supply-side shocks have become a key issue or concern for governments and businesses alike.

Using archives from the Agricultural Model Intercomparison and Improvement Project (AgMIP) and the Intersectoral Impact Model Intercomparison (ISI-MIP), we look first at the impacts of 65 years of continental and global extreme events using observation-driven models and data. We identify the most severe historical events in caloric terms at national to global scales and evaluate the ability of models and model ensembles to identify weather-induced extreme years, correctly assess the magnitude of large-scale extreme events, reproduce historical country-level variability, and reproduce spatial patterns of losses under extreme drought.

We next consider global crop models driven with large ensembles of climate model output (both under historical forcing and with future scenarios) to characterize present day risk and the extent of non-stationary risk in global crop production. We find increasing, and in many cases accelerating risk, of extreme global loss events even in scenarios with little to no climate-induced long-term mean changes. In some cases, one-year global-scale production loss events that would have recently been called 1-in-100 year events are estimated to occur every 30 years by mid-century, and every 10-20 years by end-of-century. We discuss some regional and global protective measures that might be introduced, including increased trade, stock-hoarding, crop breeding, and improved forecasts, monitoring, and modeling.

K-L2.5-03

Future landscapes of crop water supply and demand

T. Oki (1)
(1) University of Tokyo, Tokyo, Japan

The real hydrological cycles on the Earth are not natural anymore. Humans are now driving changes in atmospheric processes through emission of green-house gases and land cover changes directly and indirectly. Global mean temperature is projected to rise approximately proportional to the cumulative total anthropogenic CO2 emissions from 1870 (AR5, IPCC WGI). Temperature rise itself will have direct impacts on the availability of water resources through changing flow regimes in snow-dominant or glacier-effluent river basins, and it will also be associated with sea level rise because thermal expansion is one of the major causes of observed and projected sea level rises. Further, climate change is projected to alter hydrological cycles: changing temporal and geographical patterns of hydrological components, such as precipitation, evapotranspiration, runoff, and ground water recharge, and particularly in their extremes. Consequently, the frequency of floods and/or droughts is projected to increase some parts of the world.

However, as articulated in the AR5 of IPCC WGII, "Risk of climate-related impacts results from the interaction of climate-related hazards (including hazardous events and trends) with the vulnerability and exposure of human and natural systems", increasing frequency of natural hazards, such as torrential rainfall or long-lasting heat wave, alone will not cause damages on human and natural systems, and both climate and social changes are relevant for planning sustainable development in the future.

AR5 (WGII) also says "Significant co-benefits, synergies, and tradeoffs exist between mitigation and adaptation and among different adaptation responses; interactions occur both within and across regions". Mitigation and/or adaptation actions should not be planned in an isolated manner, but should be integrated into wider frameworks, such as integrated water resources management and sustainable development. It would preferably be integrated into a risk management framework assessing and managing possible global risks, and ultimately pursue increasing human well-beings.

These issues will be discussed with reviews of the latest estimates of water demand and supply in the future.

K-L2.5-04

Planetary opportunities in crop water management: Potential to outweigh cropland expansion

J. Jägermeyr (1)
(1) Potsdam Institute for Climate Impact Research (PIK), Potsdam, Germany

A major humanitarian challenge for the 21st century is to feed the growing world population in face of climate change and sustainability boundaries. However, as the planetary boundaries for freshwater and land use are being approached rapidly, there is little potential for additional cropland appropriation or irrigation water diversion. In addition, competition between food production, bioenergy plantations and biodiversity conservation increases pressure, while considerable yield gaps remain in many world regions and various water conservancy methods proved instrumental to boost yields in a sustainable way. In the here presented modeling study we investigate, at global scale, to what degree smart on-farm crop water management might contribute to a sustainable global yield increase. We do this under current and projected future climate conditions and under the constraint of environmental flow requirements to represent the planetary boundary for human freshwater use and its regional pattern. We recalculate from this potential how much cropland expansion could be avoided and also quantify associated financial investment needs. The portfolio of management options studied here consists of methods aiming for elevated crop water productivity (irrigation improvements and expansion with thus saved water) and an optimal use of on-field precipitation water (reducing soil evaporation and collecting surface runoff for supplemental irrigation).Global yield simulations based on hypothetical scenarios of these management opportunities are performed with the process-based agro-biosphere model LPJmL, driven by reanalysis data and GCM ensemble simulations. We consider a range of 20 climate change projections to cover respective uncertainties, and we analyze the effects of increasing CO2 concentration on the crops and their water demand. Crops are represented in a process-based and dynamic way by 12 crop functional types, each for rainfed and irrigated areas, per 0.5° x 0.5° grid cell. Irrigation is represented through a newly implemented dynamic irrigation module that accounts for beneficial and non-beneficial irrigation water consumption. Our results show that irrigation shifts to more efficient systems can save substantial amounts of water (54-76% of non-beneficial water consumption) at the basin level, and if used to transform rainfed into irrigated systems, can increase crop yields significantly in many major river basins (14-18% global production increase). Large-scale irrigation transitions are however very expensive. Moreover, affordable low-tech solutions for small-scale farmers on water-limited croplands can increase yields to a similar extent. A simulated global ~15% yield increase from a low-intensity water management scenario could outweigh, i.e. possibly avoid, an estimated 120 Mha of cropland expansion under current climatic conditions. A maximum-intensity water management scenario shows the potential to increase global yields by more than 35% without expansion or withdrawing additional irrigation water. Climate change will have adverse effects on crop yields in many regions, but as we show such adaptation opportunities have the potential to mitigate or compensate these impacts in many countries. Overall, proper water management (sustainably maximizing on-farm water use efficiency) can substantially increase global crop yields and at the same time relax rates of land cover conversion.

K-L2.5-05

Agricultural Adaptation to Climate Change in Rich and Poor Countries

D. Lobell (1)
(1) Stanford University, Department of environmental earth system science, Stanford, United States of America

This talk will review the evidence on the effectiveness of adaptation in reducing climate change impacts in different countries. Much of the model-based evidence is relatively weak, not only in that it relies on models, but that it depends on strong assumptions about what farmers would do in the absence of climate change. A few observational studies have been published in recent years, which will also be reviewed. Overall, the challenge of adapting to climate change is formidable, and rapid learning will be essential for achieving as much reduction in impacts as possible.

K-L2.5-06

Adaptation to Extreme Weather Events by Farmers in China

J. Huang (1)
(1) Chinese academy of sciences , Center for chinese agricultural policy, Beijing, China

Growing evidence indicates that climate change has aggravated the intensity and frequency of extreme weather events in the past and will future aggravated in the future. Overcoming the challenge of increasing extreme weather events, particularly drought and flood, has captured much attention in many developing countries. In China, the annual average crop area suffering from serious drought and flood has also increased in recent decades. Key issues to be discussed in this presentation include: how farmers have responded or adapted to the extreme weather events? What are major measures that have been taken by farmers when they face serious drought and flood? How effectiveness of these measures in mitigating the risk resulted from the extreme weather events? How policy can facilitate farmers to better adapt to the rising intensity and frequency of extreme weather events in the future? Based on primary data from a large-scale field survey in China, the results show that when faced with severe drought or flood, farmers do take various measures to mitigate the climate risk. Most measures taken by farmers are related to investment in and management of water used in agricultural production. The local irrigation infrastructure, policy supports and early warning information services as well as farmers' social capita have facilitated farmers to take the adaptive responses. In addition, existing village, household and plot characteristics also significantly Further analysis shows that the adaptation through farmers' responses significantly reduce crop yield loss and risk of crop yield. The presentation concludes with several policy implications.

L3.1 - Socio-economics and Instruments for Transforming the Energy Sector: Economic Policy Tools for Mitigation of Energy-related GHG Emissions

K-L3.1-01

The economic and policy structure of energy transitions

M. Grubb (1)
(1) University College London, Institute of Sustainable Resources, London, United Kingdom

This presentation will summarise key structural lessons from quarter of a century's debate and experience in seeking to foster low carbon energy transitions, offering a new framework to explain how climate and energy challenges can be tackled more effectively whilst containing energy bills. It will explain three domains of socioeconomic processes each of which involves different actors and decisionmaking characteristics. These three domains operate at different scales of time and social entities and rest on different theoretical foundations. The unique characteristic of energy and climate change is that the issues raised span all three domains in approximately equal measure. The policy implication is the need for three distinct pillars of action, each being approximately equally important.

Drawing on the book Planetary Economics, co-authored with Professors Hourcade and Neuhoff, the presentation will explain from these foundations how the different pillars are complementary and why only packages spanning all three are credible, economically efficient and environmentally effective – and hence, politically stable.

K-L3.1-02

Carbon Markets: Past, Present and Future

B. Pizer (1)
(1) Sanford School of Public Policy, Duke University, Department of economics, Duke, United States of America

Carbon markets are substantial and expanding. There are many lessons from experience over the past 10 years: fewer free allowances, careful moderation of low and high prices, and a recognition that trading systems require adjustments that have consequences for market participants and market confidence. Moreover, the emerging international architecture features separate emissions trading systems serving distinct jurisdictions. These programs are complemented by a variety of other types of policies alongside the carbon markets. This architecture sits in sharp contrast to the integrated global trading architecture envisioned 15 years ago by the designers of the Kyoto Protocol and raises a suite of new questions. In this new architecture, jurisdictions with emissions trading have to decide how, whether, and when to link with one another, and policy makers overseeing carbon markets must confront how to measure the comparability of efforts among markets and the comparability of markets to a variety of other policy approaches.

An important recent development is the 2014 U.S. Environmental Protection Agency (EPA) proposed rules to regulate fossil fuel power plants under existing U.S. law. Final rules are expected this summer. The rules' key features include state-by-state emissions rate targets and considerable flexibility for the states to achieve them. This flexibility includes the states' choice to implement the targets through traditional regulation or the use of carbon markets. If implemented through carbon markets, states face additional questions about carbon market design. Different strategies for emissions reductions and regulation design will have important near-term consequences, in terms of the cost of electricity generation and market prices, and important long-term consequences, in terms of retirements and new investments. These consequences can vary significantly from region to region and from stakeholder to stakeholder.

The long-term consequences are particularly important in terms of the legacy for future policies. If current regulations turn out to be inadequate to address future mitigation goals, debate could begin again over federal legislative options, namely, a tightening of the existing program, an explicit national trading program, emissions taxes, or other alternatives to reduce emissions such as renewable or clean electricity goal. In this event, it will be important to understand how responses to the current proposed regulation may both affect the ability of the electricity industry to respond cost effectively to any new policies in the future as well as the distribution of future costs across stakeholders.

K-L3.1-03

Carbon Pricing Future in China

J. Kejun (1)
(1) Energy Research Institute , National development and reform commission, Beijing, China

A global 2 Degree temperature increase was identified as a political target for climate change. The newly published IPCC AR5 presents a lot of research on scenarios, policies for the 2 degree target. Carbon pricing is one of the key policy options for CO2 emission mitigation. In China, CO2 emissions trading was adopted as a policy for China's low carbon development. The emission trading was launched in 2011 in 7 pilot cities and provinces. An implementation of carbon tax in China was widely discussed, and now is under decision making process in government. This presentation summarizes the analysis of a carbon tax based on IPAC model simulation, and discusses the choice between carbon tax or emission trading in China. In the modeling analysis, in order to support the global 2 degree target, CO2 emissions in China have to reach peak before 2025 and then start deep cut on CO2 emissions. In IPAC modeling analysis, feasibility analysis for this emission scenario was developed. By using this detailed analysis modeling tool, it is feasible for China to peak CO2 emissions before 2025, and start deep cut after that, reaching more than 70% cut by 2050 compared with that in 2020. In the analysis, various policies were considered, including energy efficiency improvement, fuel switching in end use sectors, low carbon power generation, land use mitigation, carbon pricing etc. Based on China's policy making regime, these policies could be implemented in different government agencies according to their functions. There has been a significant progress on energy efficiency improvement since 2005 when China started the energy conservation program as a national fundamental strategy. And in recent years, renewable energy development in China is also playing the main role in the world, accounting for nearly one third of the global production capacity for renewable energy added per year.

However, we do need to consider an economic method for GHG mitigation in China. We have started analysis on carbon tax and emission trading from 2005, by now ETS is undergoing, and a carbon tax was proposed to government. In the modeling analysis, it is found that carbon pricing has significant effects on CO2 emissions mitigation to reach the global 2 degree target, and could be implemented in China. By reviewing the progress of ETS in China, we have discussed the advantages and disadvantages of both carbon tax and ETS, and suggested the future pattern for carbon pricing in China. Carbon tax is strongly recommended as a national policy for GHG mitigation. A system to combine carbon tax and ETS in China is also proposed.

K-L3.1-04

India's Energy and Climate Debate: Uncertainties in Future Emissions and the Scope for Co-benefits

N. Dubash (1)
(1) Centre for Policy Research, New Delhi , India

India occupies a dual position in global climate debates. As a large and rapidly growing economy, India's future energy and emissions trajectory holds considerable importance for global efforts to address climate change. On the other hand, India starts from a very low base of energy use and emissions on a per capita basis, illustrating the considerable future energy needs required if India is to meet the development needs of Indian citizens.

This duality frames Indian climate and energy policy. Given the low levels of current energy usage, poor quality of infrastructure and the need to provide jobs for large numbers of people entering the workforce, the only acceptable starting point from a domestic point of view is India's energy needs, rather than carbon limitations. However, Indian policy formulation is able to consider climate impacts through explicit consideration of 'co-benefits' of alternative development policies. Hence, understanding and operationalising co-benefits is an important theme in Indian energy and climate policy.

This study reviews recent national energy and climate modelling studies to assess the projected range of future emissions, energy demand patterns and energy supply futures. What emerges is a wide variation in projected business as usual futures. Policy scenarios included are a carbon tax, and bottom up demand and supply mix scenarios, leading to a relatively modest deviation from reference cases until 2030.

Key results include: a projected doubling or tripling of carbon dioxide emissions, and an increase in coal use by 2.5–3 times, despite considerable increase in renewable energy use. However, these projections assume continued high GDP growth rates until 2030, which partially drive these results.

Despite the importance of co-benefits, the studies do not systematically assess the co-benefits arising from various climate policies. However, a review of global integrated assessment models applied to South Asia do suggest that air pollution and energy security co-benefits in particular can be considerable.

Looking to the future, the co-benefits framing of India's climate policy is likely to result in sector by sector policy formulation, driven primarily by sustainable development and energy security concerns, with some attention to climate benefits. The co-benefits analysis suggests that the climate gains in terms of 'bending the curve' could be substantial. In order to assess the magnitude of potential reductions in CO2 will require more careful attention to sectoral scenario construction in future model runs.

K-L3.1-05

Mitigation of Energy-related GHG Emissions in Brazil

E. La Rovere (1)
(1) Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

Brazil is one of the largest developing economies in the world. Its long-run developmental pathway needs to face huge challenges, such as: poverty eradication, reduction of inequalities, food security, access to energy and water, public security, technological innovation and competitiveness. Climate change will have to be added to this list, due both to the country high vulnerability to climate change and to its important contribution to global GHG emissions. In this context, this presentation summarizes an analysis of the social and economic implications of different GHG emission mitigation scenarios for Brazil.

Brazilian voluntary commitment to reduce emissions until 2020 shall be reached thanks to the sharp cut on Amazon deforestation achieved since 2004. As the economy grows, emissions related to the combustion of fossil fuels for energy production and consumption have been increasing significantly and are expected to become the dominant source of GHG emissions over the next decade. Mitigation policies and measures, beyond those included in governmental plans, have been identified and grouped in scenarios up to 2030, according to expert judgement on assumptions about its economic and political feasibility, resulting in different penetration rates of technological and management innovations.

Comparative analysis of the scenario results has allowed for highlighting economic (GDP, inflation, trade balance, industrial competitiveness) and social (employment, income distribution, low income household consumption patterns) implications of lower carbon pathways in Brazil. These results provide new insights as an input to the national debate on the strategy to curb down country's GHG emissions up to 2030.

In the past, different policy tools have been used in Brazil to foster the development of renewable energy in Brazil, including: a mandatory blending of ethanol to gasoline; soft loans to increase ethanol production; fiscal exemptions for planted forests of fast growing species such as eucalyptus and pinus, used for charcoal manufacturing; tendering of hydropower plants to be built through public/private partnerships; feed-in tariffs for power generation from wind farms, solar PV and biomass; among others. These instruments have enabled Brazil to reach a level of 45% of renewable energy in total energy supply in 2010, against a world average of 13%.

Now, different command/control and economic instruments may be used to promote a transition to a even lower carbon energy system: the creation of domestic

carbon allowance market is under study by governmental bodies; and the possibility of increasing fossil fuel prices by a variety of taxation schemes is also considered.

The study findings highlight that if command and control measures coupled to microeconomic policies are able to overcome the barriers to mitigation options, decoupling of economic growth and GHG emissions would be possible: additional mitigation scenarios, on the top of existing governmental plans, might increase GDP, employment and household income of the poorer income classes, providing a "win-win" outcome. The gain of income is higher than inflation for low and middle income classes, helping to reach a better income distribution pattern. However, under a global carbon tax scheme, applied on burning of fossil fuels in Brazil as well, GDP is slightly lower. Even though, the use of the carbon tax revenues to decrease labour charges and foster job creation might keep employment levels and preserve social development gains.

The Brazilian case illustrates the relevance of choosing the appropriate instruments to overcome the economic/financial and non-economic barriers to the mitigation options, according to the national circumstances, in order to achieve a transition towards a lower carbon society.

Abstract not communicated

L3.2 - Transformational Energy Technologies

K-L3.2-01

Game Changing Energy Technologies

S. Benson (1)
(1) Stanford University, Stanford, United States of America

Successful transformation of our energy system will require game-changing technological innovations. Some of these innovations are here today - for example photovoltaics and wind turbines. Some are likely to be coming soon, but require additional time and effort to decrease costs and scale them up to the enormous size of our energy system. Looking to the future, additional game changing technologies are needed and on the horizon: carbon capture and storage, renewal fuels made without plants, radiative cooling, just to name a few. Now is an incredibly exciting time be involved in this important research endeavor. Indeed it is the challenge and opportunity of the century. In this presentation I will highlight the tremendous progress that has been made in renewable energy and present emerging innovations needed for a more sustainable energy future.

K-L3.2-02

Prospects for Carbon Capture and Storage

G. Hill (1)
(1) BP Alternative Energy, Global carbon sequestration technology group, London, United Kingdom

Carbon Capture and Storage (CCS) is likely to be a key technology in a world that has a plentiful resource of fossil fuels and cares about limiting CO2 concentrations in the atmosphere. With almost 20 years of development experience, CCS has still to break through the demonstration phase. However internationally a number of large scale projects are about to come on line which might change this perception. This talk will examine what our experience has taught us to date and what challenges remain for CCS.

K-L3.2-03

Energy Systems Integration

M. J. O'malley (1)
(1) Energy Institute and Electricity Research Centre, University college dublin, Dublin, Ireland

Energy systems have evolved from individual energy devices into complex integrated systems that have strong coupling between energy vectors across spatial and temporal scales. Energy Systems Integration (ESI) is the optimization of energy systems across these energy vectors and scales. ESI is most valuable at the interfaces where the coupling and interactions are strong and represent a challenge and/or an opportunity. ESI control variables are technical, economic, regulatory with a strong human dimension. ESI benefits include increase reliability and performance, minimisation of cost and environmental impacts and in particular, increased penetration of renewable energy sources.

L3.3 - Managing Transitions in Cities: Towards resilient, low-carbon cities

K-L3.3-01

Transition and transformation towards low carbon, resilient cities

X. Bai (1)
(1) Australian National University, Canberra, Australia

The facts that link cities and climate change are simple - cities contribute majority of CO2 emissions, and due to the high and growing concentration of population in cities and the geographic locations of world major cities, cities are also increasingly exposed of, and would suffer from, the impacts of climate change. It is increasingly recognized that transition and transformation towards low carbon and resilient cities are critical, and what we do in our cities, and how we do it, may largely determine our collective futures under climate change.

The importance of looking at cities in climate change is paramount, and the need for the role of cities to be better recognized and for cities to be better integrated in international climate change negotiations is essential. However, the real challenge lies in how can we initiate, manage, and achieve transitions and transformations that enable cities to become low carbon and more resilient. Drawing on recent studies and several examples, this paper explores such challenges and potential leverage points, from the following four aspects:

a) The complex and multifaceted linkages between cities and climate change: The linkages between cities and climate change are complex and multifaceted. Cities are the largest contributor of CO2, but they might also be more efficient in terms of delivering the same level of services. Recent research shows that cities impacts on climate change have multiple pathways that go beyond contribution to CO2 emission. Such complexities are not fully recognized, nor they are reflected to inform policy and practice.

b) Contextualizing low carbon concept in rapidly urbanizing regions: The concept of low carbon and

resilient cities often becomes a relative term and context specific. In regions undergoing rapid urbanization and economic growth, the goal of achieving low carbon and resilient cities can have drastically different meaning, which is often contradicted by other objectives that are more pressing and thus given higher priority. For example, how to reconcile the tremendous need to provide urban housing and other infrastructure vs the task of reducing total carbon emission? Competing priorities exist within the cities, but can also be dictated by the national policy and thus beyond the city's administrative capacity.

c)The need to focus from transition to transformation: Transition can be defined as the shifting of system state, in terms of carbon emission quantity, level of resilience. Transformation on the other hand, means fundamental changes in the society, that involves different actors perspective, awareness, behaviour, culture norm, and business governance practices. Much of the efforts in low carbon cities are focused on transition. Research shows majority of consumption based carbon are from upstream indirect emission, which can only be addressed via transformational changes.

d) The need for a better understanding of urban systems processes and interaction: Cities are rapidly changing system with interlinked actors and processes. There are synergies, trade-offs and feedbacks between actions within different sectors, with direct and flow on effects. Such interactions, and in particular the feedbacks, are not well understood. As far as cities are concerned, it probably is not true that all the science needed to take action is out there. Further, the sector or actor that initiates a climate mitigation or adaptation action might be responsible for and own the action, but not the flow on effects, positive or negative. A better understanding of urban system processes and interactions can help identify leverage points and target the most important interactions and actors, which in turn will enable cities to harness synergies while limiting trade-offs.

O-L3.3-01

Urban Climate Change Adaptation and Resilience

C. Rosenzweig (1)
(1) NASA Goddard Institute for Space Studies, New York city, United States of America

Cities are acting as world leaders in climate action. This is a crucial stage where significant opportunities are emerging for the co-production of knowledge between researchers and stakeholders. This discussion will draw on the Urban Climate Change Research Network's (UCCRN) Assessment Report on Climate Change and Cities (ARC3) as an example of the co-production of climate knowledge for cities. The discussion will also highlight the work being done by the New York City Panel on Climate Change (NPCC) to aid in developing science-based policy solutions for resiliency in the metropolitan region of New York City.

The objective of the UCCRN is to bring together experts working on global-scale, climate change and cities assessments in order to simultaneously present state-of-the-art knowledge on how cities are responding to climate change and to define emerging opportunities and challenges to the effective placement of this knowledge in the hands of local stakeholders and decision-makers.

The First UCCRN Assessment Report on Climate Change and Cities (ARC3) was published in 2011 by Cambridge University Press, and articulates urban climate risk frameworks, climate science for cities, and derives policy implications for key urban sectors — water and sanitation, energy, transportation, public health — and cross-cutting issues through land use and governance. The ARC3 report, containing 46 city adaptation and mitigation case studies, represents a four-year effort by 100+ scholars from over 50 cities in both developing and developed countries, and is the first-ever global, interdisciplinary, cross-regional, science-based assessment to address climate risks, adaptation, mitigation, and policy mechanisms relevant to cities.

The UCCRN is now working towards launching the next installment in this ongoing series, the Second UCCRN Assessment Report on Climate Change and Cities (ARC3-2, which has been submitted to Cambridge University Press for publication. The ARC3-2 Report is scheduled to be launched at COP21 in Paris in December 2015. The UCCRN is also launching its Case Study Docking Station later this year, providing examples of urban mitigation and adaptation initiatives from 100 cities across the globe.

New York City, one of the cities included in UCCRN's Case Study Docking Station, is a leading example for urban climate change adaptation and resilience. The New York City Panel on Climate Change (NPCC) is an independent body that advises the City on climate risks and resiliency. Utilizing the best available data, NPCC science informs New York City's comprehensive climate policies, positioning residents and planners to confront expected future changes in the most effective way possible. The NPCC was established in 2008 by then Mayor Michael Bloomberg as an ongoing collaboration between scientists and key stakeholders in the City of New York to integrate resilience against the future impacts of climate change into long term sustainable planning.

The NPCC released its first report in 2010 outlining the key impacts that climate change is projected to have on the city through 2080. In February of this year, the NPCC released its second report, Building the Knowledge Base for Climate Resiliency (NPCC 2015). This provided climate projections for temperature, precipitation, and sea level rise through 2100 for the first time, representing advancement in the science for resilience. New topics covered in the NPCC 2015 report also include public health, with a focus on extreme heat events, coastal storms, and enhanced dynamic coastal flood modeling, which incorporate the effects of sea level rise. The work of the NPCC has been used by New York City planners to guide key adaptation initiatives. This science information was included in rebuilding efforts after Hurricane Sandy in 2012 through the Special Initiative on Rebuilding and Resiliency, in the City's $20 billion adaptation plan for climate change, and most recently in Mayor de Blasio's One NYC initiative for approaching sustainability, resiliency, and equality simultaneously in the 21st century.

O-L3.3-02

Shaping low carbon infrastructures – major requirements and illustrative examples

M. Fischedick (1)
(1) Wuppertal Institut, Wuppertal, Germany

Reduction of GHG emissions caused by cities plays a decisive role in the battle against climate change. Due to rapid urbanization in many parts of the world, particularly in the developing world, appropriate solutions have to be found for growing cities and even new agglomeration areas. In cities with mature infrastructures, their exemplary roles are especially important in demonstrating the cornerstones of a low-carbon transition, such as in their building and equipment operation including deep retrofits, general procurement and mobility system transformation.

Systematic and coordinated strategic urban planning with effective stakeholder participation is of high importance for developing low-carbon urban infrastructures. Specification of mitigation priorities has to start at the very beginning with carefully identifying and addressing the needs and the challenges in each of the key sectors (including basic needs of inhabitants). The planning shall be based on robust scientific analysis, shall start with a solid analysis of the given urban infrastructures, the GHG emission sources (GHG inventory) and their endogenous and exogenous driver. In addition the whole bunch of mitigation options (from smart energy efficiency services to decentralized renewable energy supply structures) has to be considered and properly assessed.

As consequence of high fixed costs of urban infrastructure measures and the long life span of those investments, within the planning process lock-in risks and path dependencies have to be considered carefully. In the long term with the growing implementation of energy efficiency measures to minimize embodied energy becomes more and more important. A better understanding of the value chain and of about how to change the existing relationships is therefore key.

For shaping suitable low-carbon infrastructures no blueprint is available and specific conditions of every city are crucial. However, exchange of experience can play an important role in finding the right solutions. With this regard international city networks and bi- or multilateral partnerships (e.g. in the context of existing twinning towns) can help to exchange experience of how to steer

urban transition processes successfully and how to set a solid fundament to achieve an appropriate implementation culture.

Cities often are the crucial driver and forerunner for significant changes on the national level (or even the international level). They are often focal point for political and cultural changes and provide the right framework for development and testing of (niche) innovations, innovations that have the potential for the necessary changes of socio-economic regimes (including institutional settings and consumer behavior respectively routines). With this regard cities can also be seen as perfect real laboratories. In cities socio-technical texture of modern societies can be found (comprising energy and transport system, provision of food and education etc.), but in comparison to states with a lower grade of complexity. Learning formats can be better placed under those conditions.

Against that background the presentation will provide major requirements for shaping carbon infrastructures and will give illustrative examples for successful practical steps.

Strategic approaches for enhancing climate change adaptation of species and ecosystems

W. Foden (1)

(1) Global Change and Sustainability Research Institute, University of the Witwatersrand, Gauteng, South Africa

Even under best case mitigation scenarios, most species and ecosystems must undergo adaptation if they are to avoid extinction and maintain their functions under climate change. Published observations of such adaptation now number in the thousands and include shifts in species' distributions and the timings of seasonal activities such as animal migrations and plant phenology. A large literature is also emerging, however, on the negative impacts of climate change on less adaptive species and ecosystems. The broad spectrum of impacts includes physiological stress and mortality, population and distribution declines, food web disruptions, and increased competition with dispersive 'climate change immigrants'. Climate change challenges conservation strategies to make a strong shift from traditional preservationist approaches towards promoting adaptive changes while minimising negative impacts. Here I discuss emerging approaches for enhancing climate change adaptation of species and ecosystems and outline some of the key gaps and challenges in this field.

Projecting climate change impacts on species and ecosystems is an important early step in effective adaptation planning. This has driven rapid development of a suite of approaches and methods for assessing the vulnerability of species and ecosystems to climate change, generally by co-opting methods used for other purposes. Each differs in its strengths, weaknesses, resource requirements and suitability to different contexts, and no single one has emerged as clearly superior, nor seems likely to do so in the near future. This introduces a considerable challenge for conservation practitioners, who must select between and learn to apply sometimes complex methods for their focal areas, ecosystems or species. Although filled in part by the forthcoming IUCN SSC guidelines for assessing species' vulnerability to climate change, the gap between academic developments and their accessibility to practitioners remains a concerning challenge. Equally, assessing how human responses to climate change will impact on natural systems (e.g., changes in agriculture

and new infrastructure such as dams and sea walls) is an important gap for species-focused climate change vulnerability assessment in particular.

A range of approaches have emerged for enhancing climate change adaptation of species and ecosystems. These include those focused on landscapes (e.g., increasing protected area connectivity and permeability), sites or site networks (e.g., creating habitat refuges and decreasing non-climatic stressors), and species (e.g., enhancing evolutionary potential through translocation or ex situ conservation). Most are extensions or modifications of existing conservation approaches and, to date, there has been little investigation of their effectiveness for minimising climate change impacts, nor of their potential unforeseen maladaptive effects. Since conservation under climate change is unprecedented, we can expect errors and failures along with successes. Development of an evidence base from which we can learn will facilitate the rapid advancements needed in this important emerging field, and will help to avoid both potentially negative actions and wasted resources. Even while climate change adaptation strategies and our skill at implementing them improve, their potential to minimise losses of ecosystem function and extinction is finite. Reducing greenhouse gas emissions and thereby limiting the rate and magnitude of climate change are vital for the success of climate change adaptation initiatives.

K-L3.4-02

Operational interventions to assist the adaptation of terrestrial biodiversity to climate change

G. Midgley, (1)
(1) Stellenbosch University, Stellenbosch, South Africa

The rate and extent of projected anthropogenic climate change over the next century may be unprecedented in several million to tens of millions of years. This perturbation to the climate system is occurring during an inter-glacial phase, which is a naturally warm phase in the context of the Pleistocene epoch, which prior to the Holocene Epoch of the past 12000 years, has predominantly (more than 80% of the time) seen global temperatures of roughly 5°C cooler than the Holocene, and atmospheric CO2 levels of 180 to 200 ppm vs the 280 ppm CO2 of the Holocene prior to the onset of the Anthropocene. Scenarios of 500+ ppm CO2 and possible warming in excess of 3°C represent a fundamental ecological shock to terrestrial ecosystems globally, especially in the light of the much cooler planetary history of the Pleistocene. Nonetheless, ecosystems and their component biodiversity have been exposed to repeated warming and cooling cycles and have clearly coped with these, indicating the potential for substantial natural adaptive capacity, and inherent resilience.

One clear adaptive response has involved geographic range shifts, especially at higher latitudes in the northern Hemisphere where temperature exerts a dominant control on growing season, biome distributions, and the geographic distribution of species. This observation, together with observations of incipient range shift responses has led to the application of a paradigm largely of "passive" adaptive planning. That is, using projected geographic shifts of species in response to future change, the spatial planning of areas that anticipate the direction and preferred routes for range shifts to facilitate receptive landscapes. Under extreme scenarios involving high rates of climate change on flat landscapes with a high "climate velocity" more active approaches have also been explored, including assisted migration. A final safety-net approach of gene or seed-banking has also been proposed. Such approaches seem relevant for low temperature ecosystems that are rapidly experiencing warming, and may reach levels that could exceed existential tolerance limits established during Pleistocene times.

However, in the subtropics and tropics, where water availability and disturbance regimes exert control over ecosystem structure and function, it is far less clear how important range shifts have been for natural adaptation. In these ecosystems, for example, the past changes in atmospheric CO2 levels have had critical direct impacts on ecosystem distribution, with tropical forests losing significant areal coverage due to the limiting effect of low atmospheric CO2 on tree production. This may have interacted with the fire regime to allow flammable grasslands to expand and dominate tropical regions, possibly enhanced by an ascendant grazing vs diminishing browsing fauna.

Under these conditions, ecosystems respond according to changing disturbance rules, and not climate rules, and thus individual range shifts may be less important, but community effects may be more important as entire ecosystems may change their structure and function over large areas, thus changing habitat conditions for consumers, and indeed interacting with consumer responses. With future atmospheric CO2 projected to approach levels not seen for more than 20 million years, direct CO2 impacts may strongly influence ecosystem and habitat shifts due to changing fire regime and water use efficiency in water-limited ecosystems, potentially encouraging the re-establishment of more woody biomes. This opens the potential for active management response versus the passive landscape planning approach. Active management would involve strategic decisions about desired future states, achievable through the use of fire and graze/browse management responses.

Conservation practitioners would benefit by considering both active and passive adaptive strategies for biodiversity conservation, as both may have relevance, albeit with different emphases, in low and high latitude situations. Much can be learned from experience in active interventions long practiced in tropical and sub-tropical situations involving fire management, browse-graze manipulation, and translocation/reintroduction of animal species. An urgent effort is also required to understand the strength of the CO2 fertilization effect on water-limited ecosystems, and the potential of this process to transform the structure and function of fire and grazing-controlled ecosystems.

Abstract not communicated

L3.5 - Benefits of mitigation of climate change for coastal areas

K-L3.5-01

Benefits of mitigation of climate change for coastal areas

R. Nicholls (1)
(1) Tyndall Centre for Climate Change Research, Southampton, United Kingdom

This presentation will review the possible benefits of mitigation of climate change for coastal areas with a strong emphasis on sea-level rise. This is one of the most certain consequences of human-induced global warming and has significant impacts. Importantly, there is a long-term 'commitment to sea-level rise' due to the long thermal lags of the ocean system and hence the response of sea-level rise to mitigation is slower than for other climate factors. Therefore, while climate stabilisation reduces coastal impacts during the 21st century, compared to unmitigated emissions, the largest benefits may occur in the 22nd century (and beyond). While we cannot avoid some global rise in sea level, we can still avoid significant losses of the Greenland and Antarctic ice sheets, with significant long-term benefits to coastal inhabitants. The available results suggest that a mixture of adaptation and mitigation policies need to be considered for coastal areas, as this will provide a more robust response to human-induced climate change than either policy in isolation. This point has been clearly articulated in coastal impact chapters of the Fourth and Fifth IPCC Assessments. This approach requires the joint evaluation

of mitigation and adaptation in coastal areas which has not been systematically considered to date. Because of the long time constants involved such assessments need to continue beyond 2100 to provide the full implications of the different policy choices. While the basic science of the commitment was available and presented in the First IPCC Assessment, the policy implications are less appreciated and need wider discussion.

K-L3.5-02

Indigenous knowledge on ecosystem cycles in Northwestern Amazon: a collaborative research towards climate change assessment in a regional scale

A. Cabalzar (1)
(1) Instituto Socioambiental, Programa Rio Negro, São Paulo SP, Brazil

Tropical rainforests are of utter importance for ecological balance and climate stability on global scale. However, as widely reported, there is a growing threat to them and their traditional peoples, deforestation performing between 15 to 20% of the global GHG emissions. The Amazon forest is the largest rainforest in the planet. Indigenous peoples have a key role in the future governance of the Amazon biome, considering that 27,5% of the whole extension of the Amazon basin consists of indigenous territories – in Brazil the percentage is about 22% and in Colombia, it is higher than 50% (http://raisg.socioambiental.org/temas/territorio-indigena). This shows significant interrelations between tropical forests, indigenous peoples and the climate change.

The collaborative research initiative here described aims at joining the efforts of IPCC WG II, as stated in its Summary for Policymakers, to more accurately address adaptation and mitigation solutions, as well as knowledge networks on the regional scale, to face climate change effects. Rather than supporting local population to adapt to climate change, this long term applied research project aims to understand how indigenous peoples are engaged with the environment through their current management practices. The notion of life cycle, integrating both sociocultural and natural aspects, is privileged as an assessment methodology. Indigenous peoples have developed detailed and sophisticated knowledge on the ecological processes, which could improve a more rich and territorialized comprehension of ecosystem transformations and climate change.

Since 2005 a collaborative research has been developed on the ecological and socio-economic cycles in the Northwestern Amazon, a region of about 250000 square kilometers of officially recognized and demarcated indigenous territory at the border Brazil-Colombia. This cross-cultural and interdisciplinary research involves a team of indigenous and non-indigenous researchers, and methodologies aimed at an effective communication and collaboration between the indigenous knowledge and Western science. This initiative aims to: (1) describe the economic-ecological and socio-cultural calendar of indigenous peoples of the Amazon northwest, from observations and recordings done by the indigenous researchers over the years; (2) monitor the annual cycles, identifying and analyzing their patterns and variations, noting possible regional effects of more extensive climate change; (3) as a future perspective, guiding environmental governance policies of indigenous territories considering climate change scenarios; (4) propose ways and methodologies to monitor climate change from the collaboration between indigenous and scientific knowledge within the Amazon basin.

Information and policies related to climate change commonly reach the local communities through biased and inappropriate ways, typically from top to bottom. This collaborative research, which emerged in the context of long-term partnership relations between regional indigenous local organizations, FOIRN (Regional Federation of indigenous organizations) and ISA (Socioenvironmental Institute), who jointly develop several projects in the areas of sustainable community development, capacity building etc.), seeks an exchange of knowledge on annual cycles. It departs from a simple methodology based on daily written logbooks kept by indigenous dwellers (trained as researchers) from various communities along the same river (about 400 km long) and some of its tributaries, usually young adults who search for additional information and interpretations with elder knowledge holders, about the phenomena they are observing. In addition, workshops are made to organize and discuss this material with researchers and advisers of ISA. The main assumption is the recognition that indigenous peoples inhabiting the same region for generations, even centuries, and relying directly on ecological and climatic processes and cycles for their own subsistence activities, are the ones who better know and understand the life cycles.

This research process has accumulated extensive material that is being organized, edited and analyzed. This poster describes the annual calendar of the Eastern Tukanoan peoples, and indicates its relevance in assessing ecosystem and climate change on a regional scale and unfolding possibilities in terms of relevant public policies.

K-L3.5-03

Effective adaptation strategies and risk reduction to global changes in small farmers in Mesoamerica

A. Solano (1) ; E. Castellanos (1) ; C. Tucker (2) ; H. Eakin (3) ; J. Barrera (4) ; R. Diaz (5)
(1) Universidad Del Valle de Guatemala, Centro de Estudios Ambientales y de Biodiversidad, Guatemala, Guatemala; (2) Indiana University, Anthropology, Bloomington, IN, United States of America; (3) Arizona State University, Arizona, United States of America; (4) El Colegio de la Frontera Sur, Tapachula, Mexico; (5) Universidad Nacional de Costa Rica, Heredia, Costa Rica

Mesoamerica is a region highly vulnerable to climate change because of its geographic location and topography. Moreover, high levels of poverty and social exclusion increase its population vulnerability. In recent years, the region has been severely affected by extreme weather events with high cost in casualties and economic impacts. A single event such as Hurricane Stan in 2005 produced an economic loss similar to the GDP increment for Guatemala for that year. Drought events are occurring more frequently and threaten food security for thousands of impoverished families who depend on subsistence agriculture.

Coffee is an export crop that has been most affected in recent years not only by extreme weather events, but also by the economic crisis as a result of price volatility in the international market and more recently by the strong incidence of coffee rust infestation. Across Mesoamerica, over 4 million people depend directly on coffee production for their livelihoods. Most producers are farmers with limited areas of land and few economic resources but their system of production results in a robust agroforestry system, which provides various environmental services.

Our Global Changes and Coffee research program has been working with small farmers in the region for the last ten years to study the adaptation strategies of families whose livelihoods are threatened by multiple pressures from global changes such as climate change, increase incidence of pests and diseases, and highly volatile international markets for their products. Our research has focused in four countries in Mesoamerica: Mexico, Guatemala, Honduras, and Costa Rica through the work of a multidisciplinary research network formed by scientists from the social and natural sciences.

In this paper, we will discuss results derived from three objectives of our research program: 1. Studying the perceptions of farmers to identify situations that affect them, 2. Identifying the barriers that limit their efforts to adapt to a multi-stressor environment, and 3. Making recommendations for stakeholders at the local and national level working to support these farmers.

Results show that most farmers who participated in this study perceive that there is a change in climate conditions, resulting in warmer days and changes in the seasonality of rainfall (change in the start and end of the rainy season). The incidence of pests and diseases has also changed: pests are observed more aggressive and more abundant. Still, farmers are mostly concerned about the high volatility of coffee prices in international markets, which of course determine the prices paid to them locally. One important strategy adopted by farmers is diversification both of economic activities and cultivated crops.

Our research shows that there are significant barriers to adaptation among farmers: limited financial resources,

insufficient technical support, low availability of key information such as weather forecasts and market variations, and difficulty in keeping local organizations active.

Adaptation should be approached as a two-way process: top-down, with national-level decision-makers developing policies and programs to increase access to financial instruments, and to improve the dissemination of strategic information on global markets and climate variability. This should be complemented with a bottom-up approach that strengthens existing social capital in the form of local organizations and cooperatives, and increases the flow of knowledge from local communities involved in processes of autonomous adaptation to national government officials and decision makers.

K-L3.5-04

Impact of country-level policies on smallholder farmer adaptation to climate change in Sub-Saharan Africa

E. Nkonya (1) ; F. Place (2) ; E. Kato (2) ; M. Majaliwa (3)
(1) International Food Policy Research Institute, Washington D.C, United States of America; (2) International Food Policy Research Institute, Washington D.C., United States of America; (3) Makerere University, Kampala , Uganda

The overarching challenge of sub-Saharan Africa (SSA) governments is to design appropriate policies that will increase smallholder farmer uptake of climate-smart land and water management (CSLWM) practices. This study was done to determine impact of policies on farmer adaptation to climate change. The study used a transboundary approach in which communities with comparable biophysical and socio-economic characteristics but residing in two neighboring countries with different policies were used. The study shows that investment in agricultural research and development, strong land & tree tenure, decentralization and investment in smallholder irrigation are the key policies that enhance CSLWM uptake and adaptation to climate change. Additionally policies that provide incentives for tree planting and protection and that give mandate to local communities to manage natural resources are key strategies for enhancing uptake of CSLWM.

The study also found that government policies that provide incentives for long-term land investments are more important than large top-down public investments that ignore the role of farmers in planning and management of such investments.

Achieving the Potential Contribution of Planted Forests to Adaptation to and Mitigation of Climate Change

JM. Carnus (1) ; P. Freer-Smith (2) ; M. Tomé (3) ; P. Tim (4) ; T. Fox (5) ; W. Kollert (6) ; C. Orazio (7) ; J. Morison (8)
(1) INRA, Department of forest, grassland and freshwater ecology, Toulouse, France; (2) Forestry Commission, Forest research, Farnham, United Kingdom; (3) ISA, LISBON, Portugal; (4) Scion, Rotorua, New Zealand; (5) Virginia Institute of Technology, Forestry, Virginia, United States of America; (6) FAO of the United Nations, Forestry, Rome, Italy; (7) EFI, EFIATLANTIC, cestas, France; (8) Forest Research, Centre for sustainable forestry and climate change, Farnham, United Kingdom

Globally, production and provision of ecosystem goods and services from planted forests are being altered by climate change. This poses new challenges to forest policy makers, local communities, forest managers and the forest-based industries which depend increasingly on wood and biomass resources from planted forests. Planted forests can also be managed to make a major contribution to removal of cardon from the atmosphere and hence the mitigation of climate change. Climate change adaptation strategies and recommendations for sustainable forest management have been developed at global or regional scales for planted forests in various environmental and socio-economic contexts, but these need to be complemented and further elaborated for implementation at local scales in close interaction with regional, national and local stakeholders. We will present territorial foresight approaches, landscape simulation tools, carbon budgeting and best practice case studies from planted forests in various temperate regions around the world. These can provide useful models and demonstrators on which to base management options to achieve effective future adaptation to and mitigation of climate change.

K-L3.5-06

Using seasonal forecasts to improve small farmers' resilience and adaptation to climate change and food security in Yatenga northern Burkina Faso

L. Some (1)
(1) Institut de l'environnement et de recherches agricoles, Gestion des ressources natutelles, Ouagadougou, Burkina Faso

Agriculture in the Sahel is strongly dependent on rainfall, hence the urgent need to disseminate appropriate seasonal climate forecasts. Since 1998, researchers in several international and regional forecast centers help of experts from national meteorological services strive to provide answers. In June 2014, these predictions were compared with indigenous knowledge based on observations of certain signs, made by people in 11 villages of the CCAFS research site in Yatenga, Burkina Faso. These two types of prediction converged and gave a season rainfall deficit trend compared to the average observed over the last thirty years. Ten farm managers in each of these villages, which produce cowpeas and / or sesame each received a radio to monitor weather information broadcast daily in local language and in French by a community radio station covering the area well. Yield squares were placed in their fields to an assessment of production. Meanwhile, ten farmers in six villages considered as control were also selected and their fields, followed in the same conditions as above. The controls did not receive information on seasonal climate forecasts through the project and have not been endowed with radios. The results show excess rainfall totals to normal in the region, but badly distributed in time and space, causing dry spells in some localities. Preliminary agronomic results do not show significant differences between the two types of monitoring operations.

Key words: Productivity, sesame cowpea, climate forecasting, Yatenga, Burkina Faso

K-L3.5-07

Joint public and private finance for ecosystem-based adaptation - an example from nature-based coastal protection in Indonesia

K. Meijer (1)
(1) Deltares, Scenarios and Policy Analysis, Delft, Netherlands

Measures to adapt to climate change can have negative environmental impacts. For example, coastal flood protection walls prevent the influx of sediment and the natural build-up of coastal areas, while increased fresh water storage in reservoirs can lead to fragmentation of river ecosystems. However, adaptation can also be done with less impact on the environment, for example by restoring mangrove forests to protect against floods. Such adaptation strategies that make use of the natural functioning of ecosystem processes are referred to as ecosystem-based adaptation. Ecosystem-based adaptation can therefore be assumed not to have negative environmental impacts but rather to strengthen or expand ecosystems and protect biodiversity.

Developing countries may require financial support to adapt to the impacts of climate change. The international community has committed to providing 100 billion USD/year from 2020 to support climate change mitigation and adaptation in developing countries. With roughly half the amount to be spent on adaptation, large financial flows can be expected in the coming decades to support the implementation of adaptation projects in developing countries. Funds should come from both public and private sources; public funds should be used to 'leverage' private sector funds. Through the provision of finance, investors and donors may steer how adaptation is implemented. The question this paper addresses is whether ecosystem-based adaptation is, or can be made, as attractive to

investors and donors as conventional adaptation.

This paper starts with a discussion of the revenue-generating potential of ecosystem-based and conventional adaptation alternatives for different types of climate impacts. Subsequently, we analyze the case of nature-based flood protection in Indonesia, which is currently being implemented as an alternative for concrete breakwaters that have been used so far. We discuss economic benefits and (financial) incentives related to both options. We pay specific attention to the financial aspects of the nature-based flood defense, which is financed through a combination of international and national public, and international private funds. Based on the analysis of the case we provide suggestions for international public funds to further promote ecosystem-based adaptation solutions and to leverage private sector finance for this purpose, and provide a first check regarding to what extent such solutions are actively or passively promoted by a selection of current funds.

K-L3.5-08

Global change adaptation in the Llobregat basin: methodology and tool for medium and long term water resources planning

A. Cabello (1) ; L. Pouget, (1)
(1) cetaqua, Sustainability department, Cornellà, Barcelona, Spain

In recent years, water resources management has been facing new challenges due to increasing changes and their associated uncertainties, such as climate, water demand or land use. In this context, the Water Change project developed a methodology and a tool which can provide support to decision makers in assessing potential future impact of global change on water resources and give guidance as to the effectiveness of possible strategies of adaptation.

The methodology focuses on the creation of global change scenarios, the analysis of impacts and the definition of adaptation strategies based on a cost-benefit analysis. The tool developed (Water Change Modelling System or WCMS) is a software-based system with a modular approach, linking different models (hydrological, water management and water quality models). The tool enables users to quantify the impacts of global change scenarios and test adaptation measures.

The methodology and tool were applied to the Llobregat river basin, a highly populated catchment under increasing water stress in the North-East of Spain. Impacts of global change scenarios on water supply were assessed for different time horizons and optimum adaptation strategies in terms of cost-benefit were proposed.

The user is free to choose the models to be run in the tool, and different scenarios of global change can be used as inputs, to assess the impacts on water resources (in terms of quality and quantity). Finally adaptation measures can be implemented to test their effectiveness. Including adaptation to global change in water resources management planning is quite challenging given the uncertainty of future predictions in terms of demand, climate and land use. The adaptation strategies chosen must minimise the risk at an affordable cost, taking into account all the scenarios which could occur at a given time horizon.

As mentioned in the Water Framework Directive, water management plans will have to include adaptation strategies taking into account the impacts of climate change on the water sector. In this context, the methodology and tool developed aim to provide support to decision makers in water management: The tool can be used in any basin and the methodology can be applied in order to evaluate different adaptation strategies, in terms of deficit reduction and costs involved. Thus water and basin agencies are likely to be interested in the final product, and they could be identified through associations such as the INBO (International Network of Basin Organisation).

For the tested case study, a total of 65 scenarios of global change were developed and run using the WCMS. The possible future impacts on water resources and on the water supply of the basin were obtained and the results show the range of impacts increases with time. According to the projections, in 2030 the deficit may reach 10% of the demand while in 2100 the deficit could reach 30% of the demand.

As a response to the impact foreseen different adaptation strategies which could be implemented in the Llobregat River Basin were proposed and assessed. Specific adaptation measures were selected to be applied to the Llobregat river basin. Each adaptation strategy was studied in detail and the amount of water gained from its application and the price of implementation were identified, with the aim to avoid water deficit at the lowest costs.

Each of these strategies was tested for several future scenarios with the aim to know which part of the drought damage has been effectively avoided and which cost (investment and operation of the measures) should be assumed. The inclusion of these alternatives into the tool and the calculation of their costs and benefits provided insight for decision-makers about how much adaptation is needed with respect to the uncertainty of future global change scenarios.

In the case of the Llobregat River Basin, the results showed benefits are significantly higher than costs and thus adaptation to Global Change is desirable. Regarding which strategy should be chosen, the decision-maker can apply different selection criteria, combining the economic values with other indicators of impact.

K-L3.5-09

Observations and guidance for land-based mitigation

M. Herold (1)
(1) Wageningen University, Wageningen, Netherlands

Progress in observations, and the development of community consensus guidelines and training materials provide underpinnings for planning, implementation and evaluation of mitigations in the forest and agricultural sector. We review the observation needs from multiple stakeholders involved in mitigation and assess how the evolution of dedicated Sourcebook for REDD+ monitoring development Global Observations of Forest Cover and Land Dynamics (GOFC-GOLD) has supported developing countries. Important developments in the context of the Global Climate Observation Systems (GCOS) are increasingly improving the usefulness of monitoring Essential Climate Variables for climate change mitigation purposes.

L4.1 - The climate, finance and trade nexus: turning a political challenge into a sustainable development opportunity

K-L4.1-01

Upgrading finance and price signals in an adverse economic context

JC. Hourcade (1)
(1) International Research Center on Environment and Development (CIRED), Paris, France

The current context of the world economy in the aftermath of the 2008 financial crisis makes difficult to implement a quickly rising carbon price to trigger ambitious low carbon transition (competitiveness issues, unemployment, political reluctance to transfers compensating the segments of population the most affected by higher energy prices).

This presentation will demonstrate that the emerging calls for upgrading climate finance will also confront this adverse context because of the tightness of public budgets. It will then propose to turn the question upside-down through

making climate finance a lever to upgrade the efficiency of the current financial intermediation in directing saving towards long term infrastructure investments.

It will then display the basic principles of financial devices apt to a) lower the investment risks on low carbon projects based on an agreed upon notional value of carbon which can be increased at a pace higher than this of a carbon price b) redirect to these investments private savings which go currently in speculative investments and liquid financial products c) foster a sustainable growth recovery out of the current fragile economic context.

It will conclude in showing how such a framework will a) reduce tensions due to the asymmetry of trade- impacts of carbon prices amongst sectors and countries b) fulfill the CBDR principle and c) increase the incentive efficiency of carbon pricing, hence its political acceptability.

K-L4.1-02

Using trade policy to ensure the viability of massive use of low carbon technologies

R. Meléndez-Ortiz (1)
(1) International Centre for Trade and Sustainable Development , Geneva, Switzerland

The recent IPCC-report clearly demonstrates the need to shift to a cleaner energy mix if we are to stay within the agreed 2-degree target of global temperature rise. In order to do so, costs of renewable energy must go down and markets need to be strengthened so as to allow for a scale-up of innovation, production and deployment of sustainable energy technologies.

Trade policy has an important role to play in this respect. Reducing tariffs and barriers to trade in services related to clean energy will make it easier for private actors to optimize their supply-chains, thereby pushing down costs. In order to further enhance trade opportunities it will also be necessary to address less tangible but nevertheless significant non-tariff barriers such as standards.

In the past few years, there has been a surge in the use of trade remedies in the area of clean energy. Whereas this to a great extent reflects a natural consolidation of the market with steeply falling prices, the pressure is strong on governments to put in place trade restrictions to protect its domestic industry.

Similarly, whereas decision-makers across the world recognise the need to scale up clean energy at home, it can be challenging to put in place policies that may be perceived as costly unless there is an encouragement specifically for the domestic industry. This has led to the proliferation of trade restrictive policies like local content requirements, which demand that a certain amount of inputs in different clean energy projects be produced domestically.

Ironically, many of these trade restrictive policies maintain costs of climate-friendly technologies artificially high.

There are several options for addressing these trade obstacles. First, there are regional trade agreements- many of the world's leading trade nations are currently involved in the negotiations of "mega-regionals" such as the T-TIP and the TPP. Second, there is a negotiation underway under a sectoral initiative aiming towards an Environmental Goods Agreement, EGA. Last, there is the option of unilateral trade reform.

The engagement and support of the climate constituency in these efforts would ensure a better alignment of trade policies with pressing climate change goals.

K-L4.1-03

Connecting emerging initiatives; the lessons for the UNEP finance inquiry

N. Robins (1)
(1) UNEP, London, United Kingdom

The UNEP Inquiry was launched in January 2014 to identify and advance policy options that can better align the US$300trn global financial system with long-term sustainable development. The Inquiry has worked through partnerships at the country level - including Bangladesh, Brazil, Colombia, France, India, Indonesia, Kenya, South Africa, Switzerland, the UK and the USA - as well as with international institutions. Its findings show that a growing number of governments, regulators, standard-setters and market actors are incorporating sustainability into the rules that govern the financial system. Across the Inquiry's work, climate change has emerged as a key cross-cutting issue, and the Inquiry has recently published an emerging framework for linking financial reform and climate security. This framework identified four priority areas: risk management and prudential regulation; capital mobilisation; system transparency; and strengthening financial culture. Cutting across these priority areas, the strategic role of central banks has emerged as a critical theme. In this session, the Inquiry will present its findings, suggesting ways in which international cooperation could be strengthened.

L4.2 - Resilience and Transformative Solutions - Refining Old Strategies and Developing New Ones for Adaptation in Island Environments

K-L4.2-01

Climate change governance and Caribbean SIDS

M. Scobie (1)
(1) The University of the West Indies, Institute of International Relations, St. Augustine, Trinidad and Tobago

The analysis of governance of climate change is extremely important, more so for small island developing states: adaptation, mitigation, climate finance, governance architectures, environmental justice, equity etc. Albeit a small proportion of the world, the peoples of these nations and their governance challenges are part of the global climate policy discourse. That said, the recent scholarly literature has focused on the science of climate change for SIDS, but there is less on the governance of climate change for SIDS in general and the Caribbean in particular. The science is clear: adaptation is needed and urgently, yet the formula to make this happen is hard to come by. What would be a useful model for the climate governance architecture in the Caribbean SIDS region? The paper puts the results of the present science and future projections into the context of existing governance arrangements and looks at the weaknesses of the present system and how those may be eliminated to improve governance effectiveness. These issues are important for climate policy practitioners in SIDS and should also be at the forefront of the minds of academics, policy makers and practitioners in donor countries as they seek to engage in the analysis of the best models for effectiveness in climate governance, especially for SIDS.

While there are studies on the global dynamics of environmental governance, governance at the local level in SIDS, and in particular Caribbean SIDS has been neglected in the literature. Transnational climate governance is becoming more complex (Andonova, Betsill, and Bulkeley 2009), with a multiplicity of new actors, roles, structures and architectures of the earth's governance (Bulkeley and Moser 2007). This fragmentation of global and local levels of authority are often a hindrance for climate change governance (Palmujoki 2013). The effectiveness, legitimacy and transparency of voluntary non-binding parallel streams of governance is under debate but reflects global engagement for governing climate change (Suiseeya and Caplow 2013) and (Kalfagianni 2014)). The challenge is to develop a global climate governance model

that balances legitimacy and effectiveness while allowing participation from stakeholders (Dryzek and Stevenson 2011). This is particularly true as vulnerable small island developing states try to find a place in the global governance debate and to govern climate change in their countries.

As in every other area of governance, climate governance works where good governance is institutionally entrenched in political systems and climate governance is difficult where weak and under-resourced institutional arrangements are present. Environmental impacts of climate change increase the social, economic and environmental governance challenges and responses of governments. At the heart of effective climate change governance is the successful political coordination of adaptation and mitigation efforts from global to local scales by state and non-state actors (Fröhlich and Knieling 2013). States and international organisations are responsible for at least a third of the initiatives (Hale and Roger 2014). The private sector has been heavily involved through private carbon certification schemes, emission trading markets and the Clean Development Mechanism (CDM) projects in partnerships with nation states (Lund 2013).

This research reviewed the 15 SIDS that form part of the Caribbean Community (CARICOM) and share mechanisms for climate change governance. Information on climate change and development impacts for this paper was obtained from semi-structured interviews with national and regional officials in climate change related posts. Secondary sources included reports and publications of multilateral development agencies, regional agencies and from the IPCC. The commonality of perspectives from the interviews was remarkable but not unexpected, key themes included: the institutions that provide the greatest support at global, regional and national levels for climate change governance and their most important impacts/contributions; the main sources of financing for climate change governance in the Caribbean and whether they were sufficient; challenges in application of funds; adequacy and effectiveness of regional mechanisms; whether time-bound project financing allowed for sustainable adaptation policies at the national level; alternative approaches for Caribbean states and what more is needed regarding global, regional and local climate change adaptation.

This paper questions whether and to what extent global governance dynamics for climate change resonate in small states. It argues that the Caribbean climate change problem is both a resource problem and a governance problem. States have limited resources due to pre-existing development challenges and insufficient external support given the unsustainability of the traditional project based financing model of climate governance. These small states face huge environmental changes that they cannot influence and weak governance architectures to respond to this new threat to development.

K-L4.2-02

Creating the conditions for transformative action – mobilising the private sector in SIDS

J. Firth (1)
(1) Acclimatise, Newark, United Kingdom

Acclimatise has worked in over 50 countries assessing the risks arising from a changing climate advising international, national and sub-national governments, NGOs, development partners and business and financial services sectors. Drawing on our experience and observations from published sources this presentation will explore a theme which we believe is a significant driver and enabler in delivering transformative solutions.

The role of the 'private sector' in resilience building and adapting to climate change remains an area which has received little attention. Most SIDS operate on a market based economy in which the private sector directly and indirectly is the largest contributor to a country's GDP. However the scope of national adaptation planning, the vulnerability and risk assessments providing the evidence base; and the recognition of the sector's role in providing and delivering solutions is rarely explored.

This is not helped by using a technical 'adaptation language' during engagement which has little relevance to those in the sector and treating the 'private sector' as a homogenous group. Within many governments the climate change portfolio is 'owned' by Ministries with environmental or natural resource based departments. These Ministries are usually under-funded and have limited political influence within governments. This in turn, constrains their ability to influence cross-sectoral decision making, national budget setting and prioritisation, and ultimately in delivering transformative change working with the private sector. If we are to respond to the climate change challenge then we need to see (in both developing and developed countries) the resilience and adaptation portfolio passing to where the power is: finance, national planning and the offices of Prime Ministers or Presidents.

K-L4.2-03

Transformative solutions in two Caribbean Insular Territories Under Climate Change Pressure : How can we reach Resilience targets ? Climate Governance in two non-independent Caribbean Insular Territories: two different paths?

J. Priam (1)
(1) Centro de Investigacion, Caribbean islands, Puerto Rico

This contribution shows how two non-independent islands of the Caribbean reflect the dynamics of climate governance in their respective Metropolis. For Puerto-Rico, the approach and solutions adopted are best understood against the background of USA climate governance, while in the case of Guadeloupe governance arrangements are more aligned with climate change policy in France and Europe. This theme is explored with reference to case studies on the first wind energy projects implemented in both Guadeloupe and Puerto Rico, and other renewable energy initiatives introduced since 2009.

We explore the differences in approach to climate change issues in the two islands by analyzing the perceptions and attitudes of residents living near the wind farms, as well as the local press. While reflecting internationally accepted approaches to adaptation and mitigation and those of the Metropole, Guadeloupe and Puerto Rico may be considered potential "experimental laboratories" for developing transformative solutions, whose experience may be transferred to other island territories, and even to the Metropolis. A brief analysis of the overall contribution of appropriate renewable energy development to the building of resilience to climate change in these islands, is also presented.

K-L4.2-04

Innovative climate financing in Small Islands Developing States (SIDS)

V. Fayolle (1)
(1) Acclimatise, Oxfordshire, United Kingdom

Acclimatise has worked in over 50 countries assessing the risks arising from a changing climate advising international, national and sub-national governments, NGOs, development partners and business and financial services sectors. Drawing on our experience and observations from published sources this presentation will explore a theme which we believe is a significant driver and enabler in delivering transformative solutions.

As part of a joint effort to mobilize US$100 billion per year by 2020 from both public and private sources to address both the adaptation and mitigation needs of developing countries, a new global financing mechanism was established: the United Nations Green Climate Fund (GCF). Great expectations are being placed on the recently capitalised GCF: The GCF shall meet ambitious goals in terms of promoting a "paradigm shift towards low-emission and climate-resilient development pathways by providing support to developing countries to limit or reduce their greenhouse gas emissions and to adapt to the impacts of climate change" with a special emphasis on adaptation in SIDS, Least Developed Countries and Africa, as well as mobilize funds at scale in particular through private corporations, recognising that in the context of strained government budgets the private sector accounts for 70 to 85% of total global investments.

Against this backdrop, the GCF's Private Sector Facility

aims to play a key role in promoting participation of private sector actors in developing countries, with a special emphasis on domestic private sector actors and adaptation (recipients of funding). However, the specific modalities to achieve this still need to be defined. If the GCF is to scale up private investments in building climate resilience in SIDS, it is essential that it reflects up on the experience in a SIDS context gained by existing multilateral and bilateral climate initiatives, such as the World Bank's led Pilot Programme for Climate Resilience (PPCR) in the Caribbean and Pacific, that deploy concessional resources using a programmatic approach.

L4.3 - Regional Perspectives on Low Carbon Pathways: exploring the conditionalities for climate resilient and equitable development

K-L4.3-01

Regional Perspectives on Low Carbon Pathways: Exploring the conditionalities for climate resilient and equitable development with examples from India

J. Roy (1)
(1) Jadavpur University, Jadavpur, India

It is beyond debate now that future 'global' stabilization target is fundamental to manage climate change, impacts and associated risks. Mainstream debate is around the need to coordinate the national goals with global agenda. National autonomy argument in fragmented world is dominating. Also national priorities vary depending on relative speed and level on growth trajectories.

Low Carbon Pathways : Even though India has much lower per capita emissions, growth pattern of economic activities including energy supply sector are going to experience very high growth rates in coming decades. With a National Action Plan on Climate Change (NAPCC) in place since 2008 a number of actions are in place. Top down global model estimated with India specific sectoral parameter show what additional widespread actions are needed. This clearly shows need for much larger actions: policies, technology deployment, institutions and capacity building are needed. Cross sectoral implications show need for transformative change in energy supply system. Bottom up study at national, state and city level help in identification of sector specific low carbon growth potential of multiple options compared to base year emissions. Potential is high in energy supply sector, buildings sector and agriculture sector with relatively low potential in industry sector which has made much progress in the past and transport sector has huge challenges. Looked into the issue from investment need perspective the sectoral distribution gets reversed. Industry sector where low hanging fruits are already harvested, high cost options are awaiting deployment. Genuine concerns exist on the technical cost/ investment /system change. The cost effective solution list might not be the easiest to implement based on public acceptability, market entry barriers, existing policy vacuum, technical and institutional capacity available.

Resilience : Impact and Adaptation to develop a climate change proof development trajectory is much in discussion in India also evident from National Action Plan. Many adaptation needs in India e.g. flood management systems, heat and cold related health safety systems, water system security, food security systems will enhance manifold the demand for energy supply with implications for synergistic mitigation efforts. Example of extreme event led health impact study shows that there is close link between adaptation and mitigation. To enhance resilience labour productivity needs to be protected. This needs huge investment on space conditioning. Energy intensive appliances demand is on steep rise for residential, agriculture and mobility sectors not only due to climatic parameters but also due to rising income. There is scope for energy efficient technology diffusion for new technologies but activity level growth is going to take away clearly the benefits in the short to medium term. Bending of curve cannot be seen in at least in next one and half decade.

Equity : Climate justice calls for faster, larger access to modern energy. It is not about providing lighting and space cooling demand but about productive energy input supply. However, case studies on behavioural response also highlight the scope of take back effect due to behavioural response parameter of rebound effect. Experiments (solar micro grids in village electrification) are happening but scale up needs multiple interventions. Technical feasibility is not in question but strategic implementation and multi level governance issues need equal attention. So it is not only technology but behaviour and social practice matter no lesser for making transition to low carbon growth trajectory. Case studies at megacity level show how commitment to larger goal of low carbon growth through conscious decision making can only make a difference in final outcome. Analysis based on case studies of building operational energy demand lead us to conclude that when a technology becomes efficient and if end user is not consciously guided by larger goal of carbon footprint reduction but are looking at financial balance alone may not take a decision in the best interest of low carbon growth. Full economic, social and environmental benefit of appliance efficiency can be realized through better strategic management of operational behaviour of the end users. It cannot be managed by correcting market price policy alone so there is need to strategically balance between social and market norms. Context of implementation in a fast growing developing country are important to understand. Implementation of newer techno-economic solutions does affect host of actors who will be losers and gainers. Technology deployment policy needs to be strategically designed through new fiscal instrument design market correction, land policy, social goal orientation which most of the time rests either with the federal government or with other non government actors. So besides numbers and evidences, coordination among various layer of governance and choice of new policy instruments are also at the core of speed of implementation.

L4.4 - Multilevel Governance of Climate Change - New Strategies for Coordinating Policies on Mitigation and Adaptation

K-L4.4-01

The Emergence of new structures for global governance: will 'bottom up' actually work ?

D. Victor (1)
(1) University of California, San Diego, United States of America

With the failure of integrated, top-down bargaining strategies, analysts and diplomats have now turned to bottom-up methods such as "building blocks" and "climate clubs" to coordinate national climate change policies and to avoid persistent diplomatic deadlock. Decomposition of the grand problem of climate change into smaller units is

a crucial first step towards effective cooperation. But given the great uncertainty of the feasibility and costs of potential solutions, this bottom-up approach will only work if it is supported by institutions that promote joint exploration of possibilities by public and private actors along with the scaling up of successes. As politics precludes creating many of these institutions under the consensus-oriented decision rules of the UN system, engaged outsiders—including especially clubs or building blocks that can learn in the face of uncertainty—working in parallel with the UN diplomatic process will have to provide them.

K-L4.4-02

Delivering ambitious climate action and the role of multilevel governance

J. Corfee-Morlot (1)
(1) OECD, Paris, France

This presentation presents a framework for multilevel governance, showing that advancing governance of climate change across all levels of government and relevant stakeholders is crucial to avoid policy gaps between local action plans and national policy frameworks (vertical integration) and to encourage cross-scale learning between relevant departments or institutions in local and regional governments (horizontal dimension). Vertical and horizontal integration allows two-way benefits: locally-led or bottom-up where local initiatives influence national action and nationally-led or top-down where enabling frameworks empower local players. The most promising frameworks combine the two into hybrid models of policy dialogue where the lessons learnt are used to modify and fine-tune enabling frameworks and disseminated horizontally, achieving more efficient local implementation of climate strategies. Such integration generates benefits at all stages of the policy process. This includes agenda setting and strategic planning, to encourage political leadership and stakeholders' support; policy formulation and approval to promote long-term vision and near term action; local implementation to overcome obstacles, build necessary capacity, and establish reliable financing for action; feedback and evaluation; and dissemination to promote information sharing and cross-scale learning.

A review of current practices suggests the need for national governments to create a sound institutional foundation and knowledge base to support decision making and action at local levels. National governments are also essential to help deliver financial resources to support local action. Key tools include harmonized GHG inventory methods for local government use and climate risk screening and mapping tools. Institutions designed to support learning and iterative policy making include establishment of regional science-policy centres or "boundary" organisations, often located in academic institutions, to provide locally-relevant scientific and other expert information, and a means for providers and users of such information to engage in a two-way conversation that leads to usable information. Strong urban climate policy networks – working horizontally across local actors to exchange information and experience – is another key institution innovation that enhances learning and that is helping to scale up action from the bottom-up. Designing tools and institutions to strengthen multi-level governance of climate change will help governments to scale up climate action and to find cost-effective climate policy solutions to drive low-carbon, climate resilient development. It will also help national governments to deliver on ambitious climate policy goals in the coming decades.

K-L4.4-03

Climate governance in Latin America: Case studies of Brazil, Chile, Colombia and Peru

A. Rudnick (1) ; I. Rebolledo (2)
(1) MAPS Programme, Latin America, Santiago, Chile; (2) Poch Ambiental S.A., Santiago, Chile

Since 2007, there has been an increase in government institutionalization of climate mitigation actions, and many of these efforts are relatively recent and in design or early implementation stage. There is insufficient literature from developing countries that evaluates this institutionalization. It is important to monitor this trend closely to evaluate if policies and institutions created are sufficiently strong and effective to lead to the reductions required (Working group III, chapter 15, AR5 IPCC).

The institutional arrangements case studies aim at describing and documenting the governance related to climate change within MAPS Latin American countries (Brazil, Chile, Colombia and Peru). A case study per each country (Brazil, Chile, Colombia and Peru) will be conducted to describe and document, from a practitioner´s perspective, the state of the play of the institutional approaches in each country. The results can be useful for other developing countries when examining and enhancing their institutional structures.

The research questions that the country case studies aim to answer are:

- What institutional arrangements exist in MAPS LAC countries (Brazil, Chile, Colombia and Peru), at a public and national level, to address climate change?
- What institutions related to climate change mitigation (and adaptation if information is available) exist?
- How are decisions taken at a national and subnational level?
- Are the decisions and actions legally binding? How climate change decisions are institutionalised or implemented?
- If there is information available about how climate change is institutionalised in the private sector, local government and NGOs?
- How have MAPS processes benefitted from certain institutional arrangements? Has there been any changes or additions in the institutional arrangements as a result of MAPS processes or during MAPS processes? Has there been collaboration among MAPS LAC countries to share and learn from certain institutional arrangements?

Note: Mitigation Action Plans and Scenarios (MAPS) is a collaboration amongst developing countries to establish the evidence base for long-term transition to robust economies that are both carbon efficient and climate resilient. These processes involve high-level stakeholders in the research process of determining mitigation scenarios for their countries. For more information on the Mitigation Action Plans & Scenarios Programme see www.mapsprogramme.org

K-L4.4-04

Coordinating adaptation between the municipal and local level: building adaptive capacity of resource poor communities in South Africa

G. Ziervogel (1)
(1) University of Cape Town, Environmental and Geographical Science, Cape Town, South Africa

It has been acknowledged that much adaptation to climate change occurs at the city, municipal and community scale. At this local level, both government and local communities need to take action. Both groups needs to strengthen their adaptive capacity and their ability to interact with each other particularly in the face of shocks and stress, as experienced through climate change, resource depletion, economic volatility and increasing inequality. This paper draws on the experience of the FLOW Programme (Fostering Local Well-being). This is a transdisciplinary research project based in the Bergrivier Municipality, in the Western Cape that seeks to build adaptive capacity of resource poor community members and strengthen their interaction with the municipality. We suggest that individual's adaptive capacity is dependent on three interdependent dimensions, namely, 1) the development of social cohesion, 2) self-determination, and 3) connection to life-support systems. The paper will explore how the three dimensions that engender adaptive capacity have been built in the case study site. Specifically, the project has worked with youth ambassadors, local entrepreneurs and the local municipality using a range of interventions including participatory community mapping, resource flow mapping, personal and collective reflective practices, storytelling skills through video journalism and introducing community currencies. The paper will interrogate the extent to which these interventions have built adaptive capacity and the importance of including this type of work in future climate change adaptation and transformation responses.

L4.5 - Equity: A Condition to Triggering Action ?

K-L4.5-01

The necessary role of ethics and justice in climate policy'

S. Caney (1)
(1) University of Oxford , Oxford, United Kingdom

The talk will cover three points:

(1) Justice and the target of climate policy. First, it is often argued that climate policies should avoid «dangerous anthropogenic interference» (UNFCCC Article 2). Specifying what constitutes a 'dangerous' climatic changes necessarily requires the use of normative criteria, and cannot be settled solely by scientific analyses of the effects of climate changes. Determining what the goal of climate policy should be requires policymakers to decide what changes, if any, are acceptable, and which are not and call for action; and this requires ethical criteria and an appeal to ideas of justice. I argue that on any plausible ethical criteria even a 2C goal permits dangerous climatic changes,and that recent calls to move away from the 2C target are misconceived.

(2) Just burden sharing. A second criterion of a just climate policy is that the burdens of combating climate change (including the costs of mitigation, adaptation and compensation) are shared equitably. Many appeal to the doctrine of 'common but differentiated responsibility'. I argue that this requires the endorsement of both a polluter pays principle and an ability to pay principle, and suggest how they should be combined.

(3) My first two points emphasise the need for principles of justice (in both specifying what should be the target of climate policy and how burdens should be shared). My third point draws on this to emphasise the importance of transcending a pure Cost Benefit Approach for evaluating targets and policies.

Analysis of equity (including as related to ambition) in submission of INDCs

D. Waskow (1)
(1) World Resources Institute, Washington DC, United States of America

The preparation of Intended Nationally Determined Contributions (INDC) is an important opportunity for countries to provide information about how their contributions are equitable. The COP decision agreed at Lima invites each country to describe in its INDC its contribution is "fair and ambitious, in light of national circumstances, and how it contributes towards achieving the objective of the Convention as set out in its Article 2." A description of equity should include the use of a holistic set of quantitative and qualitative indicators that provide the international community and domestic stakeholders with essential information that includes emissions responsibility, capabilities (including economic and development capabilities), vulnerability and capacity to adapt, potential to act, and co-benefits of action. The information provided can be applicable to both mitigation and adaptation components of INDC. The INDC should also address how the INDC contributes to the global level of ambition for emissions reduction and collective effort for adaptation. Providing robust information and a narrative concerning equitability can provide enhanced transparency; enable comparison of contributions among countries; increase international understanding of what is equitable in the context of specific national circumstances; and enable linkages of the contribution with national sustainable development objectives. Doing so can generate constructive discussions both within and among countries about equity and motivate increased and more equitable collective action, and it can help provide direction in establishing common benchmarks and frameworks concerning equity in the UNFCCC. The presentation will provide a proposed framework for describing equitability in INDCs, as well as a review of how countries have thus far provided information on equity in their INDCs.

Equity in the 2015 Agreement

X. Ngwadla (1)
(1) Council for Scientific and Industrial Research, Pretoria, South Africa

The inclusiveness, durability and effectiveness of the 2015 Agreement largely hinges on how questions relating to equity, and/or perception of fairness by Parties to the UNFCCC are achieved by the agreement. The diversity of the basis for making a judgement of what is fair has translated into a false dichotomy of qualitative vs quantitative treatment of equity in the agreement. The second dichotomy has been created in terms of options for national vs international discipline in the application of a common framework for addressing equity.

In Ngwadla & Rajamani, (2014) proposals and options for addressing the divergences on the technical and legal options for operationalising and Equity Reference Framework (ERF) in the 2015 Agreement. The ERF is framed on the determination of the required global effort and a determination of relative fair contributions by Parties, covering both mitigation and adaptation in its definition of the required effort. Its application and reflection in the agreements presents flexibility in both 'top-down' and 'bottom-up' or hybrid approaches in a global agreement.

Several other tools and approaches have proposed for apportioning mitigation responsibility based on a variety of metrics. The ERF is however premised on an envelope of metrics for historical contribution to emissions, capability of countries to respond, and development needs, as such outcomes are presented in a range and median of relative fair efforts by Parties. The envelope of metrics could be informed by the various proposals and metrics, including those various parties have presented as part of equity information in their INDCs.

The strength of the ERF further lies in its ability to be applied in different architectural and legal options, as it can be reflected as an integral part of the agreement, however couched in a language that reflect concerns pertaining to prescriptiveness and sovereignty of states. At the other end of the spectrum of options, it could be expressed as an external process through a declaration and run representative external organisations, with a view of providing a moral pull for fairness in the agreement.

In pursuit of a durable agreement, and that present day political realities do not confine the agreement coming into effect in 2020, several options still remain to have enabling provisions for an ERF kind of approach, taking into account options for aggregate application of such a framework, as well as self-application of such a multilaterally agreed framework.

Man versus Climate: what we learn from paleodata on the vulnerability of tropical ecosystems

AM. Lézine (1) ; S. Ivory (2) ; F. Bassinot (3) ; C. Hély (4) ; P. Braconnot (5)
(1) LOCEAN, Paris, France; (2) Institute at Brown for the Study of Environment and Society, Brown University, Providence, United States of America; (3) Laboratoire des Sciences du Climat et de l'Environnement/IPSL, CEA-CNRS-UVSQ - UMR8212, CEA-CNRS-UVSQ - UMR8212, France; (4) Institut des Sciences de l'Evolution, Isem umr cnrs 5554, ird 226, université de montpellier, ephe cirad, Montpellier, France; (5) LSCE-IPSL, Gif-sur-Yvette, France

The timing and amplitude of the end of the Holocene humid period and the transition toward of the present day arid/semi-arid conditions in the northern tropics has been the subject of multiple debates involving many scientists from both model and data communities. Several scenarios have been developed to discuss the abrupt or gradual character of this period and to identify the forcings at work. These debates have mostly focused on regions under the Atlantic monsoon influence with a specific emphasis on the iconic "Green Sahara". This region is well known to have hosted flourishing prehistoric cultures evidenced by widespread archaeological remains, rock paintings and carvings and abundant tropical faunas during the Holocene. Based on paleohydrological and archaeological evidence, it has been shown that the end of the "Green Sahara" period in northern tropical Africa and the initiation of present day arid conditions in the Sahara Desert were latitudinally time transgressive with the lake phase ending from 6.5 ka (between 26 and 28°N) to 3.5 ka between 20° and 16° N.

This late Holocene climate crisis was widely recorded across the tropics. Here we present a synthesis of paleohydrological and paleoenvironmental data in two specific areas: (1) the dry northern tropics from West Africa to East India (10-30°N) to compare the behavior of the Atlantic and Indian monsoon systems at the northern edge of the present day rain belt and the mechanisms responsible for the dramatic regime shift (humid/arid) (2) West and Central Africa to discuss the impact of this crisis on the natural ecosystems (i.e., the equatorial forest) and the adaptation of human populations.

Abrupt African Quaternary Climate and Vegetation Change

M. Claussen (1) ; S. Bathiany (2) ; V. Brovking (1) ; S. Egerer (1) ; V. Groner (1) ; C. Reick (1)
(1) Max Planck Institute for Meteorology, Hamburg, Germany; (2) Wageningen University, Wageningen, Netherlands

Pronounced changes in African climate, specifically during the transitions between glacials and interglacials, have been found in palaeo climatic archives. Some geological records suggest abrupt climate shifts others, more gradual transitions. Here, we discuss data and simulations aiming at understanding these changes. African climate and vegetation shifts were likely induced by large changes in ice masses, ocean circulation and monsoon dynamics which, in turn, were triggered by variations in the Earth orbit around the sun and subsequent alteration of meridional insolation gradients. It is shown that abrupt change, or 'tipping, could result from a strong feedback between vegetation and climate at different times at different locations. Moreover, strong feedback in one region can lead to 'induced tipping' in other, seemingly stable regions. However, the diversity of plants can affect the strength of biogeophysical feedback. Regions rich in plant diversity may stabilize the system leading to more gradual transitions. As alternative hypothesis, abrupt changes may also emerge from intrinsic threshold behaviour of hydrological systems and ecosystems. Finally, an assessment is made to which extent abrupt climate and vegetation changes in this region are likely to happen in the future.

Varved lake sediments provide opportunities for high-resolution paleolimnological investigations that may extend monitoring surveys in order to target priority management actions under climate warming. This paper provides the synthesis of an international research program relying on >150 years-long, varved records for three managed perialpine lakes in Europe (Lakes Geneva, Annecy and Bourget). The dynamics of the dominant, local human pressures, as well as the ecological responses in the pelagic, benthic and littoral habitats were reconstructed using classical and newly developed paleo-proxies. Statistical modelling achieved the hierarchization of the drivers of their ecological trajectories.

All three lakes underwent different levels of eutrophication in the first half of the XXth century, followed by re-oligotrophication. Climate warming came along with a 2°C increase in air temperature over the last century, to which lakes were unequally thermally vulnerable. Unsurprisingly, phosphorous concentration has been the dominant ecological driver over the last century. Yet, other human-influenced, local environmental drivers (fisheries management practices, river regulations) have also significantly inflected ecological trajectories. Climate change has been impacting all habitats at rates that, in some cases, exceeded those of local factors. The amplitude and ecological responses to similar climate change varied between lakes, but, at least for pelagic habitats, rather depended on the intensity of local human pressures than on the thermal effect of climate change. Deep habitats yet showed higher sensitivity to climate change but substantial influence of river flows. As a consequence, adapted local management strategies, fully integrating nutrient inputs, fisheries management and hydrological regulations, may enable mitigating the deleterious consequences of ongoing climate change on these ecosystems.

O-1101-01

The Mediterranean Basin in a warmer and drier world: what can we learn from the past?

J. Guiot (1) ; D. Kaniewski (2)
(1) CNRS, CEREGE, Aix-en-Provence, France; (2) University of Toulouse 3, Ecolab, Toulouse, France

Since the late-nineteenth century, surface temperatures have non-uniformly increased worldwide. The repercussion of the global warming in drylands, such as in the Mediterranean, may become a main source of concern

in a near future, as it is often accompanied by increased droughts, that will severely degrade water supply and quality. History shows that access to water resources has always presented a challenge for societies around the Mediterranean throughout the Holocene (roughly the last 10,000 years). Repeatedly, adverse climate shifts seem to have interacted with social, economic and political variables, exacerbating vulnerabilities in drier regions. We present a reconstruction of the Holocene climate in the Mediterranean Basin using an innovative method based on pollen data and vegetation modeling. The method consists in calculating the inputs of the vegetation model so that the outputs fit the pollen data, using a Bayesian framework. This model inversion is particularly suited to deal with increasing dissimilarities between past millennia and the last century, especially due to a direct effect of CO2 on vegetation. The comparison of far past and last century shows that the intensity of century-scale precipitation fall, amplified by higher temperatures and then evapotranspiration, is unmatched over the last 10,000 years. The recent climatic change is then unprecedented during the last 10,000 years in the Mediterranean Basin. We show also that adverse climate shifts are often correlated with the decline or collapse of Mediterranean civilizations, particularly in the eastern Basin. The main consequence is that, over the next few decades, Mediterranean societies are likely to be much more critically vulnerable to climate change, than at any dry period of the past.

O-1101-02

Long-term ecological dynamics of an alpine lacustrine ecosystem during the Holocene in the French Alps (Lake Petit, 2200 m a.s.l): regime shift and resilience of algal communities

R. Cartier (1)

(1) Aix-Marseille Université, CNRS, IRD, Collège de France, UM 34 CEREGE, Aix-en-Provence, France

Multidisciplinary investigations on lake sediments in the Mediterranean Alps enable tracking back the dynamics of lacustrine ecosystems as well as their response to human activities and climate change. Such external forcing may lead to a variety of lake responses, ranging from gradual changes to sudden regime shifts. Sediments from Lake Petit (2200 m a.s.l., Southern French Alps) were particularly relevant for a coupled palaeoecology of landscape and palaeolimnology study providing (1) exceptional richness in preserved bio-indicators and (2) a well-studied context with archaeological, palynological and geochemical data (Brisset et al., 2013).

The lacustrine ecosystem has been reconstructed for the last 5000 years using microfossil analysis (diatoms and Pediastrum) and organic matter composition of sediments (TOC, TN) (Cartier et al., in press):

- From 4800 to 4300 cal. BP, Lake Petit was a stable diatom productive water body dominated by alkaliphilous diatoms. Nutrients were supplied by the chemical weathering of podzols that developed under conifer woodlands. This overall stability was suddenly interrupted at 4200 cal. BP by a major detrital pulse that triggered a drop in diatom productivity and diversity probably climate-linked with the "4.2 ka event";
- From 4100 to 2400 cal. BP, diatom productivity decreased whereas the algae Pediastrum developed. Diatom assemblages subjected to terrigenous inputs from continuous erosion of pasture soils, were more diversified;
- Finally, from 2400 cal. BP to the present day, diatom assemblages reveal a slight acidification and nutrient enrichment of waters concomitant with increasing human pressure in the catchment.

Results obtained at Lake Petit provide a good example of abrupt regime shift in mountain systems in response to rapid climatic event, and further by incremental change triggered by human activities beyond critical threshold.

O-1101-03

How humans feed flood: lessons from the past

E. Brisset (1) ; F. Guiter (2) ; C. Miramont (2) ; T. Troussier (2) ; Y. Poher (2) ; E. Anthony (1)

(1) Aix-Marseille Université, CNRS, IRD, Collège de France, UM 34 CEREGE, Aix-en-Provence, France; (2) Aix-Marseille Université, CNRS, IRD, UMR 7263 IMBE, Aix-en-Provence, France

Future projections on alpine climate changes suggest that more hydrological extreme can be expected to increase the river flood risk in this region. During mountain-river floods, the amount of sediment rushing down slopes constitutes a threat for society, burring floodplains and devastating people and infrastructures. This hydro-geological phenomenon poses hazards in mountainous areas of the world because they occur on steep slopes having abundant sediment available. By promoting land degradation, human are susceptible to modify the sensitivity of landscapes to natural hazard. As a result, it is crucial to investigate how humans have transformed geomorphic response to river flood on historic timescale, and what this means for our present and future. Here we explore since when mountain-river flood are linked to human agencies and to what extent man influence nature.

To address these issues, we examined the geomorphic response during flood events to vegetation cover and land-use changes over the last 7400 years for a large mountain lake of the European Alps, the Lake Allos (44°14'N, 6°42'35''E, 2230 m a.s.l.). Indeed, the sediments of the Lake Allos are a reliable geological archive to reconstruct flood deposits calendar over long time scale as their suspension load produce a distinct detrital layer contrasting to background sedimentation allowing their identification, counting and dating.

Our results show that the progressive increase in human activities (domestic livestock grazing) was not followed by a progressive increase in erosion at Allos. At 2000 cal. BP, the flood record shows an abrupt transition in sediment load and in event frequency which have been multiplied by a factor of four. Since this date, precipitations of higher intensity were able to mobilise and transport larger amount of sediment and precipitations of lesser intensity were more frequently able to trigger sediment inputs.

These results indicate that a threshold in the sensitivity to erosion in the source area were attaint due to several millennia of human pressure. These results also argue that humans, by changing sensitivity of landscapes for their activities, have considerably amplified geomorphic responses to natural hazards.

O-1101-04

Interdisciplinary and transboundary work to rebuilt extreme hydrological events in the Rhine Graben (France – Germany - Switzerland) during the last six centuries (TRANSRISK and TRANSRISK² Programs)

B. Martin (1) ; R. Glaser (2) ; F. Giacona (1) ; N. Holleville (1) ; I. Himmelsbach (2) ; B. Furst (1) ; J. Schönbein (2) ; L. With (1) ; P. Wassmer (3) ; MC. Vitoux (1)

(1) CRESAT, Université de haute – alsace, mulhouse, France; (2) Institut fur Physische Geographie, Albert ludwig university, Freiburg, Germany; (3) Laboratoire de Géographie Physique, Université paris 1 panthéon-sorbonne, paris, France

The franco – german projects TRANSRISK (2008 – 2011) and TRANSRISK² (2014 – 2017) have made it possible to elaborate a comparative chronology of the floods in the area of the Upper Rhine over a long period (1480 – 2015), paying attention to the description of the events (characteristics, climatic and human causes, consequences) as well as to the management by those in charge at the local scenes of the risk. The objective was to understand the evolutions and to make comparisons at all scales, particularly between France and Germany. This interdisciplinary work (historians, geographers, anthropologists, sociologists, linguists) has been done by researchers from Germany and France on both side of the Rhine between Basel and Strasbourg. The interest of that

research is twofold:

- It is carried out on a territory which is limited and relatively homogeneous, but divided by borders between three nations, Switzerland, France and Germany, and these two last countries have been three times at war between 1870 and 1945.

- It is really concerning a major stake of territorial management: the prevention of floods, a hazard not well known in its spatio-temporal characteristics on account of the wars and of the many political and administrative changes that this territory has gone through.

The researches in the archives have thus made it possible to establish a database including over 3.000 events related to the floods between 1480 and nowadays, involving the Rhine, and 13 tributaries on both side on the border. The most important of those floods have been mapped, classed and compared, revealing at the end a real underestimation of flood risk and the necessity of building new flood scenarios for the future. That's why these research programs are involved into many actions of flood risk management, concerning, for example, memory and risk culture, as well as modelling of extreme events in a historic – progressive approach.

About scenarios, if no pattern of coherent and synchronized evolution appears for all the rivers, the reconstruction of the underlying climatic conditions permits to determine 4 broad types of situations favourable to flooding in that area. And, facing an extreme situation that has already occurred yet in a past not so far away, neither the actors of prevention, nor the people are really prepared. That's also the reason why we have developed a website (linked to social networks) to share information on historical floods (www.orrion.fr), even if floods need a real contextualization to try to make them comparable over time and space. But the chronologies demonstrate, on the one hand, the importance of conditions on a local scale, and, on the other hand, all the aggravating or lessening role of human factors. They generate variations in time and space of the vulnerability to floods, which are manifest on different scales, revealing in particular a real "borderline effect" between France and Germany.

What those studies also point out, however, is that the fight against floods has been at all times the manifestation of political will, mostly a reaction to disaster, and thus has been constantly re-defined in any context of important changes in the political structures. This is of course a lesson for the future.

Learning from the Past to understand the Presente and predict the Future: The Mexican Quatermary Mammal Database

J. Arroyo-Cabrales (1) ; I. Ferrusquía-Villafranca (2) ; E. Johnson (3) ; J. Ruiz-González (2) ; E. Martínez-Hernández (2) ; J. Gama-Castro (2)

(1) INSTITUTO NACIONAL DE ANTROPOLOGIA E HISTORIA, LABORATORIO DE ARQUEOZOOLOGIA, MEXICO, D. F., Mexico; (2) UNIVERSIDAD NACIONAL AUTONOMA DE MEXICO, Instituto de geologia, MEXICO, D. F., Mexico; (3) MUSEUM OF TEXAS TECH UNIVERSITY, Department of anthropology, LUBBOCK, TEXAS, United States of America

The Pleistocene and modern mammal faunas of southern North America partially differ in taxonomic composition, distribution, and physiognomy. The former faunal complexes are part of the ancient landscape in which early people may have interacted. Differences between the Pleistocene and modern faunas have been attributed either to climate change, to human-impact driven extinctions, or even to catastrophic phenomena, like a meteorite impact. México's Pleistocene mammal record is analyzed in time and space, emphasizing the study of the Rancholabrean Chronofauna; furthermore, available isotopic data is reported for supporting paleoenvironmental inferences. Palynological and paleosol records are reviewed as an independent check of the interpretation e from mammals. The integration of the information provides the basis for a proposal regarding Late Pleistocene climate change trends across the country, and whether people were involved in the mammalian community response to climate change in terms of extinction or biogeographic shifting within and outside the country. This approach supports an explanation for the differences between southern North America's Pleistocene and modern mammal faunas. This difference is the combined results of individual species extinctions and range modifications that affected and changed the vertebrate biota physiognomy and taxonomic composition. The available fossil record, however, does not portray this major biogeographic shifting of species in detail due to the lack of associated chronometric data. The analysis of disjunct (i.e., separated from the main range) and of demonstrably relict species may be an alternative to provide greater detail and understanding about the response of individual species to climate change during the Late Pleistocene. The Late Pleistocene mammal record was analyzed by morphotectonic provinces that were grouped into four larger geographic units to examine zoogeographic distribution, any variance in distribution (extinctions, extirpations), and environmental conditions inferred from that distribution and variance. Time and space biases exist, with records favoring the Late Pleistocene (Rancholabrean) and the Trans-Mexican Volcanic Belt (TMVB), particularly the Basin of México. Nevertheless, biological communities throughout the country experience profound changes in species composition and structure. Such a pattern was due not to direct human impact but to the consequences of environmental changes throughout and particularly at the end of the Pleistocene. The shifting of ecological and climatic zones was not a simple matter of displacement and range adjustments. Such conditions, among other things, allowed stenotopic species (restricted tolerance to a narrow range of environmental conditions) to extend their range beyond narrow parameters, and eurytopic ones (broad tolerance to a wide range of environmental conditions) to thrive extensively across the country. The coexistence of a highly diverse group of mammals indicates a community structure organized differently than that of today in order to facilitate the complex relationships that coexistence would have required. The disruption of these biotic interactions would have created a coevolutionary disequilibrium situation. The available information on México's Pleistocene mammal, palynological, and paleosol records allows only broad trends to be discerned in the complex environmental-biota interplay and what role, if any, early people played in extinction. A critical need exists to fill in the time and space gaps in these records. Solid radiocarbon chronologies need to be developed that can anchor the various records and provide the framework for more in-depth analyses of environmental changes and individual species response. In a focused radiocarbon dating program, TMVB province and mammoth would be a reasonable target. The most concentrated research has been in this province and mammoth is the most ubiquitous Late Pleistocene mammal. Research needs to continue and expand in the other provinces in order to have a representative sample across the country. While research in the Northern provinces has been most fruitful in terms of mammal-human interactions during the latest Pleistocene, the Gulf Coastal Plains (Eastern province) has great potential in illuminating that interaction as well. México's record is critical in understanding the continent-wide affects of Pleistocene climatic changes on plants, animals, and humans. This initial synthesis forms a first-order interpretation and basis for future research directions.

P-1101-02

Vulnerability of North Eastern region of India - a global biodiversity hotspot - due to anthropogenic threats and climate change process

S. Baruah (1) ; N. Hazarika (2) ; K. Mazumdar (3)

(1) Independent Consultant, Guwahati, Assam, India; (2) State Project Officer GOI-UNDP programme, , Assam state disaster management authority, Guwahati, India; (3) Programme Officer, Response, Assam state disaster management authority, Guwahati, India

Climate change poses major threats to all levels of biodiversity from genes to landscapes while local level changes within landscape affects its composition and abundance. The North Eastern region (here after referred as 'NER') India refers to the easternmost region of India consisting of the contiguous eight sister states. The region is biogeographically and culturally distinct from rest of India and has strong ethnic and cultural ties with East Asia

and Southeast Asia. The NER of India is expected to be greatly affected by climate change as well as increasing anthropogenic threats on biodiversity because of their geo-ecological fragility, strategic location vis-à-vis the Eastern Himalayan landscape,trans-boundary river basins and the inherent socio-economic instabilities.

Analysis of forest cover statistics of NER of India for last twenty years that is from 1991 to 2011, reveals that there was an overall growth of forest cover of 1274 KM2 .in the region. But individual state level data reflects loss of forest cover in majority of the states during the first decade (1991-2001) , the state of Nagaland being the highest (-976 KM2) followed by Mizoram(-908 KM2), Manipur (-732KM2)and Arunachal (-709KM2) and Meghalaya (-273KM2). Seismically NER is one of the six most active regions of the world, the other five being Mexico, Taiwan, California, Japan and Turkey. The region has experienced 18 large earthquakes (M=7) during the last hundred years including the great earthquakes of Shillong (1897, M=8.7) and Assam-Tibet border (1950, M=8.7) .

The state of Assam in NE India represents highly flood-prone region characterized by severe hazards of floods. With more than 40 percent of its land surface susceptible to flood damage, the total flood prone area in the Brahmaputra valley is about 3.2 Mha. The Brahmaputra valley had experienced major floods in 1954, 1962, 1966, 1972, 1974, 1978, 1983, 1986, 1988, 1996, 1998, 2000 and 2004. According to census statistics 1991-2011 the population in all the states grew by approximately 30 percent between first decade and continued with 20 percent in the next decade. This rapid increase in population density in the region is responsible for large scale destruction and alteration of forest areas, overexploitation of biodiversity resources. While reviewing the agricultural statistics for 17 years period that is 1989-2006 ,it has been observed that there is decrease of gross cropped area in many states particularly the Assam being the highest with about 60% followed by Tripura with about 45% , Arunachal Pradesh 25% and Manipur 10% This is reflected in the general trend of decrease in par capita availability of agricultural land . The trend of mean rain fall activities observed in the region for four decades from the year 1968 to 2008 which shows distinct local variations. During Pre monsoon season from 1990 to 2008 there is a decreasing trend of rainfall with 1996 and 2008 is lowest. This indicates local dry conditions or draught. Similarly 1977 and 2001 shows the very high rain fall indicating more storms, floods and associated disasters. In monsoon season there is a general trend of high rainfall activities with 1988, 2005 being highest indicating major floods in the region and crop and property damage. The trend of atmospheric temperature of the region for the pre monsoon season is found to be going high during from the year 1990 to 2008 indicating prolonged warmer period coupled with decreasing rain fall observed during the season. Again in the monsoon it continues with the rising trend over the past decades clearing indicating increasing warming process may be with response to global warming process. Looking at the data of the buildup areas for the years 1989 and 2006 ,there is enormous rise in build up area due to urbanization in all the NER states. The exploration of fossil fuels viz oil, gas and coal industries in the region is increasing the air, water and land pollution and thereby increasing the vulnerabilities of the biodiversity and ecosystems from these anthropogenic activities coupled with the climate change process.

P-1101-03

Impact of global SST gradients on the Mediterranean runoff changes across the Plio-Pleistocene transition

F. Colleoni (1) ; A. Cherchi, (1) ; S. Masina, (1) ; C. Brierley, (2)
(1) Centro Euro-Mediterraneo sui Cambiamenti Climatici, Bologna, Italy; (2) University College of London, Department of Geography, London, United Kingdom

This work explores the impact of the development of global meridional and zonal SST gradients on the Mediterranean runoff variability during the Plio-Pleistocene transition, about 3 Ma. By means of a stand-alone atmospheric general circulation model, we simulate the separate impact of extra-tropical and equatorial SST cooling on the Mediterranean runoff. Results show that total annual mean Pliocene Mediterranean runoff is about 40\% larger than during the pre-industrial period due to more increased extra-tropical specific humidity. As a consequence of a weakened and extended Hadley cell, Pliocene northwest Africa hydrological network produces a discharge 30 times larger than today. Our results support the conclusion that during the Pliocene, the Mediterranean water deficit was more reduced than today due to a larger river discharge. While the cooling of equatorial SST does not imply significant changes on the Pliocene Mediterranean hydrological budget, the extra-tropical SST cooling increases the water deficit due to a decrease in precipitation and runoff and river discharge from this area reduces to pre-industrial level. From our simulations there are evidence that the modern atmospheric circulation over the Mediterranean started to develop at least 3 Ma. The main teleconnections acting upon the Mediterranean area, i.e. the North Atlantic Oscillation during winter and the ``monsoon-desert'' mechanism during summer are already at work in our Pliocene simulations. Finally, our results also suggest that in a climate state significantly warmer than today, changes of the Hadley circulation could potentially lead to increased in water resources in northwest Africa.

P-1101-04

Mid-Holocene drought impact on the active Lazaun rock glacier in the Italian Alps

JN. Haas (1) ; B. Dietre (1) ; M. Hirnsperger (2) ; D. Bressan (2) ; C. Walser (3) ; I. Hajdas (4) ; K. Lang (5) ; V. Mair (5) ; U. Nickus (6) ; D. Reidl (1) ; H. Thies (7) ; D. Tonidandel (5) ; K. Krainer (2)

The study of a 40 m-long ice and debris core from the rock glacier Lazaun in the southern Ötztal Alps (South Tyrol, Italy) revealed a mid-Holocene drought impact around 4000 cal. BP. Plant macrofossils embedded in the ice indicated the overall formation of the rock glacier around 10'300 cal. BP with two superimposed rock glacier lobes persisting active since then. The inferred age-depth model implied very stable sedimentation conditions for snow, ice and rock debris throughout the Holocene, with the exception of a mid-Holocene drought event. This multi-centennial drought period around 4000 cal. BP was probably related to reduced snow accumulation, prevailing warm climate, and a general Mediterranean/Central European climatic reorganization. The palaeoecological study of the ice/debris samples and the quantification of pollen, cryptogam spores, non-pollen palynomorphs, charcoal particles as well as plant and animal macrofossils allowed tracing the former climatically and anthropogenically induced vegetation changes at alpine altitudes (above 2600 m a.s.l.).

Glacier fluctuations integrate both temperature and precipitation, and these signals are often a challenge to separate. However, in the end of 20th-early 21th centuries

the glaciers demonstrate a coherent pattern of uniform retreat, despite the great difference in their morphology, sizes, location and other characteristics. For our global overview of Holocene glacier fluctuations we used 189 time series of glacier fluctuations based on 14C, TCN, OSL, tree rings, sediments from proglacial lakes, and speleothems. We compared the glacier variations with orbital, solar and volcanic forcings and considered the scale and the rate of modern glacier retreat in the context of Holocene natural variability. The general trends of Holocene glacier fluctuations in the extra-tropical areas of the Northern Hemisphere are broadly coherent and agree with the dynamics of the Northern and mountain tree lines. Overall summer temperature, forced by orbitally-controlled insolation, is the most probable driver of increasingly more expansive advances through the Holocene in these regions. In the Southern Hemisphere, glaciers in New Zealand appear to follow the orbital trend, which is opposite to the Northern Hemisphere (less expansive advances through the Holocene). Glacier fluctuations in monsoonal Asia and in Southern South America generally do not correlate with the orbital trends and instead responding to more high resolution forcings in these regions. Glacier advances during Neoglacial clustered at 4.4–4.2, 3.8–3.4, 3.3–2.8, 2.6, 2.3–2.1, 1.5–1.4, 1.2–1.0, 0.7–0.5 ka BP correspond to general coolings in the North Atlantic. Some of these episodes coincide with multidecadal periods of low solar activity, but it is unclear what mechanism might link small changes in irradiance to widespread glacier fluctuations. One cluster of glacier advances at 1.7–1.6 ka does not fit this pattern and probably corresponds to a very strong volcanic eruption (232 CE). Thus, no single driving mechanism explains all ice expansions. The rate and the global character of glacier retreat in the 20th-early 21st centuries appears to be unusual in the context of Holocene glacier changes, however retreating glaciers in most regions are still more extensive today than they were in the Early and/or Mid-Holocene. Since contemporary retreat is occurring during an interval of orbital forcing that is favorable for glacier growth, a combination of factors other than orbital forcing, primarily strong anthropogenic is likely in effect. Due to the delayed reaction of glaciers to climatic changes, retreat will continue into future decades. In some cases the large changes inferred from glacier records are more pronounced than reconstructions based on higher resolution records and models driven by solar forcing. This observation may indicate that other proxies and model results tend to underestimate the amplitude of Holocene climate change.

Monsoonal changes recorded by Lake Chad sedimentary archives during the Neolithic

F. Sylvestre (1) ; P. Amaral (1) ; P. Deschamps, (1) ; N. Waldmann, (2) ; K. Tachikawa, (1) ; D. Delanghe, (1) ; N. Thouveny, (1) ; E. Bard, (1) ; M. Garcia, (1) ; JC. Mazur, (1) ; JC. Doumnang, (3) ; G. Menot, (1) ; F. Rostek, (1)

(1) Aix-Marseille University, CNRS, IRD, Collège de France, Cerege, Aix-en-Provence, France; (2) University of Haifa, Department of marine geosciences, Haifa, Israel; (3) University of N'Djamena, Department of geology, N'Djamena, Chad

During the last 20,000 years, Northern Africa experienced dramatic climatic and subsequent environmental changes, characterized by a succession of contrasted period. It is now well established that the Last Glacial Maximum (LGM) was dryer followed by a wetter middle Holocene, punctuated by dry events. The numerous Holocene paleolake records document a fairly consistent pattern of a moister early-Holocene resulting in a "Green Sahara" followed by a general aridification ca. 5000 years ago, which still persist today.

However, despite the number of detailed reconstructions increasing during the last decades, a coherent history of the climatic changes has not been yet elucidating. Pronounced differences in the apparent timing and amplitude of these hydrological changes inferred from truncated outcrops point to regional climatic variability fluctuations as well as site-specific influences which could biased the evolution of water balance. Increasing the numbers of observations and reconstruction contribute to arise regional patterns, and rend complex the identification of the climatic signal.

In this paleoclimatic history, one of the main attractive phase, still debated, is the end of the mid-holocene humid period. The increasingly arid conditions after 5,000 years forced Neolithic societies to improve their organization in order to optimize natural resources, in particular freshwater supplies, and help to explain the rise of civilizations that flourished along main rivers such as Nile, Euphrate or Indus. This climatic change corresponds in time with the gradual modulation of the insolation, whereas data from marine records evidenced that environmental changes could be more rapid and abrupt than expected by the sinusoidal insolation curve. But on the continent, the data tell us another history. Lake Yoa record collected in the northern Chad in Sahara desert show that vegetation and dust flux changed gradually, in concert with the slowly weakening monsoon.

In this context, we present new records with original data depicting past tropical hydroclimate history since the LGM from the key, but yet poorly investigated, Lake Chad. In Northern Africa, Lake Chad appeared as one of the main emblematic site during this period of time. Reaching 10 times its surface area, e.g. 340,000 km2 compared to today, e.g. 14,000 km2, it was one of the main water tower during this period. Almost exclusively fed by the Chari-Logone river system that originates from the wet tropics, where precipitation is directly controlled by the West African Monsoon and the seasonal migration of the ITCZ, this particular configuration makes this terminal lake a very sensitive indicator of climate and the environment evolution of north-central Africa at various time-scales. Then, here we present continuous records from past environmental and climatic changes during the last 20,000 years. We highlight coherent monsoonal changes, compared with those from the closest oceanic basins, e.g. tropical Atlantic and Indian oceans, as well as at the scale of the continental tropical belt. Moreover, drastic hydrological changes are recorded, occurring in few centuries, matching with North Atlantic cold spells indicating that Northern African climate could switch from a state to another, quickly, which drive in consequence, ecosystem and human adaptations.

Past climate event suggests severe and long-lasting consequences of fossil fuel burning

RE. Zeebe (1)

(1) University of Hawaii at Manoa, Department of Oceanography, Hawaii, United States of America

Carbon release rates from anthropogenic sources have reached a record high of ~10 Pg C/y in 2014. Due to uncertainties in climate system feedbacks, the impact of the rapid carbon release on the Earth system is difficult to predict. Hence geologic analogues from past transient climate changes are urgently sought after to guide future climate assessments. Throughout the past 66 Myr, the currently known climate aberration with the highest carbon release rate is the Paleocene-Eocene Thermal Maximum (PETM) – an event characterized by future-relevant total carbon release/peak warming and a surprisingly long duration of at least 50,000 years. Based on time-series analysis of stable carbon/oxygen isotope records and carbon cycle/climate modeling, we determine the initial carbon release during the PETM onset. This constrains the maximum sustained PETM carbon release rate to less than ~1 Pg C/y. Given currently available records, it follows that the present anthropogenic carbon release rate is unprecedented during the past 66 Myr by at least an order of magnitude. Future ecosystem disruptions will hence likely exceed the relatively limited extinctions observed at the PETM. Moreover, unforeseeable future responses of the climate system are possible as the Earth system has effectively entered an era of no-analogue state.

Understanding a warming world by studying the Pliocene

A. Haywood (1)
(1) University of Leeds, Uk national centre for atmospheric science, Leeds, United Kingdom

The investigation of warm intervals of the Pliocene epoch has intensified dramatically over the last 10 years. The reasons for this are varied but undoubtedly the availability of progressively higher temporal and spatial resolution environmental records is a key driver. These reconstructions are providing new insights into environmental change during the Pliocene, which enable us to investigate local and regional climate response to an atmospheric CO2 concentration akin to the modern. Furthermore, the use of Climate and Earth System Models in a Pliocene context has been encouraged as a means to test the predictive ability of models, and to understand climate processes generating regional patterns of environmental change.

This presentation will summarise the current state of knowledge of the Pliocene Earth System derived from proxy data and model outputs. In particular it will focus on key aspects of the climate system such as the reconstruction of atmospheric CO2, ice sheet and sea-level change, surface temperature change and polar amplification, the hydrological cycle, ocean circulation and the monsoons.

Challenges in environmental reconstruction and modelling will be highlighted with a summary of emerging initiatives, which are designed to enhance our ability to use warm intervals of the Pliocene as a mechanism to understand the dynamics and drivers of a warming world.

K-1102-03

Climate change and variability : lessons from the past

P. Braconnot (1)
(1) LSCE-IPSL, Gif-sur-Yvette, France

Past climate states provide a unique opportunity to evaluate model performance outside the range ofrecent observed climate variability. They provide test cases of our understanding of climate feedbacksand thresholds that are not observed in modern variability and that could lead to major changes in thefuture. Because of this, past climate simulations of the Last Glacial Maximum (21 000 years BP), themid-Holocene (6000 years BP) and the last 1000 years have been considered as part of the lastmulti-model CMIP5/PMIP3 experiments (Taylor et al. 2012, Braconnot et al. 2012), so as to put intoperspective future climate changes and provide complementary model evaluation. Using the resultsof these simulations and of mode-data comparisons, this presentation will provide an overview ofrecent analyses of climate sensitivity and feedbacks, hydrological cycle in the tropical regions, andinterannual climate variability. It will highlight the new possibilities offered by the modeling of thebiochemical cycles and tracers or by the high resolution records that provide information oninterannual to multi-decadal variability. Finally, it will discuss the constraints these analyses bring onthe credibility of climate model as well as the new questions that will be addressed in the next phaseof the Paleoclimate Modeling Intercomparison Project (PMIP).

Linking past, present and future climate change to adaptation in the African Sahel

A. Giannini (1)
(1) Columbia University, International Research Institute for Climate and Society, Palisades, NY, United States of America

The semi-arid African Sahel has received unique attention in the climate science community and beyond since inception of persistent drought at the end of the 1960s. This attention is reflected in the efforts of Working Groups 1 and 2, summarized in the Assessments Reports of the Intergovernmental Panel on Climate Change going back to the first, published in 1990. Initially, drought in the Sahel was attributed to rapid population growth leading to mismanagement of land resources. The hypothesis of a positive bio-geophysical feedback tied human-induced baring of the soils to a reduction of precipitation, which further exacerbated the loss in vegetation cover [Charney 1975, in Q J Roy Meteor Soc]. In the more recent ~10 years the climate of the Sahel has again emerged as the focus of active research, this time as a possible «canary in the coal mine» for anthropogenic climate change. Advances in climate science have first conclusively tied persistent drought to subtle shifts in the surface temperature of the global oceans [Giannini et al. 2003], «freeing farmers of blame» in the drought, then partially attributed these shifts to the influence of greenhouse gases and aerosols [Held et al. 2005, in Proc Nat Acad Sci; Booth et al. 2012, in Nature]. However, in the meantime the region has partially recovered from drought, and is experiencing an increased frequency of flooding [Tall 2010, in Proc Env Sci], underlined, to the extent that it has been documented, by a subtle increase in the intensity of precipitation [Lodoun et al. 2013, in Env Develop; Alhassane et al. 2013, in Secheresse].

Here I present a novel interpretation for the role of the oceans in effecting precipitation change in this region: Sahel rainfall responds to the relative temperature of the North Atlantic, source of the moisture that converges in the region, with respect to the global tropical oceans. The temperature of the global tropical oceans, which is communicated first vertically through deep convection, then laterally by atmospheric waves [Chou and Neelin 2004, in J Climate; Held and Soden 2006, in J Climate; Sobel et al. 2001, in J Atmos Sci], broadly determines the threshold for convection. The temperature of the North Atlantic relative to that of the global tropical oceans measures the potential for the moist, but cool air that is converged onto the African continent from the adjacent ocean to lead to deep convection and precipitation.

This interpretation consistently explains past drought, partial recovery, and the current alternation of wet and dry states on time scales from daily to interannual. It also sheds light on the uncertainty in future projections, relating them to the uncertainty in patterns of sea surface temperature change [Giannini et al. 2013, in Env Res Lett]. This contribution aims to frame the physical context in which to discuss societal response to drought, and its applicability to adaptation to current variability and future change.

Long-term evolution of feedbacks in a GCM run to equilibrium

A. Hannart (1) ; JL. Dufresne, (2) ; C. Li, (3) ; R. Knutti (4)
(1) CNRS, IFAECI, Buenos Aires, Argentina; (2) CNRS, Lmd, Paris, France; (3) Max Planck Institute for Meteorology, The Ocean in the Earth System, Hamburg, Germany; (4) ETH, Zurich, Switzerland

Equilibrium climate sensitivity (ECS) is a common measure of Earth's global temperature response to radiative forcing. To first order, Earth's radiative imbalance decreases linearly with global temperature anomaly when a step forcing is applied. ECS is thereby assumed to be constant and inversely related to the linear feedback coefficient (λ). The validity of this linear approximation has been increasingly questioned recently, with several studies consistently showing that feedback are state- and time-dependent. But can these deviations from linearity significantly shift the final equilibrium state actually reached by a GCM as compared to the linear extrapolation based on the first few centuries given by ECS, or even imply a bifurcation leading to a vastly different equilibrium? What are the dominant physical processes that explain them? Here we analyze the evolution of feedbacks over a six thousand years-long integration to equilibrium of the coupled climate model ECHAM5/MPIOM under atmospheric CO2 quadrupling - the only simulation to equilibrium of a state-of-the-art GCM available to our knowledge. Consistent with previous studies, the global feedback λchanges significantly over the entire integration, but more surprisingly its evolution is markedly non-monotonous. Indeed, while λ progressively decreases (1.5 down to 0.4 Wm-2K-1) during the first thousand years of the run - which is the period partly analyzed by most previous studies and hence yields consistent findings, we observe a steep increase in λ(0.4 up to 1.8 Wm-2K-1) throughout the remaining five thousand years, until the equilibrium is reached. This evolution is predominantly driven by: (i) a steeper

and steeper increase in cloud feedback over the entire simulation which is mainly associated to decreasing low level cloud fractions over high latitude oceanic areas; combined with (ii) a non-monotonous evolution of water feedback characterized by a moderate increase during the first thousand years followed by a steeper and steeper decrease until equilibrium, both being mainly associated to changes in relative humidity over tropical land areas and near the surface. We discuss implications of these results for the above two questions: while the assumption of a linear global feedback may be a useful approximation in energy balance models for the century time scale temperature response, we argue that its validity has not been demonstrated to represent the final equilibrium. In particular, our results suggest that a change in the sign of λ on the very long term, thereby implying a bifurcation potentially leading to a vastly different equilibrium, can not be discarded, given that the relevant processes are poorly understood.

Past and future aerosol emission reductions and their impact on Arctic climate

HC. Hansson (1) ; VD. Varma, (2) ; NJA. Acosta (3) ; Ø. Seland (4) ; T. Iversen (5)
(1) Stockholm University, Environmental Sccience and Analytical Chemistry, Stockholm, France; (2) STockholm University, Meteorology, Stockholm, Sweden; (3) Stockholm University, Environmental science and analytical science, Stockholm, Sweden; (4) Norweigan Meteorological Institut, Research, Oslo, Norway; (5) Norweigan Meteorological Institute, Research, Oslo, Norway

INTRODUCTION

Large changes in the magnitude and spatial patterns of global aerosol emissions have occurred during the 20th century and are projected to continue over the coming century. It is not clear how the Arctic climate has been affected by changes in global and European aerosol emissions. As more and more countries adapt different strategies to reduce air pollution, it is important to examine how this will affect not only the top-of-the-atmosphere radiative forcing, but rather the climate and other parameters important for society. Of particular relevance for the Arctic are the reductions in sulfate emissions from industrial activities, domestic heating, and power production that have taken place in Europe during the latest decades. These changes provide an opportunity to in detail by available observations study how regional emissions over Europe have affected the global and specifically the Arctic climate. This to bring more confidence in projections of how future air pollution emissions will affect especially the Arctic climate.

METHODS

Transient climate simulations over the industrial period (1850 to present) from the Norwegian Earth system model NorESM (Kirkevåg et al., 2013) with different emission levels have be conducted and analysed. The simulated aerosol number size distribution and mass composition have been evaluated versus in-situ observations from different European measurement networks. The analysis is focused on Europe and the Arctic and how surface radiative flux and temperature changes relate to different emission scenarios. We present results from a comparison between the actual estimated emissions 1850 to 2005 NorESM simulations with simulations using constant 1980 SOx emissions for Europe while all other are the actual emissions. We will also present climate projections, 2015 - 2080 with global emission of sulfur, organic and black carbon according to Current Legislation (CLE) or Maximum Feasible Reduction (MFR), assuming CO2 emission according to RCP4.5.

CONCLUSIONS

The simulations show a significant change in the Arctic temperature as a result of the past air quality regulation in Europe giving strongly decreased SOx emissions especially during the 1990-ties. However the effect in Europe is quite smaller. Comparing with the actual temperature change in the Arctic implies that the sulphate aerosol contribute with about 20% of the temperature increase in the Arctic. In the projections with CO2 emissions according to RCP4.5 the future temperature will increase in the Arctic will be about 3 K but with in an air pollution emission reductions according to MFR it will be about 4 K.

These is only results from simulations with one model and have to be corroborate by other models but also by detailed studies to identify the key processes and evaluation of the models towards observations. However our results strongly imply that a continued strong temperature increase will prevail for many years forward.

Deep past carbon cycle and climate crises

G. Ramstein (1) ; Y. Donnadieu (1) ; Y. Godderis (2)
(1) LSCE, Gif-sur-Yvette, France; (2) CNRS , Géosciences environnement toulouse, Toulouse, France

Deep past carbon cycle and climate crises

Relationships between carbon cycle and climate are intensively studied for ongoing global warming. There are also in the geological past of the Earth, key periods when huge changes of atmospheric carbon led to drastic cooling: Snowball episods at Neoproterozoïc [800-600 Ma]. Another period of interest is the so-called «terrestrialization» of the continents which also led to a large decrease of atmospheric carbon but without producing an important cooling during Late Devonian [379-359 Ma]. For the first time period, we will show how tectonics-climate perturbation altered sufficiently the carbon cycle and the climate to produce a long lasting global glaciation. It is also the same carbon cycle that allow to escape from a frozen planet. For the second time period :Late Devonian also corresponds to a drastic decrease of atmospheric CO2 associated with vegetation development on continents but paradoxically this decrease doesn't produce a cooling of the Earth because mainly of albedo feedback.

We shall discuss how these deregulations developed and which processess associated with atmospheric carbon-tectonics - biosphere and water cycle may explain the onset and the decay of such crises.

O-1102-05

Causes and consequences of mid-Holocene aridity in mid-continental Eurasia in the CMIP5 simulations

S. Harrison (1) ; K. Izumi, (2) ; G. Li, (3) ; P. Bartlein, (4)
(1) University of Reading, Reading, United Kingdom; (2) Laboratoire de Météorologie Dynamique, IPSL, CNRS, Paris, France; (3) Macquarie University, Department of biological sciences, North Ryde, Australia; (4) University of oregon, Department of geography, Eugene, United States of America

The extent of mid-continental drying in Eurasia during the mid-Holocene is an example of a persistent regional mismatch between models and observations. The CMIP5 mid-Holocene simulations show drier conditions in Eurasia, particularly between 45°-60° N, whereas several types of palaeoenvironmental data systematically show that the region was wetter than today. At the same time, the models show significantly higher summer temperature, whereas observations indicate that summers were cooler. The simulated temperature bias can be up to 4-6 °C. Temperature biases in the CMIP5 historical (20th century) simulations are linked to systematic biases in evapotranspiration. Diagnosis of the surface energy balance in the mid-Holocene CMIP5 experiments shows that the simulated increase in summer temperatures results from the simulation of too-low evaporative cooling because of water limitation. Surface water- and energy-balance interactions play a similar role in mediating the temperature response in CMIP5 future simulations.

Climate Change in the Past 2000 Years and its impact on society on the Tibetan Plateau

T. Yao (1) ; X. Yang (1) ; P. Yao (1) ; N. Wang (2) ; L. Tian (1) ; B. Xu (1) ; H. Zhao (1) ; J. Gao (1) ; DR. Joswiak (1)
(1) Chinese Academy of Sciences, Institute of tibetan plateau research, Beijing, China; (2) Chinese Academy of Sciences, Cold and arid regions environmental and engineering research institute, Beijing, China

Temperature variation on the Tibetan Plateau (TP) in the past 2000 years is reconstructed using stable oxygen isotope in five ice core records on the TP, including Dunde ice core in northeast TP, Guliya ice core in northwest TP, Dasuopu ice core in south TP and the Puruogangri and Tanggula ice cores in central TP. The integration of those ice core records reveals the synchronicity of large-scale climate changes in Tibet, such as the warming in the 7th century, 12-13th centuries and the present, and the cooling in the 3th century, 16th century, and 19th century. We referred to human historical documentary record since A.D. 620 for possible responses of social, economic and military activities to climate changes. By focusing especially on human activities and social development directly determined or indirectly influenced by climate from historical documentary record, we quantified those events into five aspects, i.e., basic resources, economic development, military strength, national coherence, and cultural and religious development, to study social development on the TP by A.D. 1900. Our results show a close Tibetan societal response to climate changes in the past 2000 years, particularly before the modern ages.

O-1102-07

AMOC Evolution in the Last Deglaciation:Forcing Mechanism, Thermohaline Instability and Implications

Z. Liu (1)
(1) University of Wisconsin-Madison, Atospheric and Oceanic Sciences, Madison, United States of America

The forcing mechanism and instability of the Atlantic Meridional Overtuning Circulation (AMOC) over the last 21,000 years is studied using transient simulations under realistic forcings in the NCAR-CCSM3. First, in addition to the strong millennial AMOC variability forced by melting water fluxes, the background AMOC is determined by two opposing effects: the intensification by the rising atmospheric CO2 and the reduction by the retreating ice sheet, both through the sea ice feedbacks in the North Atlantic. As a result, the AMOC strength does not change significantly after the deglaciation. Second, the model AMOC exhibits a monostable behavior. This monostable AMOC, which has been observed in almost all state-of-art coupled general climate models (CGCMs), is likely to be caused by a systematic model bias that is associated with the tropical bias, the resulted freshwater flux and AMOC freshwater export. This AMOC over-stabilization bias needs to be improved in these CGCMs to allow for a credible projection of AMOC evolution in the future.

O-1102-08

Different vegetation responses to climatic droughts in the Mediterranean basin

C. Gouveia (1) ; R. Trigo (1) ; S. Beguería, (2) ; SM. Vicente-Serrano (3)
(1) Instituto Dom Luiz (IDL), Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal; (2) Estación Experimental de Aula Dei, Csic, Zaragoza, Spain; (3) Instituto Pirenaico de Ecología, Zaragoza, Spain

A number of recent studies have identified a significant increase in the frequency of drought events in the Mediterranean basin. Climatic droughts are relatively frequent in the Mediterranean region as a consequence of the large interannual variability of precipitation, and long periods with low precipitation. Several studies characterized climatic droughts in the Mediterranean region, emphasizing the spatial and temporal complexity of this phenomenon.

The use of remote sensing data holds a great potential since it allows analyzing large regions with a consistent dataset with high spatial and temporal resolution. Several studies analyzed the impact of droughts on the natural vegetation and crops using remote sensing data. The majority of the studies about drought impacts on the vegetation cover considered droughts as a precipitation shortage regarding the normal climatology. Nevertheless, recent drought episodes in the frame of a warming scenario have shown that large evapotranspiration rates associated to high temperatures are equally relevant and may trigger severe droughts. Therefore, in the present scenario of temperature rise it is necessary to acknowledge the impacts of both reduction in precipitation and increase in evapotranspiration rates.

The aim of the present work is to analyze in detail the impacts of drought episodes on vegetation in the Mediterranean basin behavior using NDVI data from (from GIMMS) for entire Mediterranean basin (1982-2006) and the multi-scale drought index (the Standardised Precipitation-Evapotranspiration Index (SPEI).

Correlation maps between fields of monthly NDVI and SPEI for at different time scales (1-24 months) were computed in order to identify the regions and seasons most affected by droughts. Affected vegetation presents high spatial and seasonal variability, with a maximum in summer and a minimum in winter. During February 50% of the affected pixels corresponded to a time scale of 6 months, while in November the most frequent time scale corresponded to 3 months, representing more than 40% of the affected region. Around 20% of grid points corresponded to the longer time scales (18 and 24 months), persisting fairly constant along the year. The strongest control of droughts on vegetation dynamics is obtained during February and May for drier clusters in areas with low water balance values. Accordingly the wet and cold seasons present low water balance values that implies shorter time scales over dry cluster, whereas high water balance values implies longer time scales over Central and Atlantic clusters.

The occurrence of most affected areas over regions presenting low water balance values highlights the strong dependence of vegetation with climate variability. Furthermore, this conclusion is reinforced by the strong control of drought on vegetation activity observed for Arid and Steppe clusters located over areas with higher absolute values of water balance. The projected increase in frequency of drought episodes emphasize the need for an early warning drought system covering the entire Mediterranean basin. However, our results highlight that this requirement is dependent of vegetation types, season of the year and relative location of the regional sector considered. We are confident that our results will provide a useful tool for drought management plans and will play a relevant role in mitigating the impact of such episodes within the context of climate change.

Observed large leads of Atlantic circulation slowdowns with respect to tropical precipitation events: A challenge for current climate models

C. Waelbroeck (1) ; P. Burckel, (1) ; S. Pichat, (2) ; J. Gherardi (3) ; H. Arz, (4) ; J. Lippold, (5) ; T. Dokken, (6) ; F. Thil, (1)
(1) LSCE/IPSL – CNRS, Gif-sur-Yvette, France; (2) LGL-TPE, Ecole normale supérieure de lyon, Lyon, France; (3) Ifremer, DAEI, Issy les Moulineaux Cedex, France; (4) Leibniz Institute for Baltic Sea Research, Rostock, Germany; (5) Oeschger Centre for Climate Change Research, University of bern, Bern, Switzerland; (6) BCCR, University of bergen, Bergen, Norway

Marine cores MD09-3257 and GeoB3910 were retrieved off northern Brazil at ~4°S, 36°W and 2340 m water depth; their chronology is derived from a corrected and calibrated radiocarbon-based age-depth model. As in other marine cores from this area, XRF measurements show marked Ti/Ca and Fe/Ca peaks over the last glacial that have been interpreted to reflect increased terrigenous input due to increased precipitation and runoff from the adjacent continent. These terrigenous peaks can be shown to be coeval with precipitation events recorded in speleothem d18O records from South America in the 0-30°S latitudinal band, which are considered to reflect southward shifts of the intertropical convergence zone during Greenland stadials.

New sedimentary 231Pa/230Th measurements from core MD09-3257 show that large changes took place in the overlying water mass flow rate over the last glacial in conjunction with millennial precipitation events. Furthermore, our C. wuellerstorfi δ13C data indicate that water ventilation was reduced at ~2340 m in the tropical Atlantic during Greenland stadials, in phase with the reduction in water mass flow revealed by Pa/Th data. Our results thus demonstrate that major slowdowns of the Atlantic Meridional Overturning Circulation (AMOC) upper circulation cell took place during Greenland stadials.

Because both rainfall events and changes in ocean circulation are recorded in the same sediment core, we were able to reliably determine that the AMOC started to slowdown 1420 ± 250 and 690 ± 180 (1σ) y before the onset of two large South American precipitation events associated with Heinrich stadials.

Our data open new prospects concerning causal mechanisms of rapid climate changes. More specifically, current climate models simulate a rapid response of the tropical climate to AMOC changes, whereas our results indicate that there is a large lead of AMOC changes with respect to tropical climate changes. Therefore, more work, both data- and model-wise, is necessary in order to achieve a better understanding of the highly nonlinear behavior of the climate system observed in climate archives and ensure that comprehensive climate models used for climate projections capture the full extent of ocean-ice sheets-atmosphere interactions.

Impact of Climate Change on Onset, Amount and Length of Rainy Season over West Africa as Simulated by COORDEX Models

E. Adefisan (1)
(1) Federal University of Technology, Akure, Department of Meteorology and Climate Science, Akure, Ondo State, Nigeria, Federal Republic of

The onset of rainfall signals the commencement of viable rainfed agricultural activities and it is therefore very essential for planning farm operations in West Africa. Impact of climate change on the rainfall onset dates (RODs), rainfall cessation dates (RCDs) and hence the length of rainy seasons (LRS) as well as the rainfall amount during the season over West Africa is therefore a welcome idea. The data used was from the Coordinated Regional Downscaling Exercise (CORDEX-Africa) and comprises of daily rainfall for four of the participating regional climate models of scenario A1b of the Intergovernmental Panel on Climate Change (IPCC). The simulated data was divided into two with 1981-2000 serving as present and 2031-2050 representing the near future. RODs was found to be delayed by two weeks (14 days) over most part of West Africa and a delay of three weeks (21 days) over most part of Sierra Leone, Liberia, Guinea, western flank of Cote d`Ivoire and some parts of Mali. RCDs were seen to be earlier in the near future than present in most part of West Africa. LRS which is the difference between the RODs and RCDs show that there is a reduction of between 15 and 25 days over the areas mentioned earlier. There was an extension of about 15days over other areas between the coastline of West Africa and 15oN. The annual rainfall amount shows an increase over all high grounds of West Africa and the immediate environment as well as the coastline of West Africa. Apart from these, most West African sub-region experiences reduction in the annual rainfall amount ranging from 120mm to about 300mm. On a closer look of rainfall amount from June to September (JJAS) rainfall amount, it follows the same trend as that of the annual amount but with more significant reduction in the near future. From coast to about 6oN, there is an average reduction of between 0.2 to 0.6mm/day (24 to 73mm). From about 6oN to 14oN there is an increase in rainfall amount of about 0.7mm/day. There is a significant reduction of JJAS rainfall amount on the leeward side of Cameroonian's Mountain of 1.4mm/day.

P-1102-02

Climate Variability in Nepal: A Time Series Approach

RB. Bista (1)
(1) Patan Multiple Campus, Tribhuvan University, Economics, Lalitpur, Nepal

Climate variability in Nepal has become a big environmental issue. This paper investigates empirically and analytically whether climate variability exists or not in different altitude, whether its direction moves and what will be its future direction. We use time series model based on the secondary data of hydrology and metrology collected from Department of Hydrology and Metrology, the Government of Nepal.

The time series analysis finds climate variability in the different parts of Nepal in which all months have variability of temperature and rainfall precipitation. From 1975 to 2010, temperature raises annually by 20 C. However, rainfall is found declining. It is forecasted change of temperature by 60c over next 40 years. In case of rainfall, it is forecasted constant and results drought in high altitude and flood in low altitude. Climate variability may be a big threat in the different parts of Nepal.

P-1102-03

How will climate change affect the vegetation cycle over France? A generic modelling approach

D. Carrer (1) ; N. Laanaia (1) ; JC. Calvet (1)
(1) Meteo France, CNRM-GAME, Toulouse, France

The expected response of climate to the increase in greenhouse gas concentration during the 21st century is a 2-3°C warming in Europe (IPCC 2007). However, the sign of the response differs from a climate model to another. Two climate models predicting the same sign in the response of temperature and precipitation, but presenting different magnitudes of change, can lead to very different impacts. This is particularly true if we examine how climate conditions would affect the vegetation cycle. In particular, the implementation of adaptation strategies of agriculture to climate change is conditioned by the knowledge of impacts and of the associated uncertainties. The new generation of generic Land Surface Models (LSMs) that include the carbon cycle of the biosphere and represent vegetation growth provides a wealth of information on this issue.

In the framework of the ORACLE ANR project, CNRM has produced 150-yr (1950-2100) simulations over France of the biomass of various vegetation types (straw cereals, grasslands, broadleaf and coniferous forests) and of the soil water content associated to each of these vegetation types. The ISBA-A-gs generic LSM, able to work at various spatial scales (local to global), was used. Thirteen climatic simulations from the 4th IPCC assessment report, disaggregated at a spatial resolution of 8 km by 8 km, were used to drive the ISBA-A-gs model, over 191 grid-cells representing the main French agricultural and forest regions. Statistical methods were used to quantify the impact of climate change and the agreement between climate models between near future (NF) (2020-2049), far future (FF) (2070-2099) and a reference past period (1970-1999). Everywhere in France, the duration of dry (wet) periods within one year increases (decreases), up (down) to + (-) 30d in NF conditions. For all the vegetation types, leaf onset and the annual maximum LAI occur earlier. On the other hand, large regional discrepancies are simulated for the senescence period (e.g. earlier in western and southern France for broadleaf forests, later in eastern France) for both NF and FF. The length of the growing period is often more uncertain in FF than in NF in relation to differences in climate models. These simulations will be extended to the Euro-Mediterranean area and coupled with a hydrologic model. The new IPCC simulations will be used to complete this work.

ACRONYMS:
- ORACLE : Opportunités et Risques pour les Agro-ecosystèmes et les forêts en réponse aux changements CLimatiquE, socio-économiques et politiques en France
- ISBA-A-gs : Interactions Soil-Biosphere-Atmosphere model, including photosynthesis and vegetation growth
- LAI : Leaf Area Index

P-1102-04

Identifying future climate change hotspots over Southeast Asia

F. Cruz (1) ; J. Dado (2) ; K. Cheng Chua (1) ; E. Gozo (1) ; G. Narisma ()
(1) Manila Observatory, Quezon City, Philippines; (2) Tokyo Metropolitan University, Department of geography, Hachioji, Japan

Southeast Asia is one of the regions most vulnerable to the impacts of a changing climate in a globally warmer future. In this study, climate variables from multiple CMIP5 global climate model output have been analyzed to describe the spatial extent and magnitude of future changes over the region. Potential climate change hotspots, i.e. areas indicating strong response to changes in climate, can therefore be identified. This is important for adaptation planning in the different sectors, including agriculture, on which the developing economies in this region are highly dependent. Initial results show that in the 2030s under the Representative Concentration Pathway (RCP) 4.5 scenario, high changes in the mean climate are likely to occur over Indochina, a region described by high seasonality in rainfall. On the other hand, significant changes in the extremes are noted over the Maritime Continent. However, changes in the location and intensity of these hotspots may still occur depending on the time period and emissions scenario.

P-1102-05

Recent sea-surface pH and SST changes in the eastern equatorial Pacific (Clipperton Reef) inferred from coral geochemistry

D. Dissard (1) ; D. E. (2) ; T. Correge (3) ; M. Mcculloch (4)
(1) IRD, Paris, France; (2) LSCE, Gif-sur-Yvette, France; (3) EPOC, Bordeaux , France; (4) UWA ARC, Perth, Australia

Increased atmospheric CO2 concentrations from 280 (pre-industrial value) to 390 ppmv (present value) have decreased global surface ocean pH by approximately 0.1 unit. Estimates of future atmospheric pCO2 suggest a further decrease of 0.3 pH units by the end of the century. Geochemical records preserved in the carbonate skeleton of shallow water coral presentations provide one of the few means to reconstruct changes in seawater carbonate chemistry. However, since the early 1990´s, when the potential of δ11B in biogenic carbonate as proxy for paleo-pH was realised, only few studies report on the recent decadal to centennial pH record, which is the appropriate timescale for studying the effects of ocean acidification driven by anthropogenic emissions of CO2.

The French island of Clipperton is the easternmost coral atoll in the Pacific Ocean located approximately 1200 km off the coast of Mexico. Due to the small number of ecological niches suitable for coral reefs development, almost no coral-based climatic records exists from the eastern Pacific. The possibility to work on Coral presentations from Clipperton's therefore represents a unique opportunity to obtain information on surface seawater properties (e.g. T°C, carbonate chemistry) of this key area of the central eastern Pacific Ocean. As part of this study we have undertaken, boron and oxygen isotope compositions and elemental ratios (Sr/Ca, Mg/Ca, B/Ca, Li/Mg) have been analysed over the last 80 years of a coral core retrieved in a colony of Porites australiensis (located 10°17.506N/109°13.508W, Clipperton island, 10m depth). Boron isotopes were measured by MC-ICPMS, while elemental concentrations were determined using ICP-QMS. Isotopic compositions and elemental concentrations were used to quantify changes in seawater environmental parameters - and their significance on the global or more regional Pacific oceanic circulation will be discussed.

P-1102-06

The Past is an Essential Element of the Future

E. Griffin (1)
(1) National Research Council Canada, Dominion Astrophysical Observatory, Victoria, BC, Canada

In the natural world, changes happen almost constantly, sometimes rapidly, often very gradually. Those gradual changes demonstrate two important aspects of our living world and its climate: (1) how systems are evolving by natural processes and internal stimuli, and (2) how modulations arebeing forced on them through external stimuli such as alterations to conditions, food patterns and their supplies, or imposed anthropogenic interference. Evolutionary changes have their own characteristic time-scales and are controlled, but forced changes can be accelerated beyond tolerance. Measuring that second type is the subject of this paper.

To understand the nature and rate of changes that are imposed by external stimuli, research MUST access observations and records throughout all the time-spans that are modelled. Modern modelling needs data in electronic formats, but since electronic ("born digital") recording and archiving only commenced about 30 years ago, the output from those models can only be reliable over that time-span. Unfortunately, the anthropogenic interference that may have caused the changes we nowseek to measure was already happening 30 years ago, so to obtain a more reliable base-line we must dig out much earlier data. Therein lies the challenge, because pre-digital data were recorded on paper, film, photographic plates or books, or (a bit more recently) on magnetic tapes that used primitive formatting without meta-data. Transforming any of those historical observations into modern electronic formats is an extra procedure that may require expert assistance and equipment as well as extra funding, with the result that a great many pre-digital data are still in theirvirgin analogue states and are thus inaccessible to modern research. They are constantly at risk of physical degradation and damage, and - worse still - of being dismissed as "unwanted" and thrown away.

The CODATA Task Group "Data At Risk" (DAR-TG) is investigating the plight of historical scientific data, and is actively raising awareness of them in order to help secure for science the information that they alone provide. The matter is growing increasingly urgent; although that information is totally unique to the relevant scientific domains on account of the long time-spans which are represented, fashion and convenience still overlook or ignore them. However, when historical data have been recovered and researched (and there have been some very notable and ingenious efforts, as this paper will describe), the results can be fascinating, even startling.

This conference is an ideal opportunity to reflect on the dangers of NOT including sufficiently historical data when trying to model climate change. Without them, hopes of modelling and predicting conditions in the future will without doubt be seriously compromised

P-1102-07

Geochemical evidence of past atmospheric circulation along a 40-50°N longitudinal transect across Europe during the last climatic cycle

C. Hatté (1) ; C. Gauthier (2) ; DD. Rousseau (3) ; P. Antoine (4) ; M. Fuchs (5) ; F. Lagroix (6) ; O. Moine (4) ; A. Sima (7)
(1) CEA, Laboratoire des sciences du climat et de l'environnement, Gif-sur-Yvette, France; (2) CNRS, Laboratoire des sciences du climat et de l'environnement, Gif-sur-Yvette, France; (3) CNRS, Institut National des Sciences de l'Univers, Paris, France; (4) CNRS, Laboratoire de géographie physique, environnements quaternaires et actuels, Meudon, France; (5) University of Giessen, Department of geography, Giessen, Germany; (6) CNRS, Institut de physique du globe de paris, Paris, France; (7) CNRS, Laboratoire de météorologie dynamique, Paris, France

Highlighting the impact on regional scale of global climate changes is a major issue in climatology and paleoclimatology. While large large (global or continental) scale studies help evaluating the direct physical forcing of climate on ecosystems, constraining the effect of this forcing at local to regional scales is essential to evaluate ecosystem feedbacks on climate.

In paleoclimatology, isotopic organic geochemistry (d13Corg) of typical loess is now widely used to investigate past precipitation (average annual values and monthly distribution) and thus to tackle the impact of past climate changes on a regional scale. This type of study has been applied to several loess-paleosol sequences along a 40-50°N transect from Western France to central Ukraine.

The d13Corg analyses were performed in parallel with those of other climate and environmental proxies like grain size, pedology, paleomagnetism and malacology. The investigated records cover the last climate cycle with sedimentation rates as high as 0.15 and 1 mm/yr during periods of loess deposition.

All these records show alternating periods of more or less pronounced climatic pejoration (glacial stadial) and improvement (glacial interstadial). The combined analysis of all sequences for each climatic episode allows us to propose a schema of intensity of past climate change effects on the European continent. Here we highlight two precipitation gradients that prevailed during most of the last glacial period: a West-to-East decreasing gradient in mean annual precipitation and a North-to-South reinforcement of the seasonality.

On increasing global temperatures: 77 years after Callendar

E. Hawkins (1) ; P. Jones, (2)
(1) University of Reading, Dept. of meteorology, Reading, United Kingdom; (2) University of East Anglia, Norwich, United Kingdom

In 1938, Guy Stewart Callendar was the first person to demonstrate that the Earth's land surface was warming. Callendar also suggested that the production of carbon dioxide by the combustion of fossil fuels was responsible for much of this modern change in climate. It is now 77 years since Callendar's landmark study and we demonstrate that his global land temperature estimates agree remarkably well with more recent analyses.

P-1102-09

Climate change signals in Kenyan Rift valley lakes

E. Koech (1) ; L. Ogallo (2)
(1) University of Nairobi, Meteorology, nairobi, Kenya; (2) University of Nairobi and IGAD Climate Prediction and Applications Centre (ICPAC), Nairobi, Kenya

Climate over Kenya is largely Arid and Semi-Arid, making drought the most common hazard. Floods and many other local hazards occur with most of them being location specific. These climate extremes often have far-reaching impacts on various life-supporting and economic sectors including agriculture, tourism, food security, health, livestock, water resources, settlement, infrastructure, and environmental resources, among others. Climate change leads to increased frequency of droughts and other climate extremes with devastating impacts on livelihoods in many developing countries including Kenya. Thus, no country can have sustainable livelihoods and development without an effective disaster risk reduction and climate change adaptation policies. Such policies require good knowledge of the past, present and future climate at specific locations that are often missing in many developing countries.

This paper presents the space-time patterns of climate extremes in the Rift Valley parts of Kenya in order to delineate the evidence of changing climate. This is evident in the changes in the Kenyan Rift Valley lake levels. These lakes include Lakes Naivasha, Magadi, Elementaita, Nakuru, Baringo and Bogoria. Rainfall data from nearby stations were used to present past and present patterns of climate trends and the associated extremes. The lake level changes were used with an assumption that lake water inflow, outflow, evaporation, water uses, among other relevant factors remain constant. The results show fluctuating lake levels for specific periods corresponding to changes in precipitation trends. From September 2013 to date, there has been a significant lake level rise that has expanded the lakes' extents for several kilometres and even submerging nearby hotels and schools. Finally, this study simulates future climate change scenarios in the Rift Valley in 2030, 2050, 2070 and 2100 that are critical for all future planning over the region.

P-1102-10

Variations of the Antarctic Circumpolar Current (ACC) and of the Austral ocean in the Kerguelen sector during the Deglaciation and the last Climatic Cycles: implications for global climate mechanisms

A. Mazaud (1) ; E. Michel (1) ; X. Crosta (2) ; F. Eynaud (2) ; V. Bout-Roumazeilles (3) ; S. Jaccard (4) ; M. Paterne (1) ; P. Robert (2)
(1) Laboratoire des Sciences du Climat et de l'Environnement (LSCE-IPSL), Cea-cnrs-uvsq, Gif-sur-Yvette, France; (2) Environnements et Paleoenvironnements Oceaniques et Continentaux (EPOC), University bordeaux1, Pessac, France; (3) Geosystemes,, University lille i, Villeneuve d'Ascq, France; (4) Institute of Geological Sciences & Oeschger Centre for Climate Change Research, University of bern, Bern, Switzerland

Sedimentary cores were collected with the Casq and Calypso coring systems of the RV Marion-Dufresne during the IndienSud-1 and 2 expeditions in 2011 and 2012 in the Kerguelen sector of the South Indan Ocean. These cores allow producing high-resolution, well-dated records, which document past climate and ocean circulation changes during the last climatic cycles, with a focus on the last deglaciation.

Past Changes in the intensity of the Antarctic Circumpolar Current (ACC) are investigated using environmental magnetism methods, which trace amount and size of sedimentary magnetic grains transported by this current. Oxygen isotopes and foraminifera faunal assemblages trace hydrological and temperature changes, while vertical mixing is documented by δ13C. A precise age scale will be derived from 14C ages determinations, augmented by regional correlations (magnetic susceptibility) to well-dated cores in the same area, thanks to a tephrochronological study of the marine cores and peat cores from the Kerguelen archipelago.

Results document a stronger ACC current during glacial intervals than during interglacials over at least the last 600 kyrs. This pattern is opposite to observations of flow of the NADW branch (WBUC) south of Greenland in the North Atlantic Ocean. It suggests an inter-hemispheric antiphasing between ACC and NADW at Milankovitch timescales, with a strong circulation in the deep North Atlantic when the ACC is weak, and vice versa (thus with an ACC correlated with the GNAIW intensity). During the last deglaciation, temperature and vertical mixing increased prior to changes in the ACC current intensity. A decrease (or northward migration) of the ACC occurred later during the deglacial process. It could be associated to the rate changes of the AMOC and to deep ocean ventilation. Observed changes appear to be closely connected to atmospheric CO2 changes during the last deglaciation.

P-1102-11

Assessing the potential impacts of climate change and reforestation on rainfall onset and cessation over West Africa

M. Mounkaila Saley (1)
(1) West African Climate Service Center for Climate Change and Adapted land Use (WASCAL), Meteorology, Ondo State, Akure, Nigeria, Federal Republic of

This study investigates the potential impacts of climate change and reforestation on the rainfall onset and cessation over West Africa. It uses two observations (GPCP and TRMM) and two RCMs RegCM and WRF forced respectively with HadGEM and ECHAM for the present-day climate (1971-2004) and projected future climate (2031-2064) under rcp45 conditions. Four definitions (DEF1, DEF2, DEF3 and DEF4) of rainfall onset dates (ROD) and one of rainfall cessation dates (RCD) based on rainfall threshold are used in this study. The results show that both observations (GPCP and TRMM) produce similar results of ROD/RCD in each climatic zones of West Africa (respectively Guinea, Savanna and Sahel). HadGEM and ECHAM fail to simulate the spatial distribution of ROD/RCD and produce later/early ROD/RCD in all definitions as observed. However, RegCM and WRF perform better than their driven GCMs (HadGEM and ECHAM) in simulating the ROD/RCD over the region. The potential impacts of

climate change due to elevated greenhouse gas (GHGs) show that the temperature would likely increase over West Africa in both RCMs and also in the GCMs (HadGEM and ECHAM) more consistently over the Sahel. On the other hand, elevated GHGs would lead to a decrease in rainfall as indicated by the RCMs and GCMs although the decrease is much more consistent again over the Sahel. As for the future ROD, increase in GHGs indicates that regardless of the definitions used, northern Nigeria would have delayed RODs. The vertical structure of the monsoon dynamics in the areas where the highest impacts of climate change (i.e. latest ROD) are observed for each definition shows that the elevated GHGs in the future under rcp45 condition would induce shallower monsoon flow essentially over the Sahel. However, there was no agreement between the RCMs (RegCM and WRF) on the potential impact of climate change on the RCDs due to elevated GHGs, for while RegCM indicates delayed RCDs over the Sahel and early RCDs over the Savanna, WRF produces early RCDs in all the areas. From both models, the projected impact of reforestation under the rcp45 condition indicates that West African climate would be cooler in most areas with more rainfall during the rainy season especially over the reforested zone. The cooling effect is more consistent and higher over Savanna but reforestation would induce a warming over some surrounding areas. Regardless of the definitions used, reforestation over Savanna area would induce early ROD over most areas in West Africa as obtained from both models, except over north of Nigeria. The potential impact of reforestation on the RCDs (under rcp45 conditions) again produces divergent results by the RCMs. While RegCM indicates delayed RCDs over the reforested area and early RCDs over Sahel, WRF produces delayed RCDs over all the climatic zones.

P-1102-12

Spatial and temporal variability in observed and future projected precipitation in Bia basin (Ivory coast-Ghana)

M. N'diaye Hermann (1) ; KK. Lazare (1) ; YN. Alexis (2) ; KY. Morton (2) ; S. Issiaka (2)

(1) Centre de Recherche en Ecologie, Laboratoire géologie marine, sédimentologie et environnement, Abidjan, Ivory Coast; (2) Université Nangui Abrogoua, Laboratoire géosciences et environnement, Abidjan, Ivory Coast

The phenomena of drought and desertification that affected many African countries south of the Sahara have not spared the Ivory Coast, especially from the 1980s. The impact of these events resulted in significant climatic disturbances including abnormal extension of the dry season, the irregularity and the poor distribution of rainfall and significant reductions in agricultural yields in the southeast zone. The question is to know is that these same phenomena will repeat in the future in the medium term (2030-2050) or long-term future (2070 and beyond).

Attempts to assess the changes between the observed (or historical) and future projected monthly rainfall for six stations throughout Bia basin have been made with descriptive statistics and value analysis. We obtained the monthly rainfalls data from Coupled Model Intercomparison Project Phase 5 (CMIP 5) dataset. These data is downscaled using the change factor approach for 30 1981 to 2010 (period 0), simulation from 2021 to 2050 (period 1) and from 2070 to 2099 (period 2). The historical and projected rainfalls are obtained from RCP 2.5, RCP 4.5, RCP 6 and RCP 8.5 scenarios, which are based on a model HadGEM2-ES and model IPSL-CMSA-MR. The first order Markov chain model was used to describe the occurrence of sequences of wet or dry years. For the comparison of values, the return period estimates are obtained. To examine temporal changes in drought, a cluster analysis was conducted by Self Organizing Map (SOM) for Matlab. The within-group linkage and the hierarchical clustering analysis method were performed using the value of the monthly. The number of optimum cluster was determined when the similarity between merged clusters decreased sharply according to the number of groups. HadGEM2-ES and IPSL-CMSA-MR represents the precipitation annual cycles quite well in Bia basin with the respective average correlation coefficients of 0.78 and 0.80. From the descriptive statistics, we find that the numbers of heavy rainfall events will increase in the future. The total precipitation is projected to remain unchanged or slightly increased, compared to the observation. From the annually value analysis, we can observe that expected return periods for dry episodes are almost constant, ranging from 1.20 to 1.45 years. In accordance with this we should conclude that no significant differences could be established among the different stations of the basin. The short return period (1.05 years), reflecting the state of having a new dry episode, is observed in the Bia region during the period 2071 to 2099.

Subsequently, the monthly values with similar trends were grouped into two different clusters where the region G1 corresponds to Northern and G2 the Southern region. The map shows that future droughts are projected to frequently occur in all regions, especially from the -2021s to the early 2050s. The droughts in the Bia basin between the year 2026 and 2027 are distinct from the other regions in the same period. These were previously confirmed to be quite intense over annual timescales. For the period 2032-2035, intense droughts are expected to occur nationwide, which may also continue in the regions. After this period, sporadic drought is expected to occur in some regions, with more intense ones from the 2070s in the region G1 and G2. Lastly, in the year 2099, a short, intensive drought is expected to occur in all regions.

P-1102-13

Response of North Atlantic storm track to climate change in the CNRM-CM5 simulations

T. Oudar (1) ; E. Sanchez-Gomez (1) ; F. Chauvin (2) ; L. Terray (1)

(1) CERFACS/CNRS, Sciences de l'Univers au CERFACS, URA1875, Toulouse, France; (2) Météo-France, CNRM-GAME, Toulouse, France

Climate variability in Europe is largely controlled by North Atlantic storm tracks. They are associated with transport of energy, momentum, and water vapour, between the equator and the pole. Extratropical cyclones have caused severe damages over some regions in north-western Europe, since they can combine extreme precipitation and strong winds. This is why it seems relevant to study the impact of climate change on the extratropical cyclones, principally on their intensity, position or lifespan. Indeed, several recent studies have focused on this subject by using atmospheric reanalysis and general circulation models (GCMs). The main conclusions obtained from the CMIP3 simulations showed a decreasing of the total number of cyclones and a poleward shift of their tracks in response to global warming. In the recent CMIP5 exercise, the consensus is not so clear, probably due to more complex retroactions acting in the different models. Thus, the question of changes in North Atlantic storm-tracks with warming remains unanswered.

The main goal of this work is to explore the changes in the North Atlantic storm-tracks in the past decades and to analyze the role of the external versus the internal variability on these changes. We will use different sets of atmospheric reanalyses and the climate simulations performed with the climate model CNRM-CM5, built up by the CNRM-CERFACS modelling group as a contribution to CMIP5. To characterize the extratropical cyclones and their tracks, the tracking scheme developed at Meteo France by Ayrault (1995) has been used. It is based on the detection of maximum of relative vorticity at 850 hPa.

The algorithm has been applied to the ERA40 and 20CR reanalyses. Even though the 20CR reanalysis covers the whole 20th century, we show, in this study, that it is not adapted to assess trends in the atmospheric fields before 1950, due to some discrepancies in the assimilated observations. However, in the second part of the 20th century, the 20CR reanalysis seems coherent to ERA40.

In a second part, we investigate the effect of external forcings on the North Atlantic storm tracks recent trends in the simulation performed with CNRM-CM5. We compare a control simulation with the historical simulation, in which all the external forcings have been prescribed. We show that the model fairly well reproduces the storm genesis locations as well as the following tracks. In the historical period (1850-2005), the model shows a decrease in the number of storms in the southern North-Atlantic, when all the forcings (anthropogenic and natural) are prescribed. In the scenario (RCP8.5), the tendency seen in the all-forcings historical run is confirmed and reinforced.

Finally, we use the idealized simulations to study the effects on storm-tracks when only one kind forcing is prescribed to the climate model. Here we show that the response of North Atlantic storm-track is coherent to the one found in the

historical simulation when only an increase of 2% CO2 per year during 30 years is precribed, suggesting that, in the CNRM-CM5 model, the impact of the CO2 forcing is the dominant to explain the trends in the North Atlantic storm-tracks.

P-1102-14

Impacts of natural external forcings on the Amazon regime rainfall modulated by the tropical Atlantic Ocean during the past millennium

L. Prado (1) ; I. Wainer, (1)
(1) Universidade de Sao Paulo, Instituto Oceanográfico, Sao Paulo, Brazil

Tropical climates are strongly influenced by the moisture influx from the adjacent oceans. In 2005 and 2010, dryness events observed in the Amazon Basin were strongly related to positive anomalies of sea surface temperature over the tropical North Atlantic. These changes in the Amazon water cycle had important consequences to the population, economy and ecosystems. In recent past climates, there is evidence of drier conditions in the Amazon Basin during the Little Ice Age (1400 to 1700 Common Era, C.E.) and wetter conditions during the Medieval Climate Anomaly (950 to 1250 C.E.). These periods were associated with variations of natural external forcings, as the solar and the volcanic forcings. The variability of tropical oceans is influenced by the amount of energy received by the Sun and also by atmospheric changes due to volcanic eruptions, because both consist of radiative forcings. As the Amazon Basin moisture influx is related to the tropical Atlantic conditions, any changes in this ocean will impact on the Amazon rainfall regime. Here we will present the effects of the solar variability and the volcanism of the past millennium (850-1850 C.E.) on the tropical Atlantic conditions and consequent impacts on the Amazon rainfall regime. We will use single-forcing experiments monthly outputs from the National Center for Atmospheric Research-Community Earth System Model (NCAR-CESM) to the past millennium, when natural external forcings prevailed over the anthropogenic forcing. Air-sea interaction processes in the tropical Atlantic will be estimated from the model outputs, and then related with changes in the rainfall regime over the Amazon Basin. These results will contribute to a better understanding of the natural forcings on the tropical climate.

P-1102-15

Impact of climate variability and change on meteorological droughts over Southern South America

JA. Rivera (1) ; OC. Penalba, (2) ; D. Araneo, (1)
(1) Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA), Programa Regional de Meteorología, Mendoza, Argentina; (2) Universidad de Buenos Aires (UBA) – CONICET, Departamento de ciencias de la atmósfera y los océanos, Buenos Aires, Argentina

Droughts are perceived as one of the costliest and least understood natural disasters, given the difficulty in defining its beginning and end, its slow development and its multiple regional aspects. Southern South America (SSA) was no exception to this hazard, whose impacts were evident in the reduction in crop yields, reduced cattle products, streamflow deficiencies and consequently problems for hydroelectric power generation. This research addresses the observed spatial and temporal variability of precipitation and meteorological drought over SSA during the 20th century, and the expected impacts of climate change on these variables. The Standardized Precipitation Index (SPI) was used as a short- and long-term drought indicator, given its suitability for the study region. Observed trends in the area affected by drought conditions were assessed through a non-linear approach based on the residual of the empirical mode decomposition, a recently proposed methodology which is robust in presence of non-stationary data. Trends indicate the existence of a low-frequency variability that modulates regional precipitation patterns at different temporal scales, and warns about possible future consequences in the social and economic sectors if trends towards an increase in the drought affected area continue. This non-linearity was also evident on the temporal behavior of other hydrometeorological variables, like the annual number of dry days over Argentina, and on the streamflow deficiencies over the central Andes and Patagonia. Moreover, links with decadal oscillations as the PDO were identified in the modulation of the decadal component of the annual cumulated deficit volume in the central Andes of Argentina.

The future assessment of precipitation and meteorological drought conditions was performed through a CMIP5 multi-model ensemble based on 15 Global Circulation Models (GCMs) forced under two future scenarios (RCP4.5 and RCP8.5). Changes in meteorological drought characteristics were identified by the difference for early (2011-2040) and late (2071-2100) 21st century values with respect to the 1979-2008 baseline. Future climate conditions are expected to modify the regional characteristics of meteorological droughts over SSA, but the range of uncertainty in the expected changes is high. A significant increase in the number of drought events for most of the 21st century sub-periods and scenarios is projected for the multi-model ensemble outputs. The mean duration of drought events will be shorter, with no significant changes in the severity of droughts and the occurrence of multi-decadal changes in the number of critical dry months is likely, although the significance in the changes depends on the region, future time horizon and scenario. These results overlap with a projected increase in precipitation over most of the regions, which has a strong seasonality and, therefore, will have some implications upon the future meteorological drought developments and the agricultural and hydrological practices in SSA. It is expected that the outcomes of this study will provide a measure of the likelihood of further drought changes under the CMIP5 framework, which was a key factor of the IPCC's AR5.

Comparaison de méthodes de réduction d'échelle pour des moyennes et des extremes de précipitations au Sénégal

MA. Sarr (1) ; O. Seidou (2) ; Y. Tramblay (3) ; S. El Adlouni (4)
(1) Centre de Suivi Écologique, Dakar, Senegal; (2) University of Ottawa, Civil engineering, Ottawa, Canada; (3) IRD – HydroSciences Montpellier, Montpellier, France; (4) Université de Moncton, Département de mathématiques et de statistique, Moncton, Canada

Au Sénégal, les chutes de pluie au cours de ces dernières années provoquent régulièrement des dégâts importants dans divers secteurs. Ainsi, il est donc important de comprendre l'évolution future des régimes de précipitations extrêmes pour fournir des outils à la prise de décisions.

Deux techniques différentes de réduction d'échelle ont été appliquées aux sorties de quatre (4) Modèles Climatiques Régionaux (MCR) à six (6) stations sélectionnées au Sénégal. La première technique de réduction d'échelle est la méthode Delta-Change. Elle est appliquée sur la moyenne annuelle des précipitations ainsi qu'aux périodes de retour calculées sur 5, 10, 20, 50 et 100 ans sur la base des précipitations quotidiennes. La seconde technique utilise la méthode de transformation Quantile-quantile qui permet de modifier les distributions mensuelles de précipitations simulées du MRC et ensuite calculer les périodes de retour de 5, 10, 20, 50 et 100 ans des précipitations journalières. Tous les événements de précipitations extrêmes sont calculés par l'ajustement de la distribution de GEV. Un test de Kolmogorov-Smirnoff est utilisé pour évaluer la performance de la transformation de Quantile-quantile ainsi que l'ajustement de la distribution de GEV pour les précipitations quotidiennes maximales.

Les résultats montrent que les deux méthodes, appliquées aux sorties du même modèle climatique, sont généralement homogènes sur la direction du changement. En revanche, elles conduisent à de différentes projections dans la direction et dans l'intensité du changement des précipitations extrêmes. Les changements projetés dans les précipitations moyennes sont à la baisse, excepté pour un MRC sur une station. Les changements projetés dans les précipitations extrêmes ne sont pas uniformes ni à toutes stations, ni à toutes les périodes de retour. Les résultats suggèrent également que le choix de la méthode de réduction d'échelle a plus d'effet sur l'estimation des précipitations quotidiennes extrêmes des périodes de retour égales ou supérieures à dix ans que le choix du modèle climatique.

Bidecadal North Atlantic ocean circulation variability controlled by timing of volcanic eruptions

D. Swingedouw (1) ; P. Ortega (2) ; J. Mignot (3) ; E. Guilyardi (4) ; V. Masson-Delmotte (5) ; P. Butler (6) ; M. Khodri (3) ; R. Séférian (7)

(1) Universite de Bordeaux, UMR CNRS 5805 EPOC, Pessac, France; (2) University of Reading, Ncas climate, Reading, United Kingdom; (3) Institut Pierre Simon Laplace, Locean, Paris, France; (4) LOCEAN/IPSL, UPMC case 100, Paris, France; (5) IPSL/LSCE, Gif-sur-Yvette, France; (6) Unversity of Bangor, Bangor, United Kingdom; (7) Météo-France, Toulouse, France

Understanding the mechanisms driving Atlantic Meridional Overturning Circulation (AMOC) decadal variability is critical for climate predictability in the Northern Hemisphere. North Atlantic paleoclimate proxy records exhibit variance at the bidecadal scale but the drivers of this variability remain poorly understood. Here we show that the subset of CMIP5 historical simulations that produce such bidecadal variability exhibit a robust maximum in AMOC strength 15 years after the 1963 Agung eruption, followed by a second maximum in the 1990s, caused by the reset of a bidecadal cycle. The mechanisms at play involve salinity advection from lower latitudes and explain the timing of Great Salinity Anomalies observed in the North Atlantic in the 1970s and 1990s. Simulations as well as Greenland and Iceland paleoclimate records indicate that coherent bidecadal cycles were excited following five Agung-like volcanic eruptions during the last millennium. Over the last decades, climate simulations and a conceptual model reveal interference patterns associated with the timing of subsequent volcanic eruptions. Destructive interference caused by the Pinatubo 1991 eruption may have led to a stable AMOC in the 2000s. Our results imply a long-lasting impact of volcanic eruptions on AMOC, North Atlantic Ocean and climate, and potentially significant multi-decadal predictability following the next large volcanic eruption.

P-1102-18

The CMIP5 GCMs ensemble climate change scenarios for Republic of Moldova's vulnerability and adaptation assesssment

L. Taranu (1) ; I. Bercu (1) ; D. Deveatii (1)

(1) Climate Change Office of the Ministry of Environment of the Republic of Moldova, Chisinau, Moldova

In the present study we assessed the patterns of climate change computed from global climate model output gathered as part of the Coupled Model Intercomparison Project Phase 5 (CMIP5; Taylor et al., 2012) in temperature and precipitation conditions over the Republic of Moldova (RM) Agro-Ecological Zones (AEZs) as a consequence of the enhanced greenhouse gas (GHG) concentrations until the end of the 21st century. Totally, 21 global coupled atmosphere ocean general circulation models (GCMs) were downloaded and assessed. The projections were made under the Representative Concentration Pathway (RCP) scenarios RCP 2.6, RCP 4.5, and RCP 8.5 and climatic changes over the RM's AEZs for the near term (2016-2035), midterm (2046-2065) and long term (2081-2100), which are given relative to the reference period of 1986-2005. The CO2-equivalent concentrations in the year 2100 for RCP 2.6, RCP 4.5 and RCP 8.5 are 421 ppm, 538 ppm and 936 ppm, respectively (Meinshausen et al., 2011). The first feature to highlight is that, for temperature, the ensemble average changes consistently have the same sign across scenarios and their magnitude increase from the low RCP 2.6 radiative forcing pathway to the high GHG ones RCP 4.5 and RCP 8.5, as we move into the later decades of the 21st century.

The CMIP5 projections reveal warming in all seasons for the three RM's AEZs, while precipitation projections are more variable across scenarios, sub-regions and seasons. Annual changes for temperatures are very homogeneous over the RM's AEZs. The rate of warming is higher under RCP 8.5 scenario reach +4.6 °C; medium +2.4 °C under RCP 4.5; and smaller +1.3 °C under the RCP 2.6 scenario by 2100. The ensemble, driven by RCP 8.5 emission scenario, estimate that the RM's AEZs will experience the most significant warming during summer from +5.9 °C in Northern up to +6.1 °C over Southern AEZ's by 2100. The pattern of change derived from the ensemble RCP 2.6 models is quite similar, but the magnitude of change is lower from +1.3 to +1.5 °C. The warming would be higher during winter up to +4.6 °C over Northern, although in Central and Southern AEZ's temperature rise will be lower up to +4.2 °C according to the RCP 8.5 scenario. The RCP 2.6 scenario reveals less intense warming over the RM's AEZs from +1.2 to +1.4 °C.

The ensemble projections from the RCP 8.5 forcing scenario that the RM's AEZs would exhibit a general annual decrease in precipitation varying from 9.9% in Northern to 13.4% to Southern AEZs. Controversially, according to RCP 2.6 scenario is projected moderate increase in precipitation from 3.1% in Northern to 5.1% to Southern AEZs by 2100. Winters have been estimated to be wetter in the RM by the end of the 21st century. The ensemble projections show the largest increase in precipitation from 4.0% (RCP 2.6) to 11.8% (RCP 8.5) in winter over Northern and the lowest one from 3.0% (RCP 2.6) to 7.4% (RCP 8.5) in Central parts of the country by 2100. The precipitation decrease will be more extended in the RM's AEZs during summer; the greatest rainfall reduction from 13.2% (RCP 4.5) to 25.1% (RCP 8.5) is projected in Central AEZs and the lowest one from 7.4% (RCP 4.5) to 18.1% (RCP 18.1) in Northern areas. Obtained scenarios is planned to use in near future for vulnerability and adaptation assessments of key socio-economic sectors.

P-1102-19

South American precipitation changes simulated by PMIP3/CMIP5 models in past and present climates

C. Vera (1) ; L. Diaz, (2)

(1) Centro de Investigaciones del Mar y la Atmósfera (CIMA), UMI-IFAECI, CONICET-UBA-CNRS, Buenos Aire, Argentina; (2) Centro de Investigaciones del Mar y la Atmósfera (CIMA), UMI-IFAECI, CONICET-UBA-CNRS, Buenos Aires, Argentina

Significant precipitation changes have been identified in many regions of South America using both, paleoclimatic proxy records of the last 700 years and instrumental observations of the more recent decades. Such changes are not clearly understood yet, besides that they largely impact the socio-economic activities of the countries that the regions encompass. The availability of the climate simulations included in the Fifth Phase of the World Climate Research Program-Coupled Model Intercomparison Project (CMIP5) and the Third Phase of the Paleoclimate Modelling Intercomparison Project (PMIP3) provides an excellent opportunity to assess the ability of current models in representing those precipitation changes. Therefore, that assessment is briefly discussed here as well as the exploration of the main dynamic mechanisms that might explain them.

The following experiments of the PMIP3/CMIP5 set were considered: the pre-industrial experiment, which not include any external forcing; the Historical experiment, which was obtained forcing models by both, natural and anthropogenic sources, observed between 1850 and 2005; and the Last Millennium which which span the period from 850 to 1850 and is obtained considering the natural forcing estimated for that period. Multi-model ensemble means (MEM) were computed for each experiment over the periods under study.

The Andes Mountains are one of the regions in South America in which paleoclimate studies have been focused on. In particular, in both, the Altiplano, a high-level plateau (around 3800 m), located in the Andes between 15°S and 21°S, and the subtropical Andes, located in central Chile at around 33°S, wetter-than-normal conditions were identified during the 17th century within the period known as Little Ice Age (LIA). On the other hand, drier-than-normal conditions were detected at both regions in the second part of the 20th century in association with the more recent global warming period (GWP). Although MEM are capable of representing the thermal changes in South America estimated in both periods, they do not properly represent the expected precipitation changes, except in the subtropical Andes during the GWP. The large uncertainties associated with the model simulations might be due to their limitations in reproducing the regional precipitation, especially over complex topography. On the other hand, models seem

able to represent the large-scale circulation changes that would explain the precipitation changes observed at those two regions in a physically consistent way. It was found that in the Altiplano, wetter (drier) summers in LIA (GWP) seem to be related with a stronger (weaker) upper-level eastward zonal flow, well represented by the MEM. On the other hand, models consistently show that wetter (drier) winters in the subtropical Andes in LIA (GWP), seem to be associated with a stronger (weaker) westward zonal flow in the low troposphere, induced in turn by hemispheric changes related to a negative (positive) phase of the Southern Annular Mode (SAM).

Southeastern South America (SESA), encompassing the most productive economic areas of 6 different countries (Argentina, Bolivia, Brazil, Chile, Paraguay, and Uruguay), is another region in which available records show a significant precipitation increase by the end of the XX century not only as as compared to that observed at the beginning of that century, but also to that estimated by paleoclimatic records at around 700 years ago. Both precipitation and circulation changes simulated by the models at that early period are highly uncertain. However, the MEM for the Historical experiment are able to reproduce precipitation changes observed in SESA during the GWP, although they are weaker than observed. In fact, most of the simulations reproduce the right sign of the precipitation changes in SESA during that period. However, associated uncertainty ranges (due to both inter-model dispersion and internal climate variability), are still large. In addition, it was found that mean positive precipitation trends in SESA for the Historical experiment are statistically distinguishable from those obtained for the natural-forcing-only experiment made over the 20th century, which exhibit negligible mean values. Results allow concluding that the anthropogenic forcing has at least a partial contribution in explaining the precipitation changes observed in both SESA during the GWP.

The oceans mediate the response of global climate to natural and anthropogenic radiative forcing, yet observations of global maritime surface climate variations in the late Holocene, and the mechanisms that drive the variations, are relatively unknown. Here we synthesize 57 sea surface temperature (SST) reconstructions, sourced from all major ocean basins, and spanning at high resolution some or all of the past 2000 years. The reconstructions are derived from marine archives (Mg/Ca, alkenones, TEX86, faunal assemblages in sediment cores, and coral), and meet strict chronological control criteria. The reconstructions are geographically sparse, however analysis of multi-millennial AOGCM output and historical gridded SST observations suggest the reconstructions are spatially sufficient to resolve global mean SST.

The reconstructions were standardised into 200-year bins and the resulting Ocean2k SST synthesis reveals a robust SST cooling trend for 0-1800 years of the Common Era (CE), with the strongest cooling after 1100 CE. The cooling trend is not sensitive to localized upwelling, marine archive type, seasonality of response, chronological control, water depth, sampling resolution, sedimentation rate, basin, latitude or hemisphere.

The Ocean2k SST cooling trend is qualitatively consistent with an independent synthesis of terrestrial paleoclimate data, and with simulations from the multimodel PMIP3 ensemble, driven by the full suite of hypothesized radiative forcings. Comparison with ensembles of single and cumulative radiative forcing simulations suggests that the cooling trend arises not from orbital forcing, but from the increased frequency of explosive volcanism and/or land use change in the most recent millennium. We find that episodic volcanic eruptions induce a net negative radiative forcing that results in a centennial and global-scale cooling trend via a decline in mixed-layer oceanic heat content.

Climate impacts of volcanic double events during the Common Era

K. Krüger (1) ; M. Toohey, (2) ; M. Sigl (3)

(1) University of Oslo, Department of Geosciences, Oslo, Norway; (2) GEOMAR Helmholtz-Zentrum für Ozeanforschung, Kiel, Germany; (3) Paul Scherrer Institut, Villigen, Switzerland

Volcanic eruptions are known to be a major driver of climate variability during the last millennium (the Common Era). Recent high-resolution polar ice core data reveal new insights into volcanic forcing during this period, improving our knowledge of the timing and the amount of sulfur released by past volcanic eruptions (Sigl et al., 2014). Here we focus on the effect of volcanic "double events", such as the major eruptions of 1808/1809 (Unknown) and 1815 (Tambora). The close temporal proximity of two eruptions creates the potential for climate impacts to superimpose. Ice core records provide evidence of other such double events, and climate proxy records are used to assess the climate impact of double compared to single eruption events. We perform climate model simulations to investigate specific volcanic double events, reconstructed from ice core records, and assess the potential for additive climate impacts. In particular, simulations are used to investigate the impact of decadal scale volcanic radiative and dynamical anomalies on the coupled climate system including vegetation, sea ice and ocean circulation changes. Our model results show that given certain conditions, two closely spaced eruptions of Tambora magnitude could have a larger cumulative climate impact than a single eruption of much greater magnitude. Based on the observational records and model results, we propose that volcanic double events are a likely agent for abrupt (decadal) climate changes, and may have had significant impacts on past civilizations.

Climate change making impacts on societies in the European/Mediterranean region during the past two millennia as seen by land-ocean palæoarchives

B. Martrat (1) ; C. Euromed-Ocean2k (2)
(1) IDAEA-CSIC, Barcelona, Spain; (2) University of Cambridge, Earth sci., Cambridge, United Kingdom

A composite of sea surface temperature (SST) reconstructions from the Mediterranean/Eastern Atlantic basins (this study; McGregor et al., 2015, submitted) is compared with a stack of terrestrial records selected to describe the temperature variability in the European region over the past 2000 years (PAGES 2k consortium, 2013, NATURE GEO.). Prior to 800 CE, the scarcity of measurements prevents us from making sound inferences about climatic changes during this interval. From 800 to 1800 CE, both land and ocean signals present common significant cooling trends (up to -1 s. d. units/millennium, $R2>0.67$, $p<0.01$), attributable to the anomalous cold temperatures registered during the Little Ice Age. The latter is a well-documented anomaly, which had strong impacts on European societies and stands out in both composites, particularly after 1600 CE. Ensembles of forcing simulations suggest that this is consistent with a global cooling trend, which arises from increased frequency of explosive volcanism and possible land use change. During the post-industrial time interval, the terrestrial composite registers almost +2 s. d. units warming since 1800 CE, in remarkable agreement ($R2=0.81$, $p=0.01$) with a reference Central England temperature record estimated independently (Met Office Hadley Centre for Climate Change, 2014). The warming is of lower amplitude in the ocean composite, only +1 s. d. units, in line with historical sea surface temperatures (Kaplan et al., 1998, J. GEOPHYS. RES.). The 20th century warming amplitude seems more pronounced as more low-latitude and close-to-land records are taken into consideration, whereas inclusion of high-latitude and/or upwelling locations attenuates it. Given the uncertainties inherent in the reconstructions available and the variety of responses to climate changes during this interval, the answer to the question whether the last century is likely the warmest climatic period of the latest 2000 years appears elusive in the Europe/Mediterranean region.

Early documentary records report of a mysterious dust cloud that was covering Europe for 12 months in 536-37 CE, which was followed by climatic downturn and societal decline globally. Tree rings and other climate proxies have corroborated the occurrence of this event as well as characterized its extent and duration, but failed to trace its origin.

By using a multi-disciplinary approach that integrates novel, global-scale time markers with state-of-the-art continuous ice core aerosol measurements, automated objective ice-core layer counting, tephra analyses, and detailed examination of historical archives, we developed a new volcanic forcing series from bipolar ice-core arrays back into Roman times. We revised the timing of major volcanic eruptions and reconstructed atmospheric aerosol loading and the spatio-temporal distribution of volcanic sulfate and tephra. Precise ice-core timescales for Greenland and Antarctica enabled us to discern tropical from Northern Hemisphere eruptions, and to identify the climate-altering role of non-tropical eruptions, such as those causing the "mystery cloud" in 536-37 CE.

Our study reconciles human and natural archives - demonstrated by the synchronicity of major volcanic eruption dates to historical documentary records and the (now) consistent response of tree-ring-reconstructed cooling extremes occurring in the immediate aftermath of large volcanic eruptions throughout the past 2,000 years.

These findings have significant implications in multiple research fields including quantification and attribution of climate variations to external forcing, and will be of benefit for historians, volcanologists as well as climate scientists.

Geochimical DNA or the identification of 1259AD volcanic glasses in ice cores

J. Savarino (1) ; E. Gautier, (1) ; JR. Petit, (1) ; A. Michel, (2) ; N. Metrich, (2) ; P. Besson, (2) ; C. Vidal, (2) ; JC. Komorowski, (2) ; F. Lavigne (3) ; V. Batanova (4)
(1) CNRS/UJF, LGGE, Grenoble, France; (2) CNRS/UCPS, Ipgp, Paris, France; (3) Université Paris1, Laboratoire de geographie physique, Paris, France; (4) UJF, Isterre, Grenoble, France

The 1259 AD unknown volcanic eruption found in polar ice cores is considered as the most powerful eruption of the last 7 000 years and could have triggered the little ice age as well as profoundly changed the political and sociological organization of the middle age. Despite its relative young age and power, the origin of this eruption has remained elusive. For years, volcanologists and glaciologists have searched for the possible origin of this mega eruption with little results. This event has thus remained as the unknown 1259AD event, limiting a possible examination in great details of the climatic consequences of this eruption. After decades of research, based on datation, geomorphological considerations and historical archives, Lavigne et al [1] have recently proposed the Salamas/Rinjani (Indonesia) as the possible volcano for this eruption.

In order to validate this proposition, we have undertaken a thorough and meticulous analysis of the geochemical composition of the tiny volcanic glasses found in the ice layer corresponding of this eruption. With a great level of certainty, the chemical fingerprint of the tiny glasses in ice is found to match the chemical compositions of the ashes layers found around the volcano. This result should open a complete review of the climatic impact of this volcano and demonstrated the feasibility of identifying the origin of volcanoes in ice cores from their geochemical fingerprint.

O-1103-04

A reconstruction of terrestrial volcanism over the last 2500 years using sulfur isotopes in ice-cores

E. Gautier, (1) ; J. Savarino (2) ; J. Farquhar, (3)
(1) CNRS/UJF, LGGE, Saint Martin d'Hères, France; (2) LGGE, Grenoble, France; (3) University of Maryland, Geology, College Park, United States of America

Ice cores provide an opportunity to reconstruct a history of Earth's volcanic activity. Many attempts have been made in the past to build a robust volcanic climate forcing model based on the ice records, but the robustness of this model depends on the statistical significance of usually a single record and on discriminating between large distant eruptions and closer, smaller eruptions.

We used ice cores drilled at Dome C (Antarctica) to measure first, the statistical weight of a single ice core record and second, to measure the non-zero $\Delta 33S$ of ice-core sulfate as a proxy for stratospheric volcanic eruptions. SO2 emitted by these events can be mass-independently fractionated ($\Delta 33S \neq 0$) during photolysis reactions in the stratosphere [1], [2], [3], [4]). The signal, recorded

in aerosol sulfate, is preserved in ice cores. The sulfur anomaly allows identification of eruptions very likely to be stratospheric, with potential climatic impact, regardless to the ice core location, the age or the magnitude of the recorded event.

In 2010-2011, five 100m-long ice cores from Dome C, Antarctica, separated by 1m, were collected to reconstruct the history of volcanism over the last 2500 years. Assumed volcanic events were identified through sulfate concentration measurements in the field, and located on the cores. We used an algorithm for the peak detection, and 51 potential volcanic events were identified. Based on this detection, a statistical evaluation of the occurrence of these 51 events in each ice core was conducted and allowed measuring the representativeness of a single ice core to reveal a history of volcanism. Following this statistical work, volcanic sulfate contained in snow and ice have been isolated, decontaminated, melted, concentrated and extracted using ion exchange methods. Each presumed volcanic event has been subdivided in 5 fractions at least, in order to differentiate the background isotopic signal from the sulfate peak. The peak itself has been divided into three portions. The results show that Δ33S and Δ36S are anti-correlated, and allow to discriminate stratospheric and tropospheric events, with the former having isotopic systematics that vary first with a positive Δ33S at the beginning of deposition and with a negative Δ33S at the end of the volcanic deposition. Such unique feature should allow us to reconstruct a robust volcanic forcing signal, independent of the size of the event record in ice.

O-1103-05

Effect of large volcanic eruptions on climate variability from inter-annual to decadal timescales: Towards a coordinated modeling assessment

M. Khodri (1) ; C. Timmreck (2) ; D. Zanchettin (3) ; M. Toohey, (4) ; V. Poulain, (1)
(1) IPSL, LOCEAN, Paris, France; (2) Max-Planck-Institute for Meteorology, Hamburg, Germany; (3) University of Venice, Venice, Italy; (4) GEOMAR Helmholtz Centre for Ocean Research , Kiel, Germany

It is now generally recognised that volcanic eruptions have an important effect on climate variability from inter-annual to decadal timescales. At the decadal scale, CMIP5/PMIP3 simulations have highlighted that clusters of eruptions can produce a long-lasting cooling such as during the 13th and the 19th centuries. This has led to the hypothesis that enhanced volcanic activity during the second half of the 13th century played a significant role in the transition towards the Little Ice Age through its impact on the thermohaline oceanic circulation and on Arctic sea ice. This hypothesis remains however speculative, as paleoclimatic reconstructions and climate simulations yield partly contradictory results.

Concerning the short-term hemispheric response to sulphur-rich volcanic eruptions, CMIP5/PMIP3 climate simulations show stronger cooling than tree-ring based reconstructions. Scarce information about the medieval and 19th century eruptions (i.e. magnitude, timing and location) have so far hampered a realistic assessment of the climatic impacts of decadally-paced volcanic events. Another possible reason for the mismatch is our limited understanding of the evolution of stratospheric aerosol formed after strong eruptions of pre-instrumental period, such as Tambora in April 1915, for which no direct observations are available.

It is therefore necessary to frame future modeling activities within common designs that separately tackle the two major steps linking sulfur emissions by volcanic eruptions and climate response: first, the chemical and microphysical transformation occurring within the stratospheric volcanic cloud; then, the aerosols' direct radiative effects and associated feedback mechanisms activated in the coupled ocean-atmosphere system. The coordinated modeling initiative within VOLMIP (Model Intercomparison Project on the climatic response to Volcanic forcing, an activity for CMIP6-) has been motivated by such necessity. VolMIP will provide new consensus forcing input data and related coupled climate simulations for some of the major volcanic eruptions that occurred during the pre-industrial period of the last millennium.

This contribution presents ongoing activities and research highlights achieved within VolMIP, illustrating how these coordinated modeling assessments are contributing towards constraining uncertainties in the climate response to volcanic forcing, improving the evaluation of climate models, and advancing our understanding of past, current and future climates.

1104 - Climate services and information: from global change to local decisions

USe of Climate Information in the context of helping prepare American military bases for climate change

L. Mearns (1) ; M. Rachel (1) ; M. Bukovsky (1)
(1) National Center for Atmospheric Research, Boulder, United States of America

We will describe the work we have performed in two projects through the Strategic Development and Research Propogram of the US Department of Defense. We are providing future climate information to a total of eight different miliarty bases in the continental US. The kinds of impacts include damage from storm surges due to sea level rise, increased hear stress and potential increased damage from erosion because of increased extreme precipitation, increased extreme fire risk, and potential changes in severe storms. We discuss how we present uncertainty information to the stakeholders (military personnel) are each base, and discuss the different levels of interest or concern we found among the stakeholders based on their prior experience with extreme events.

Climate Science for Climate Services: Creating capacity within CORDEX-Africa

C. Lennard (1)
(1) University of Cape Town, Climate System Analysis Group, Cape Town, South Africa

Within the Co-ordinated Regional Downscaling Experiment (CORDEX), the Cordex-Africa initiative has been developed to analyze downscaled regional climate data over the African domain of CORDEX, train young climate scientists in climate data analysis techniques and engage users of climate information in both sector specific and region/space-based applications. A series of engagements between African climate scientists and users of climate information under the CORDEX-Africa banner has begun and we report on the outcomes of these as well as the future plans of the programme. Established and young climate scientists from west, east central and southern Africa have analysed downscaled data from the CORDEX Africa domain and produced 9 scientific journal papers to date through a series of highly successful workshops, all first authored by early-career scientists or students. These papers have greatly enhanced the understanding of climate processes in each of the regions. Additionally, members from each region have been involved in workshops that engage users of climate information to co-explore the climate information needs of these communities. These

included (a) engagements with ecological, hydrological and agricultural scientists that helped refine some of the research questions to be addressed in later CORDEX activities, (b) with health sector practitioners in West Africa to understand their needs with respect to climate information and (c) representatives from five African cities to understand city-scale climate vulnerabilities and information needs. Planned activities include a series of workshops to analyse climate projection data in the 4 regions with input from climate information users to assess potential effect of global warming on atmospheric process and the impacts these may have in the engaged user communities.

The FODAS based climate prediction services in China

Z. Gong (1)
(1) Beijing climate center, Beijing, China

The structure of China Framework of Climate Service, what we called CFCS to compare to the GFCS is building in China. Based on climate database and climate system model, climate monitoring and prediction products is issued. We focus on climate security and disaster risk reduction. Climate security is a new concept developed by Dr. Zheng Guogang. who is the Administrator of China Meteorological administration. Climate is really related to food security, water security, energy security and ecological security, and so on. We need to assess climate impact, climate capacity, to analyze climate resource and provide climate proofing to support sustainable development of social-economy in china. As China belongs to monsoon climate and is a very vulnerable country suffered from different kinds of meteorological disasters. Therefore, Beijing Climate Center (BCC) are facing big challenge of disaster risk reduction. We need to do disaster survey, to assess vulnerability, to issue risk warning even support risk transfer. Through the user interface plan and partnership, we provide all of those climate services to decision makers, public community and economic sectors. Besides, in order to surport the capacity development of CFCS, the forecast system on dynamical and analogy skill (FODAS) is developed by BCC, which is used for supplying monthly and seasonal climate prediction services to the govement and public. FODAS is also been generalized in more than 30 provincial climate centers in China and used for regulary climate business. We are also working on developing a English version of FODAS to surport some international trainning courses held in CMA etc.

O-1104-03

The fourth generation of European-wide climate change impact assessments – lessons and outlook

HM. Füssel (1) ; J. André (1)
(1) European Environment Agency, Copenhagen, Denmark

The European Environment Agency (EEA) is a boundary organization that bridges between data providers, including the scientific community, and policy makers. Its mandate is to provide timely, relevant and quality-controlled information on the environment to European policy makers (in particular the European Commission and the European Parliament), to national and sub-national policy-makers in its 32 member countries and 7 cooperating countries, and to the broader public. In 2012 the EEA published its third indicator-based report on climate change, impacts and vulnerability, following earlier reports in 2004 and 2008. The next report is scheduled for publication in 2016, and its preparation has already started.

The 2012 EEA report presents more than 40 quantitative indicators on observed and projected climate change and its impacts, most of them with European-wide coverage. The systems and sectors covered include coastal zones, terrestrial and marine ecosystems, agriculture, forests and forestry, fisheries and aquaculture, human health, energy, transport, and tourism. However, some important impact domains are not covered because information is not readily available at the European level, impacts are hard to quantify or to measure, and/or because the influence of climate change is hard to disentangle from socio-economic, technical, cultural and political developments. Under-reported impact domains include industry and manufacturing, insurance, infrastructure (except transport infrastructure), livestock production, cultural heritage (with some exceptions), migration, and general human wellbeing. Furthermore, the report presents cross-sectoral information with a focus on territorial impacts, on the vulnerability of cities and urban areas, and on climate change costs. The cross-sectoral assessments rely on information that is not fully consistent with the sector-based indicators, because these indicators are often not amenable to aggregation due to differences in climate change scenarios, non-climatic scenarios, impact metrics, and/or incompatible modelling and assessment approaches.

This paper summarizes the availability of consistent information on observed and projected climate change and its impacts across climate-sensitive sectors and systems in Europe and identifies major knowledge gaps. It also presents the planning of the 2016 EEA report, including efforts for refocussing the indicator set in order to increase its policy relevance, improving coverage of information related to extreme weather and climate events, expanding consideration of cross-sectoral effects, and strengthening links between information on climate change impacts and adaptation-related issues. We also report on past and planned efforts at improving the assessment and reporting of uncertainties in observed and projected climate change and its impacts.

O-1104-04

Innovation in French climate services thanks to service design

P. Dandin (1) ; L. Corre, (2) ; D. L'hôte, (3)
(1) Météo-France, Centre National de Recherches Météorologiques, Toulouse, France; (2) Météo-France, Direction de la climatologie, Toulouse, France; (3) Strate, Ecole de Design, Sèvres, France

Within the framework of the French National Adaptation to Climate Change Plan, the "Drias, the futures of climate" service provides support and easy access to the French regional climate projections. Users worship the unleash of such essential materials and rank Drias as one of the major recent steps toward the development of French Climate Services. Noteworthy, Drias is a joint initiative from the French community, gathering the meteorological service, Météo-France, with the main providers of regional climate scenarios in the country, CERFACS, IPSL and CNRM.

However necessary and successful the initiative might have been, many questions arose. Some came from the scientists whereas others were raised by users. How really useful was this service for the end-users and decision makers involved in adaptation planning at local scale? Did it help them to figure out what kind of climate change was happening and what could be thought to cope with it? Had the French scientific community made all possible efforts and released the information available in the laboratories? Taking advantage of all the assets worked out in the field of climatology, could it be possible to improve the delivery? Did we miss something believing we were doing our best? With many such questions in mind, soon after the opening of the Drias service, a review and reflection exercise was initiated.

The Viaduc project has this target: to evaluate and enhance Drias, as well as to imagine future developments to support adaptation. Users had been closely associated to the building of Drias, but they were not end users. Viaduc chose to address adaptation with local communities, thinking about real needs at the end users' level. The chosen end-users are three Natural Regional Parks located in the South West region of France. Such parks are administrative entities which gather together municipalities defined by a common natural and cultural heritage. They are also rural areas in which economic activities do take place, and therefore concerned and involved in both protecting their environment and setting up sustainable economic development. Climate researchers work together with a service designer. The designer's role consists in proposing an innovative approach based on the interaction between scientists and citizens. Actually, the designer observes both partners: scientists and end users.

The first part of the project has been dedicated to investigation and questioning with relevant representatives. The Viaduc team did not initiate new actions in the parks, but insert into existing ones, trying to ease them. Three

key local economic sectors have been selected, which are forestry, agro-pastoralism and construction, relevant for each of the parks. Working groups composed of expert technicians, administrative and maintenance staff, politicians and climate researchers have been created. The sectors needs for climate information have been gauged, and concrete actions are now undertaken. They will be presented in this communication, together with lessons learnt. The second part of the project has focused on the transfer of ideas to the operational teams, in order to give life in next generation of products to some of the recommendations that came out of this thinking exercice.

The feedback from the designer and the Viaduc team on the services delivered by scientific agencies and the meteorological service do modify the classical views. It concerns all aspects of the products and services, and addresses many various subjects, from the relationship between weather and climate, the need for local and perceivable information and messages, to the necessity of a greater coherency and simplicity of the message...

A quick introduction to Drias will be made, and the Viaduc project and outcomes will be presented.

O-1104-05

World Weather Attribution: A Real-Time Effort to Assess the Influence of Climate Change on Extreme Weather and Climate Events

H. Cullen (1) ; M. Allen () ; F. Otto (2) ; D. Karoly (3) ; GJ. Van Oldenborgh (4) ; E. Coughlan (5) ; A. Van (5)

(1) Climate Central, Princeton, NJ, United States of America; (2) University of Oxford, Oxford, United Kingdom; (3) University of Melbourne, School of Earth Sciences, University of Melbourne, VIC, Australia; (4) KMNI, De Bilt, Netherlands; (5) Red Cross/Red Crescent Climate Centre, The Hague, Netherlands

Climate Central and its partners at the University of Oxford Environmental Change Institute, the Royal Netherlands Meteorological Institute (KNMI), the University of Melbourne, and the Red Cross/Red Crescent Climate Centre have established a new initiative called World Weather Attribution. World Weather Attribution aims to apply recent advances in the science of probabilistic extreme event attribution to build a real-time attribution capability designed to provide objective, science-based connections between rising greenhouse gas concentrations in the atmosphere and extreme weather and climate events, including sea level rise and its contribution to storm surges, extreme heat events, heavy rainfall events/flooding, and droughts in real-time. The goal is to design and implement a coordinated, transparent, multi-method approach that incorporates observational data, modeling studies, existing peer-reviewed research (i.e., IPCC SREX, etc.) and on the ground reports in order to better answer pressing questions about trends in risk and the role of human activity in extreme weather.

Assessing the influence of global warming in individual extreme weather events has been a goal of the scientific community for more than a decade. Advances in the field have prompted numerous studies, leading the Bulletin of the American Meteorological Society (BAMS) to dedicate an annual special issue to extreme event attribution for the past three years. Currently, these studies require months to complete and are published well after public attention to the event has peaked, and when decisions on how to rebuild, for example, have already been finalized, often without attention to climate information on how risks of such events may have changed over time.

In fact, an analysis of media coverage of three recent extreme weather and climate events (2014 UK floods, 2013 Australian heat wave, ongoing California drought) conducted by Climate Central suggests that, despite strong public interest in better understanding the underlying cause of extreme weather and climate events, a significant majority of extreme event coverage fails to provide the broader climate context. While overall weather and climate coverage results in a large number of stories in the days to weeks following the event, attribution statements are rarely provided and often inaccurate as analyses are not available until several months later, after the media and public conversation is largely over and many recovery and reconstruction decisions have already been made, often based on limited information on changing risks.

Our goal is to apply established peer reviewed methodologies developed by the attribution community over the past decade - in an accelerated manner - so as to objectively assess the event in question and equip journalists, the public and decision makers with the broader context of changing risks, in some cases specifically due to global warming. To this end, the World Weather Attribution program will make extensive use of social science through experiments and robust literature reviews on the presentation of risk, probabilities, and uncertainty to guide the most effective deployment and presentation of these accelerated attribution statements. Here we discuss ongoing research that seeks to understand public understanding of the changing statistics of certain extreme weather and climate events and how best to communicate and apply attribution information.

Spatiotemporal Visualization Method for Interrelation-based Analysis of Agriculture's GHG Emissions and Agricultural Productivity in Asian Region Using the 5D World Map System

B. Ahmad Muzaffar (1) ; A. Siti Nor Khuzaimah (1) ; S. Shiori (2) ; K. Yasushi (2)

(1) Keio University, Graduate school of science and technology, Yokohama, Japan; (2) Keio University, Graduate school of media and governance, Fujisawa, Japan

According to the Food and Agriculture Organization of the United Nations (FAO), anthropogenic Greenhouse Gas (GHG) emissions originated from agricultural activities have increased approximately two times over the past five decades. Mitigation and adaptation countermeasures must be taken to reduce or slow down the increment of GHG level as a result of unhealthy agriculture practices especially in most developing countries. Conversely, further increment in GHG emissions results in climate change and eventually affects the agricultural sustainability and food security.

To understand the complex system between GHG emissions and agriculture productivity, a regional and historical analysis is compulsory as well as for finding more viable solutions. By applying the 5D World Map system, we demonstrate spatiotemporal visualization to analyze the interrelation between agriculture's GHG emissions and agricultural productivity. In this analysis, we focus on Asian region since it is one of the largest contributors of global GHG emissions from agriculture sector itself.

The most significant contribution of this research is to unveil the interrelation-based analysis between GHG emissions and agriculture, considering the Asian countries geographical aspect and historical data records. We mapped the pre-sorted text data of Asian countries in Eastern Asia, South-Central Asia, South-East Asia and Western Asia from 1963 to 2013. Then, we visualized and analyzed the data by comparing various attributes, namely; types of GHG (CO_2, CH_4 and N_2O) and annual crops yield. As results, we are able to observe that the spatial pattern of CO_2 and CH_4 emissions are relatively similar but slightly different in N_2O emission. The temporally increasing trend of GHG emissions in some countries is observed as expected, as well as the decreasing trend in other countries, while we discovered that the spatial pattern of crop yield is contrary to expectations. Also, we emphasize the fact from real cases that the interrelation between crops yield and GHG emissions could be observed explicitly by the spatiotemporal visualization of the data. As an insight from these results, we consider to classify these countries into four clusters: 1) cluster with high agricultural productivity and high GHG emissions, 2) cluster with high agricultural productivity but lower GHG emissions, 3) cluster with low agricultural productivity and low GHG emissions and 4) cluster with low agricultural productivity but higher GHG emissions.

In this research, the visualization of specific GHG emission density by each country and its' crop yield were made possible through the 5D World Map system. The index ranking of each country in each attribute is also visualized. Besides, new knowledge and possibilities existing between climate change and agriculture sector are discovered and

extracted from the visualization. Through this analysis, the countries which appear as more effective or less effective in both interrelated agricultural productivity and environmental management were clarified in this knowledge-sharing system for encouraging a deeper analytic process of regional policy making in agricultural GHG emissions and future agriculture management.

Connecting the Dots: An Initiative on Communicating Complex Climate Science to Local Communities through Climate Change Services

SK. Amsad Ibrahim Khan (1) ; H. Malleshappa (1) ; M. Jayanthi. (1)
(1) Tamil Nadu State Climate Change Cell (TNSCCC), Department of Environment, Government of Tamil Nadu, Chennai, Tamil Nadu, India

Article 6 of the United Nations Framework Convention on Climate Change addresses the importance of climate change communication and engaging stakeholders in this issue. It highlights the responsibility of participating countries at the national, sub-national and local levels, to ensure public access to information and to promote public participation. However, this is a challenging task particulaly for developing countries like India despite of other emergent and on-going developmental challenges. In this context, this article addresses an initiative taken by the Government of Tamil Nadu, India at the local level to address the global challenge of climate change, in a case study approach. The main objective of this contribution is to showcase a method/approach to connect the dots i.e. climate change «science-policy-society» and build capacity by communicating complex climate change science and its information at local level through effective climate change services, particularly, from the perspective of developing country's initatives on tackling climate change. Thus, realizing this urgent importance, Tamil Nadu State Climate Change Cell (TNSCCC) at the Department of Environment, Government of Tamil Nadu, India has laid a road map as «Tamil Nadu State Climate Change Services (TNSCCS)» based on the guidelines of the Global Framework for Climate Services of World Meteorological Organization (WMO). This has been iniated as envisaged in Tamil Nadu's State Action Plan on Climate Change (SAPCC) in par with India's National Action Plan on Climate Change (NAPCC). TNSCCS acts as a central hub of information, data and reports about climate change of entire Tamil Nadu State. It is considered as one of the major principal mechanisms through which information about the climate of the past, present and future is routinely archived, analyzed, modeled and exchanged. Tamil Nadu State Climate Change Knoweldge Management System (TNSCCKMS) has been established and serves as a store house of locally observed and projected climate change information for the state of Tamil Nadu. Importantly, it provides a "web-based platform" and "user friendly interface" to disseminate and exchange climate change information for various communities ranging from bureaucrats, policy planners, decision makers to farmers, fishermen, students, children, general public and others. It is hoped that the information gleaned from the above mentioned method/approach of climate change services witness how best the complex climate change science can be tailored and communicated at local level. Importantly, it showcases a method/approach on capacity building through effecitive climate change information and services from global to local level.

P-1104-03

Role of social media networking in Climate policies Awareness in Sub- Saharan Africa

M. Atombo Aleya (1)
(1) Solidarity for Rural Development and Local Governance in DRC(Tshwane University of Technology), Pretoria, South Africa

Climate policies awareness and/or knowledge are much required for the based-communities to mitigate the risk based on climate change and adaptation. In this respect, to spread awareness and/or knowledge of climate policies amongst African population by using social media is critical in raising ranks of awareness on the consequences related climate change. This research surveys the role of Social media networking in contributing to climate change awareness in rural areas especially; African population living in sub-Saharan Africa where, the impact of climate change disrupts subsistence farming activities. In fact, Economy in Africa is mainly focused on agriculture and peasant activities. On the one hand, many Africans are still unaware of climate policies developed neither in the national or international scale that fit with climate change. In the other hand, Aboriginal people living in forest areas have trouble with the acceptance of certain prohibitions to hunt and harvest the wild fruits in parks and other protected areas. That is why, This study found out that, The ubiquitous of internet facilities in African continent based on mobile application are tools that can facilitate information propagation and communication, even though, these technologies practice and abilities are utilised independently by the hand users. As the rural people are vulnerable to climate change, they are also considered as key players for emerging climate policies to mitigate and cope with climate change's effects. It is a need to use Social media networking in a number of operative ways to enhance climate policies awareness or knowledge amongst them. Thus, Climate policies awareness remains the foundation of all other answers to climate change.Therefore, the main objective of this research is to interest African governments to adopt the information and communication technologies such as social media networking to conduct a viral campaign enhancing knowledge and awareness related climate policies and sustainable development in order to foster the based-communities to mitigate the risk based on climate change and to support farmers' abilities to adapt to climate change. As for the methodology that is used, this study employs both qualitative and quantitative research techniques and data are collected through semi-structured interviews with some sub-Saharan African small-scale farmers, local governments and non-profit organizations focusing on climate change and furthermore, questionnaires will be designed based on Five-point Likert scale on an interval level ranging from ''strongly disagree'' to ''strongly agree").

P-1104-04

The WASCAL regional climate simulations for West Africa - how to add value to existing climate projections

D. Heinzeller (1) ; C. Klein (2) ; D. Dieng (1) ; G. Smiatek (1) ; MB. Sylla (3) ; J. Bliefernicht (2) ; H. Kunstmann (1)
(1) Karlsruhe Institute of Technology, Institute of Meteorology and Climate Research, Garmisch-Partenkirchen, Germany; (2) Augsburg University, Institute of geography, Augsburg, Germany; (3) WASCAL Competence Center, Climate Modeling and Climate Change, Ouagadougou, Burkina Faso

With climate change being one of the most severe challenges to rural Africa in the 21st century, West Africa is facing an urgent need to develop effective adaptation and mitigation measures to protect its constantly growing population. The below-average rainfall in large parts of West Africa during the previous and the current monsoon season and the associated scarcity of food and fresh water highlight the importance of accurate predictions of future monsoon circulation for the people of this region.

WASCAL (West African Science Service Center on Climate Change and Adapted Land Use) is a large-scale research-focused program designed to help tackle this challenge and thereby enhance the resilience of human and environmental systems to climate change and increased variability. An integral part of the climate services offered by WASCAL is the provisioning of a new set of high resolution, ensemble-based regional climate change scenarios with a special focus on West Africa. These are thought to complement and provide added value t current medium-resolution climate change simulations for the region such as the CORDEX-Africa projections. The WASCAL climate change simulation experiments utilize a multi-model ensemble approach to refine RCP4.5 scenarios provided by three state-of-the-art global circulation models (MPI-ESM, GFDL-ESM2M, HadGEM2) using three regional climate models (WRF, COSMO-CLM, RegCM). Spanning an area from 25°W to 25°E and 5°S to 25°N, and providing a large number of variables at 3-hourly time steps at a horizontal resolution of 12km, these regional climate simulations will be used to assess amongst others the impact of climate and land use change on temperature, precipitation, and on onset and duration

of the rainy season.

The credibility of regional climate simulations over West Africa stands and falls with the ability to reproduce its key climatic feature, the West African Monsoon. This seasonal shift in large-scale wind patterns plays a pivotal role in every day's life, and any shift caused by climate change will greatly impact the future of this region. In our analysis, we therefore focus on the representation of the WAM in the regionally downscaled models. For the validation of the models, ERA-Interim re-analysis data is used as lateral boundary condition for the period from 1980 to 2013. We verify the models against observational data from gridded climate observational products such as GPCC, TRMM, and CRU. In addition, we employ a novel gridded precipitation database for the West African region, which is compiled from daily and monthly in-situ observations merged from various global and regional meteorological archives (GHCN, GSOD, AMMA, GLOWA) and from precipitation data provided by the national weather services and the novel WASCAL observation network.

In this contribution, we present the overall concept of the WASCAL regional climate projections and provide information on the availability of the data and its dissemination to the community. We discuss the model performance over the validation period for two of the three regional climate models employed, the Weather Research and Forecasting tool (WRF) and the COSMO model in CLimate Mode (COSMO-CLM), and give details about the novel precipitation database used to verify the models. We further present results on the climate change signal obtained from the WRF model runs for the periods 2020-2050 and 2070-2100.

P-1104-05

Challenges of scales

S. Huq (1)
(1) International Center for Climate Change and Development (ICCCAD), Dhaka, Bangladesh

There are several aspects of governance related to adaptation to climate change that need to be addressed to ensure equity and fairness in the way adaptation is implemented on the ground. Firstly, at the global level, there is the issue of governing climate change funding for adaptation in an equitable manner to ensure that the most vulnerable countries and communities are prioritised for receiving adaptation funds.

Similarly, at national level, it is important for national decision makers to also prioritise the needs of the most vulnerable communities within each country. This is true for both developing as well as developed countries.

One of the main issue in current climate governance is that the poorest communities within countries, and the poorest countries globally, possess a relatively less important voice in decision making at global and national scales. Hence, in order to adapt successfully to the adverse impacts of climate change, the empowerment of the most vulnerable within the climate governance system is a precondition.

P-1104-06

The Contribution of Climate Services to Climate Change Adaptation through the Global Framework for Climate Services (GFCS)

F. Lucio (1)
(1) World Meteorological Organization, Global Framework for Climate Services Office, Geneva, Switzerland

Climate determines the extent to which human kind can sustain livelihoods and well-being. Thus, as the effects of climate change are becoming more evident and acute, the need for effective climate services is greater than ever before. Climate services here are considered to be the provision of climate information to assist decision-making in climate sensitive-sectors. Climate services require a range of activities from generating to providing information based on past, present and future climate and its impacts on natural and human systems. These services can range from simple information such as historical climate data sets to more complex products such as predictions on monthly, seasonal and decadal time frames. Ultimately, climate services provide information and expert advice that help users make the right decisions for climate change adaptation.

Seasonal to multiyear climate forecasting has advanced to a point where it can now provide actionable information. Sophisticated climate services combine climate forecasts with information from other sectors to inform decisions on public health, agriculture, water management, disaster risk and other climate-sensitive sectors.

Recognizing the value and contribution of climate services, the international community established the Global Framework for Climate services (GFCS) at the Third World Climate Conference (WCC-3, 2009) to promote operational climate services at the national and regional levels. The GFCS aims at facilitating the development and use of services to ensure that best efforts are made to reduce the impacts of climate-related disasters and to adapt to climate change. It is catalyzing a paradigm shift from supply-driven service provision to the creation of services driven by user needs, by orienting scientific research towards practical applications to respond to those needs. Building on past and current climate service initiatives, it is enabling new services to be developed to increase the value and access to climate knowledge products for those who need them the most.

Climate services underpin climate action and adaptation in climate sensitive sectors; contribute to enhancing disaster preparedness and planning for effective response and to allow societies to build back better after a disaster.

An essential starting point for adaptation is a quantitative assessment combining characterization of hazards with vulnerabilities to derive specific services to various users. This is often hampered by the capabilities to conduct effective analysis of past data and assess changing characteristics and trends of hazards in light of climate change to support risk and impact assessment.

This paper provides an account of how the GFCS is supporting countries in the development and use of climate services for climate change adaptation.

P-1104-07

Appraising the climate services accessible to indigenous communities in Uganda

AR. Mwangu (1)
(1) Makerere University, Kampala, Uganda

Climate change is one of the most pressing challenges of our generation. Scientists predict that it will even have more adverse effects on the population in the future. Studies indicate that climate change impacts most affect people in the developing countries especially the women, elderly and children because these groups have little access to the information on climate change, they are illiterate and are concealed in poverty. Yet a big constituent of these groups especially the women are by default key resource managers whose knowledge and actions are critical in environment and natural resource management. Climate services are seldom offered in Uganda and as a result climate change is as much abstract to a wide section of people. This study will urge that in circumstances where climate services have been offered they have not been conceptualized for comprehension by the masses. Climate change continues to be portrayed as a highly scientific phenomenon far and above the indigenous communities yet they are the most affected by its impacts. The examples used in talking about climate change are distant and unfamiliar that people hardly make sense of them. Besides climate change is only linked to anthropogenic activities yet natural phenomenon like local land-use changes can have a serious impact.

With data collected through Focus Group Discussions and Key Informant Interviews, this study urges that robust climate services are urgently needed in Uganda to tackle the serious adverse effects of climate change that is choking the local communities. Disastrous effects like floods and landslides as a result of heavy rains in the Mountain Elgon region have continuously led to fatalities yet the local communities are unaware and cannot devise adaptive and mitigation strategies. Correspondingly the seasons have changed but the local farmers continue to plan their planting seasons basing on the previous seasons that has eventually led to a decline in crop yields resulting into food shortages and its associated ills of malnutrition.

It is critical that climate services are customized to the local situations for long lasting impact.

P-1104-08

Decadal climate information for improved decision-making and resilience in small-scale farming systems in Africa: Lessons from East and Southern Africa

A. Nyamwanza (1)
(1) University of Cape Town, African Climate and Development Initiative, Cape Town, South Africa

Small-scale farming systems in Africa are facing increasingly erratic and variable climate dynamics, in addition to other multiple and reinforcing non-climatic stresses and shocks. Effective responses and ultimately resilience to these adversities require, among other factors, access to and use of adequate climate information for the coming seasons and years to enable players within these systems to make informed, timely and appropriate decisions not only in the short term, but also in the medium to long term. Climate information is used in agriculture on a range of timescales, from days (weather), months (seasonal outlooks) to decades (climate change scenarios) (Hellmuth et al. 2011). In most African countries, adaptation to climate risk has focused either on the seasonal timescale or the assessment of climate change impacts several decades into the future. Awareness of and adaptation to climate risk on the decadal timescale (up to 10 years) has received less attention. Yet much policy, planning and investment decision-making falls into this time horizon, especially in areas of importance to small-scale farming systems in developing countries such as farm planning cycles, introduction of new varieties and the setting up of such projects as catchment-wide infrastructure for irrigation and water storage (Goddard et al. 2010; Stafford-Smith et al. 2011, Vermeulen, 2012). There is also increasing evidence that climate change is altering the likelihood of extreme events that impact on agriculture within the decadal timescale (IPCC 2012). It is against this background that this analysis explores the utility of climate information in small-scale farming systems in Africa on the decadal timescale. Using cases of small-scale farming systems in the Kilimanjaro Region of Tanzania, the mid-Zambezi Valley Region of Zimbabwe, and the Southern Region of Malawi, the analysis shows decadal climate information as potentially providing opportunities for innovative, flexible and proactive decision-making in response to projected climate and related dynamics. The analysis shows that although farmers will be the major beneficiaries of decadal climate information, other players, particularly service providers and intermediaries, also stand to gain thus providing a holistic perspective in dealing with the decision-making context of small-scale farming systems in Africa. The paper however also points on the need for building institutional capacity vis-à-vis coming up with stronger knowledge and information networks between climate scientists, policy makers and local communities as well as attending to issues of credibility, legitimacy and scale in the production and dissemination of decadal climate information in Africa so as to ensure uptake and appropriate use. The discussion, therefore, brings to the fore the need for the recognition of the increasing importance and role of decadal climate information vis-à-vis decision making towards resilient and adaptive small-scale farming systems in Africa.

P-1104-09

Drias, the futures of climate: a service for the benefit of adaptation

JM. Soubeyroux (1) ; P. Josse (2) ; R. Vautard (3) ; C. Pagé (4) ; S. Planton (5)
(1) Météo-France, Dclim, Toulouse, France; (2) Météo France, Direction de la Climatologie et des Services Climatiques, Toulouse, France; (3) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France; (4) CERFACS, Toulouse, France; (5) Météo-France, CNRM, Toulouse, France

The project Drias for 'Deliver Regional climate scenarios for Impacts and Adaptation of our environment and Society' was built with the basic idea that a facility was now needed for climate information delivery. Drias was funded by the Management and Impact of Climate Change programme of the French Ministry for Sustainable Development. It focuses on existing French regional climate projections obtained from national modelling groups: IPSL, CERFACS, and CNRM and was coordinated by the Department of Climatology at Météo-France, which is in charge of climatological operations and services

The resulting portal, opened in 2012, offers easy access to data and products, including a quick-look discovery, as well as the associated expertise to facilitate impact and adaptation studies:

- Several greenhouse gas emission scenarios, using different regional climate models and downscaling methods, because it is critical that users work with the idea that climate projections have to be addressed in a probabilistic mode
- Standard formats, easy access, quick looks and simple products for a wide range of users, baring in mind that many communities do not share the technical skills of climate modellers
- Expertise and guidance, especially addressing the various sources of uncertainty, and promoting best practices and know-how – one of the first requirements of users, as shown in every user needs survey.

The Drias web portal comprises three main areas: Delivery, Support, and Discovery. The Discovery area contains general information for a wide range of people, allowing them to grasp climate scenarios and visualize outputs. In the Support area, a range of documents is offered to help users make the best use of available climate information (glossary, description of methods and climate models, frequently asked questions). A hotline mechanism involving experts is also implemented at this level. The Delivery area enables users to order, in digitized format, data and products they have identified in the Discovery area.

A user committee was created at the beginning of the project, to help define effective and strategic needs, evaluate prototypes using beta testers, validate the choices made by the project team, and ensure that Drias will continue to meet user's expectations.

Drias is positioned at the interface between actors. A layer of intermediate users – or translators – is appearing in the form of engineers from the meteorological service, or from private companies already deploying activities in the field of environment, or climate experts hired by local organizations.

The partnerships around Drias must also be highlighted. Nothing could be done without the research groups or the meteorological service. A strong tribute must be paid to the governing bodies that have supported the initiative, and have placed it high on the agenda at the ministerial level, making Drias one of the most prominent actions of the French National Plan for Adaptation.

New indices, dataset and other enhances have been gradually introduced for the last three years, with confidence intervals instead of the single scenario originally, results of impact studies on water resources (ClimSec project) and more recently with the newest regionalized scenarios for France, based on the 'Representative Concentration Pathways.

But can we say that we are on the right track? Will our co-citizens be more convinced because such facilities are now in place? Undoubtedly there are many aspects of the human conscience that must be activated in order to reach the appropriate level of commitment regarding climate change. The real challenge for climate services may also appear in the training and education arena, and definitely has to deal with a wide range of human and political sciences.

P-1104-10

Climate Information for Public Health in Africa in the context of Climate Change Adaptation

M. Thomson (1) ; P. Ceccato (1) ; A. Woyessa (2) ; T. Dinku (1) ; S. Connor (3)
(1) International Research Institute for Climate and Society, Columbia University, New York, United States of America; (2) Ethiopian Public Health Institute , Department of bacterial, parasitic & zoonotic diseases research, Addis Ababa, Ethiopia; (3) Liverpool University, Geography, Liverpool, United Kingdom

Climate impacts on health are well established. Building climate smart and resilient communities is therefore essential in the face of climate variability and change. Climate information can play a role in helping societies to better manage health risks brought about by climate variability and change. However, for climate informed health decision-making to become an everyday reality, a broad coalition of partners focused on improved health adaptation and mitigation strategies is essential.

This paper describes the approach taken at the International Research Institute for Climate and Society (IRI)[1] and its partners to integrate research, operational applications and capacity building alongside policy development and advocacy in the area of climate and health in Africa. The initial focus of the IRI's health work on the development of early warning systems for climate-sensitive diseases (for example malaria and meningococcal meningitis) was built upon the institute's applied research capacity in seasonal climate forecasting. However, over time, the agenda has broadened in response to articulated user needs for information on the past, present and future climate to also better understand the mechanisms by which climate impacts on disease, map populations at risk both geographically and by season, develop early warning systems, better understand trends in disease incidence associated with climate shifts and improve the evaluation of the impacts of climate-sensitive interventions.

Central to IRI's experience throughout has been a keen awareness that climate information and products, in Africa as elsewhere, must be relevant to the health community and development partners and reflect prioritized needs within political and donor processes, while also offering innovations grounded in relevant and reliable observational data obtained through effective, efficient, credible and transparent means. The relevance of this approach to infectious disease, health outcomes of disasters and nutrition will be presented.

[1] IRI is a WHO/PAHO Collaborating Center for Malaria Early Warning and Other Climate Sensitive Diseases.

P-1104-11

Using agro weather tool for enhanced productivity under climate change and variability by communities in Kenya

J. Wamari (1)

(1) Kenya Agricultural and Livestock Research Organization, National Agricultural Research Laboratories, Nairobi, Kenya

The farming communities in Kenya produce 65% of Kenya's exports and offer employment to 80% of the population therefore ensuring food security. A survey from three counties of Machakos, Nakuru and Kakamega predominantly growing Maize-Beans-Pigeon peas, Maize-Beans-Irish potatoes and Maize-Beans-Sweet potatoes respectively showed heavy reliance on rainfall (>90). These rains have however become increasingly variable spatially shattering for example the average maize yields of 3.1, 10.4 and 5 bags-1 acre at the respective sites. Spatial and temporal changes of seasonality under climate change and variability call for changing methods to maintain these cropping systems and alternative varieties and agronomic practices as adaptation strategies for sustainable realization yield variations.

The information required by these communities need to be accurate and timely and manageably packaged and presented in easily interpretable and understandable manner. It should additionally factor indigenous knowhow and include insurance possibilities to enable confidence in its utility. An agro-weather tool using the mobile phone owned by a majority of rural folk jointly developed for this purpose. It involved collaboration with World Bank as development partner, Government of Kenya lead-departments of agriculture and meteorology, mobile line service provider Safaricom and local agro-dealers targeting 5000 households in its pilot phase and was successfully unveiled for Embu County in 2014. The tool targeted coffee and tea as cash crops and maize and beans subsistence crops dominantly grown in this county and is scheduled for up-scaling in other areas.

Beneficial information relayed included daily, weekly and seasonal forecasts, possible disasters, climate stress severity with direct and indirect severe impacts on crop production. It also offered interventional measures of suitable varieties and their productivity potential and appropriate farming activities to be undertaken to reduce, adapt and/or mitigate the negative impacts related to weather and climate.

The use the tool will be out scaled to other counties but also for pastoral communities who will require weather-related information on areas of depressed rainfall, periods of availability, frequency/resurgence of pastures/forage and the likely occurrence of killer diseases and environmental degradation. Also necessary is weather information that would cause floods/drought that would drown/kill livestock and potential benefits of using alternative methodologies.

1105a - Assessing climate observations

ORAL PRESENTATIONS

Space-based Climate Observing systems

S. Briggs (1) ; JL. Fellous (2) ; P. Lecomte, (1) ; P. Ultré-Guérard (3) ; A. Ratier (4) ; J. Bates, (5)

(1) European Space Agency, Harwell, United Kingdom; (2) COSPAR, Executive Director, Paris, France; (3) CNES, Dps/tec/d, Paris, France; (4) EUMETSAT, Director general, Darmstadt, Germany; (5) NCDC, Ashville, United States of America

The Global Climate Observing System (GCOS) provides a framework for the coordination of observations in support of the UNFCCC. The 2003 GCOS Adequacy report to UNFCCC SBSTA introduced the concept of Essential Climate Variables, variables which were considered fundamental to the understanding and reporting of climate. These were updated in the GCOS 2010 Implementation Plan, and currently comprise a list of some fifty variables. A satellite supplement focussing on the needs of the climate community for observations from Earth observing satellites was produced by GCOS in 2011, and this forms the basis for the current support of space agencies to GCOS. The Commite on Earth Observation Satellites (CEOS) has formally responded ot his with a document published in 2012. Satellite observations are critical for about two thirds of the fifty ECVs. In addition, the Committee on Space Research (COSPAR) has sponsored a roadmap study for Integrated Earth System Science in the period 2015-2025.

This paper will describe briefly the status of the GCOS and highlight the needs for satellite data which derive from it. An overview of current Earth observion satellite systems will be given, together with an analysis of how these contribute to the provision of the ECVs. Examples of satellite observations and key derived products for climate will be given.

K-1105a-02

Climate Observing Systems: Where are we and where do we need to be in the future

C. Baker (1)

(1) NOAA, Oar/arl/atdd, Oak Ridge, TN, United States of America

Climate research and monitoring requires an observational strategy that blends long term, carefully calibrated measurements as well as short-term, focused process studies. Operating climate observing networks and providing climate services, have a significant role to play in assisting the development of national adaptation policies and in facilitating national economic development. Climate observing systems will require a strong research element for a long time to come. This requires improved observations of the state variables and the ability to set them in a coherent physical (and chemical and biological) framework with models. Climate research and monitoring

requires an integrated strategy of land/ocean/atmosphere observations, including both in situ and remote sensing platforms, and modeling and analysis. It is clear that we still need more research and analysis on climate processes, sampling strategies, and processing algorithms.

K-1105a-03

Sea Level, an Essential Climate Variable and an integrator of climate change

A. Cazenave (1) ; M. Ablain, (2) ; JF. Legeais (3) ; B. Meyssignac (1)
(1) CNES, LEGOS, Toulouse, France; (2) CLS, DOS, PMC, Ramonville St Agne, France; (3) CLS, Space Oceanography Division, Ramonville St Agne, France

Sea level is an important climate variable and a major indicator of climate change. In effect, sea level integrates changes and interactions of all components of the climate system (ocean, atmosphere, cryosphere, hydrosphere); it varies globally and regionally in response to internal climate variability and external -natural and anthropogenic- forcing factors. Sea level is one of the 50 Essential Climate Variables (ECVs) defined by the Global Climate Observing System for climate change monitoring and one of the 15 ECVs accurately measured from space within the ESA Climate Change Initiative (CCI) project. While sea level is routinely measured by high-precision satellite altimetry since 20 years, providing a long, homogeneous and accurate sea level record using all altimeters satellites in orbit is the objective of the CCI 'Sea Level' project. This allows addressing major issues related to climate change and sea level (e.g., how much is the global mean sea level currently rising? Has it accelerated during the 20th century? Can we close the sea level budget? What are the factors causing non uniform sea level change? Are observed spatial trend patterns due to internal climate variability only or can we already detect the signature of anthropogenic forcing?, etc.). The sea level products already obtained in the context of the CCI project have been proved to be superior to other existing products and are of great value for climate change studies. Moreover, combining different CCI-based ECVs (e.g., glaciers and ice sheet mass balances, in addition to the sea level ECV) plus Argo-based ocean thermal expansion leads to better closure of the sea level budget, allowing addressing important new issues, such as the amount of deep ocean warming (not measured by Argo) and its role in the present 'hiatus'. Finally, such long, accurate new ECV records are essential to validate climate models used to simulate future changes expected in response to anthropogenic global warming.

1105b - Quality and availability of data for global sustainability

ORAL PRESENTATIONS

K-1105b-01

Parameterisation, ground-truthing and benchmarking: the importance of in-situ data for global sustainability

S. Harrison (1)
(1) University of Reading, Reading, United Kingdom

Many key aspects of the global system can only be measured in-situ. In-situ measurements are required for ground-truthing remotely-sensed products. More importantly, they are vital for developing process-based models and individual model parameterisations. Furthermore, in-situ measurements are used as benchmarks for model evaluation, including the historical and palaeoclimate observations used for out-of-sample model testing. Problematic features of in-situ data include being collected by individuals, using different and evolving methods, and often the same type of data is collected for different purposes. Thus, key steps in using such data are documentation, harmonization and synthesis. There has been considerable progress in creating unified data sets of in-situ measurements, but more effort is required specifically in terms of data rescue, data documentation, communal access and data stewardship. Given the utility of in-situ data in developing and evaluating models that are used to predict the likely trajectory of future climate and environmental changes, organisations such as the World Data Service and Future Earth need to provide attention to and support for data rescue, synthesis and sustainability of in-situ data.

K-1105b-02

Future Earth data and information needs

H. Mario (1) ; D. Ojima (2)
(1) Future Earth Engagement Committee, Future earth, Geneva, Switzerland; (2) Colorado State University and Future Earth US Hub, Natural Resource Ecology Laboratory, Fort Collins, United States of America

Future Earth has been set up as a platform to deliver solution-orientated research for sustainability, linking environmental change and development challenges to satisfy human needs for food, water, energy, health. This will require an effective interdisciplinary collaboration across natural and social sciences, humanities, economics, and technology development, to find the best scientific solutions to multi-faceted problems. The main aim is to provide timely information for policy-makers by generating the knowledge that will support existing and new global and regional integrated assessments. Therefore the main stakeholders are a heterogeneous group of researchers (all scientific disciplines) and policy-makers, all of them working jointly in co-designing and co-producing research agendas and knowledge. One particular priority is in developing countries, mainly in support to the Sustainable Development Goals (SDGs).

Recent advances in data collection and analysis provides a unique opportunity to observe, detect and analyze the earth dynamics at multiple scales and across interacting social ecological system processes. This data explosion has emerged through advances in remote sensing, citizen science networks, and census efforts. These data are being used in ways to enhance our understanding and to inform management decisions on ways to reduce the impact and reducing the harmful consequences and enhancing opportunities as they arise. This information era has benefits to food and water management, response to hazard, forecasting of weather and extreme events, alerting communities of dangers associated with plumes of pollutants, and detecting the presence and movement of rate and sensitive wildlife on land and in the seas. A variety of biophysical and social-economic data sets and observations are available and through coordinated integration provide additional knowledge of the state and transition of social-ecological systems across the globe in order to better inform decision makers.

Such a very ambitious goal requires a wide range of data and information. Jointly with data, it also requires the expert knowledge networks associated with such data. The main challenge is for each individual scientific discipline, to further add value to their data and to re-packaged it, so that it can be understandable, usable and integrated with the data coming from all other disciplines and what is more important accessible to decision makers.

Future Earth hopes to initiate a suite of activities, such as:

- Data inventory, integration, harmonization and experts networks of data-knowledge to support Sustainable Development
- Co-development of data harmonization to facilitate integration of social-biophysical data to derive information in support of transformations toward sustainability
- Assessing data and information needs, and data use in support to the UNFCCC Adaptation activities

Enhancing capacity to enable the flow of interdisciplinary science in support of the decision making process (resilience, water management, sustainable development).

O-1105b-01

Developing Indicators to Support Climate Adaptation and Sustainability Decision Making

R. Chen (1) ; A. De Sherbinin (1) ; M. Levy, (1)
(1) Columbia University, CIESIN, Palisades, NY, United States of America

Every day, decision makers ranging from individuals to governments make important decisions based on composite economic and social indicators on topics such as unemployment, inflation, trade, debt, and prices. These indicators reflect the shared understanding that our global economy is a very complex, interconnected system that operates on multiple temporal and spatial scales. Yet, even though the global environment is at least as complex and interconnected as the global economy—and equally critical to humanity's survival—the world lacks integrated indicators of critical environmental systems and climate change that have the quality, reliability, resolution, and relevance to support both individual and collective decision making on both short and long time frames.

We summarize experience to date in developing policy-relevant environmental indicators at global, national, and subnational levels and in tackling a range of scientific, technical, and institutional challenges related to designing and implementing useful indicators. Despite the growing diversity and volume of environmental data becoming available through new technologies, mobilizing and harnessing this "data revolution" to support sustainability science and decision making requires careful attention to user needs, establishment of suitable organizational and review processes to ensure "buy in" by stakeholders, and close collaboration with the relevant scientific communities and observational and data networks.

The ongoing development of a new set of Sustainable Development Goals (SDGs) and associated targets provides a unique opportunity to promote the integration of environmental, socioeconomic, and health data within a coherent framework of policy-relevant indicators. Such a framework would not only provide justification for continued or expanded investment in data collection and integration, but also a means to prioritize data collection efforts and improve their efficiency and efficacy. As with conventional economic indicators, the development of integrated environmental indicators is also likely to promote their use in both formal and informal decision making in both the public and private sectors.

O-1105b-02

Marine community initiatives building biodiversity data systems and products in support of global change research

K. Deneudt (1) ; S. Dekeyzer, (1) ; B. Vanhoorne (1) ; L. Vandepitte, (1) ; S. Claus, (1) ; F. Hernandez, (1)
(1) VLIZ - Flanders Marine Institute, Oostende, France

Global change research requires high quality and readily available biodiversity datasets that are standardized based on internationally accepted standards and can easily be used in integrative analyses that transcend geographic or administrative boundaries. The marine biodiversity community is progressively organizing itself to offer advanced data services and high quality data products. Diverse aspects of this work are ongoing in the framework of initiatives like the World Register of Marine Species (WoRMS), the Ocean Biogeographic Information System (OBIS), the European Marine Observation Network biological (EMODNet Biology) project and the LifeWatch European Research Infrastructure on biodiversity and ecosystem research.

The World register of Marine Species is an authoritative list of names of marine organisms. The content of WoRMS is controlled by more than 200 taxonomic experts, each of them responsible for a specific taxonomic group. The register currently holds over 419,000 species names described in literature worldwide, of which 190,400 (45%) were deemed duplicate identities. The register is a key instrument in biodiversity research, as it is used on a daily basis for taxonomic standardization and quality control of biological research and monitoring datasets.

The Ocean Biogeographic Information System is a network of OBIS nodes integrating biogeographic information for marine organisms on a global scale. Individual nodes contribute local or thematic datasets to the global system after standardizing these data based on OBIS and Darwin Core data schemas. OBIS holds 41.93 million distribution records of marine organisms from over 1,700 individual datasets.

In the framework of the LifeWatch taxonomic backbone and the EMODNet biology project large scale efforts are being initiated to collect species traits information and link this ecological attribute information to WoRMS and OBIS. These recent developments allow the creation of specific tools that have large potential for supporting applied global change research. An example is the World Register of Introduced Species, a newly launched portal that in its current state already lists over 1,400 introduced and invasive alien marine species worldwide, compiled through study of over close to 2,500 publications and collaboration with related international initiatives. In the framework of EMODnet a series of DIVA interpolated gridded abundance maps is being created for selected species reconstructing remarkable distribution patterns over time.

The generated data products are of direct relevance to global change studies on aspects like species distribution shifts, species extinction and migration, exploitation of ocean ecosystems and fish stock collapse, etc...

O-1105b-03

Multi-Disciplinary Framework for BioEnergy Assessment

W. Hugo (1)
(1) ICSU-WDS, SAEON, Western Cape, South Africa

The BioEnergy Atlas for South Africa is the result of a project funded by the South African Department of Science and Technology, and executed by SAEON/ NRF with the assistance of a number of collaborators in academia, research institutions, and government.

Bioenergy assessments have been characterized in the past by poor availability and quality of data, an over-emphasis on potentials and availability studies instead of feasibility assessment, and lack of comprehensive evaluation in competition with alternatives - both icompeting bioenergy resources and other renewable and non-renewable options. The BioEnergy Atlas addresses some of these deficiencies, and identifies specific areas of interest where future research and effort can be directed.

We develop an approach that successively constrains biomass that is potentially available with environmental, social, financial, technical, and economic constraints, leading to an objective selection of appropriate feedstocks, land allocation, techology, and feasible projects for detailed investigation. We discuss methodology, availability of biomass and potentials, and the feasibility results of four case studies in respect of biomass application: (1) co-firing of woody biomass for electricity generation; (2) use of oil-bearing crops for biodiesel producion, (3) applications for organic components of domestic solid waste and wastewater; and (4) use of woody biomass as a feedstock for an existing GTL refinery.

Findings include

- Availability is not a fixed quantum. Availability of biomass and resulting energy products are sensitive to both the exclusionary measures one applies (food security, environmental, social and economic impacts) and the price at which final products will be competitive.
- Availability is low. Even without allowing for feasibility and final product costs, the availability of biomass is low.
- Waste streams are important. There are significant waste streams from domestic solid waste and sewage, some agricultural production, and commercial forestry.
- Rural firewood use is problematic. This is a significant resource, plays a large role in the energy budget of poor and rural households, and current use means that it will have little impact on the GHG emissions balance.
- Process technologies are not all mature, cost-competitive or efficient: We have investigated 52 different process technologies in respect of costs, economy of scale,

energy efficiency, greenhouse gas emission and job creation impacts, and maturity of technology.

- Solutions are probably 'packages'. One has to balance the diversity of available resource streams and processing technologies against the need to focus resources on development of critical mass (workforce skills, support industries, expertise). Combining feedstocks and aligning with other government initiatives or subsidies can achieve such critical mass more easily.

- Solutions must be robust in future too. Feasibility studies that focus on the current situation only ignore the fact that future sustainability is strongly dependent on assumptions on relative economic growth (influences household and industrial energy consumption, and the limiting cost for energy), cost of capital and inflation (affects choices of labour- or capital-intensive industries), exchange rates and fossil fuel prices (huge effect on selection of alternatives).

- The most promising biomass source is medium-term mining and eradication of invasive alien plants, but this source is limited in time and, if exploited as proposed, will not be available after about 20 years.

There is a need to focus research and development efforts in respect of specifc technology/ feedstock combinations hat show future promise.

O-1105b-04

Soil data harmonisation and geostatistical modelling efforts in support of improved studies of global sustainability

N. Batjes (1) ; B. Kempen (1) ; J. Leenaars (1) ; R. Vandenbosch (1)
(1) ISRIC – World Soil Information, Wageningen, Netherlands

Future Earth and other large international research and development programmes aim to provide the scientific evidence base required for developing into a sustainable future. Soil, which is an important provider of ecosystem services, remains one of the least developed data layers in global land models and uncertainties are large. In this context, there is a pressing need for improved, quality-assessed soil information at multiple scale levels. ISRIC – World Soil Information, in its capacity of World Data Centre for Soils within the ICSU World Data System, is developing inter-operable web-based facilities aimed at facilitating collaborative soil mapping. The Global Soil Information Facilities (GSIF) provide a global spatial framework for collating, standardising resp. harmonising, and analysing soil data profile obtained from disparate sources. At present, the facility includes a 3D soil information services for the world at 1 km resolution (SoilGrids1km), which draws on analytical data for some 100,000 soil profiles and over 70 co-variate layers representing soil-forming factors. Global regression models were used to predict values (mean and 90%-confidence interval) for selected soil attributes (e.g. soil pH, clay content, bulk density, and organic carbon content) for six depth intervals up to a depth of 2 meter. Cross-validation for the initial run showed prediction accuracies of 23%-51%, which is promising. Being based on reproducible automated procedures, the geo-statistical predictions are improved on a regular basis. New releases will consider a larger complement of harmonised soil profiles for the World, as collated and shared for example within the broader collaborative framework of the Global Soil Partnership (GSP), as well as more advanced geo-statistical approaches that may be targeted at specific agro-ecological regions. Confidence limits generated by the SoilGrids model may be used to assess the impact of uncertainty in soil property predictions (means) during scenario/model testing — data are freely available for visualization and download at http://soilgrids.org. The SoilGrids procedure has already been applied at various resolutions, depending on specified user needs. For example, a 250m product in support of agricultural planning in Africa versus a 50 km (or 0.5 by 0.5 arc degree) product for Global Land Models that underpin IPCC-related assessments. Further, development of the overall system is already catalysing institutional collaboration and data sharing. Capacity building and collaboration with (inter)national soil institutes around the world on data collection and sharing, data screening and harmonisation, mapping and the subsequent dissemination of the derived information will be essential to create ownership of the newly derived soil information as well as to create the necessary expertise and capacity to further develop and test the system worldwide. The system can also be used as the basis for a distributed system, where national soil institutes build and provide standardised databases and digital soil maps for their respective regions, which can then be 'combined' with the SoilGrids-derived information to arrive at a product with global coverage and local ownership, possibly within the framework of the Global Soil Partnership.

O-1105b-05

Supporting Climate Science with Cryospheric Data from the National Snow and Ice Data Center DAAC

B. Johnson (1) ; S. Tanner, (1) ; A. Leon, (1)
(1) National Snow and Ice Data Center, NSIDC DAAC, Boulder, CO, United States of America

Global satellite observations are central to understanding and monitoring our climate system. The physical processes operating in the Earth's cryosphere and their interactions with climate are tightly coupled. A change in one of its component will drive change in another. To improve our understanding of how a changing climate may drive these changes and how feedback processes in the cryosphere affect climate requires continuation of long-term satellite observations, intensive field and airborne campaigns and new ways to analyze observational data and to integrate them with large-scale Earth system models. Polar science has historically involved interdisciplinary research programs, and the collection and management of large, diverse data sets.

The National Snow and Ice Data Center (NSIDC) at the University of Colorado at Boulder is a primary archive for snow and ice data in the United States. NSIDC's mission is to improve understanding of the Earth's frozen realms. This includes floating sea ice, lake ice, glaciers, ice sheets, snow cover, and frozen ground, collectively known as the cryosphere. The NSIDC Distributed Active Archive Center (DAAC) is one of NASA's Earth Observing System Data and Information System (EOSDIS) Data Centers archiving, documenting, and distributing data from NASA's Earth Observing System (EOS) satellites and field measurement programs. NSIDC DAAC data management involves activity at all stages of the data lifecycle, from planning through acquisition, preservation, publication, and distribution. A key goal for NSIDC is to meet our data user needs in a way that facilitates data use. This is accomplished through improvements in data inter-operability, usability, data searching, and visualization and analysis tools.

O-1105b-06

The World Data Service at the University of Colorado Boulder and National Snow and Ice Data Center: Data and services supporting science

L. Yarmey (1) ; R. Duerr (1)
(1) WDS-CUB National Snow and Ice Data Center, Boulder, CO, United States of America

The World Data Service at the University of Colorado Boulder (UCB) led by the National Snow and Ice Data Center (NSIDC) is a leader in connecting data and science. These connections are built through targeted programs brought together under the NSIDC umbrella categorized into three high-level categories: curated data products, research partnerships, and cyberinfrastructure research and development:

The 432 datasets in the WDS-UCB/NSIDC catalog include some of the most popular and visible datasets at the Data Center, for instance the NOAA/NSIDC Climate Data Record of Passive Microwave Sea Ice Concentration as well as decades-long sea ice extent, concentration, and thickness time-series. The Frozen Ground Data Center at WDS-UCB/NSIDC is in the process of being updated and integrated with the new Global Terrestrial Network for Permafrost system. In-situ field data such as from the Snow Data Assimilation System (SNOWDAS) are available alongside products such as the MODIS Mosaic of Antarctica Image map. All of the digital datasets are augmented by critical legacy data often in analog form, for instance the global Glacier Photo collection as well as many resources from

the rich history of the International Geophysical and Polar Years.

Ensuring a strong connection with not only scientists in both the data contributor and data re-user roles, but also the general US public and indigenous Arctic communities, WDS-CU researchers maintain tight partnerships with stakeholder communities. The Exchange for Local Observations and Knowledge of the Arctic (ELOKA) program has spent years building relationships that support and connect Community-Based Monitoring programs embedded in Arctic communities with each other and with environmental scientists. Projects looking to document sea ice knowledge, partner WDS-UCB/NSIDC researchers with shipping operations, Arctic community, and semantic experts to map understandings and advance understanding across different perspectives. A growing Arctic social science data program at WDS-UCB/NSIDC reaches out to another domain community to expand interdisciplinary context and participation in data sharing efforts. Connecting WDS-NSIDC resources to stakeholder communities requires clear communication and a shared understanding of use cases and stakeholder needs. An emphasis on usability work with website interfaces has improved connections and communication of content.

Supporting and leveraging both the management of well-described data holdings and tight connections with partners and stakeholders, WDS-UCB/NSIDC maintains a strong cyberinfrastructure research and development focus. Expertise in metadata and data brokering enables distributed data search and has been showcased in diverse venues over recent years. Web crawling for science data of relevance moves the community closer to ubiquitous data discovery. Once relevant data are found, reading and analysis tools support data use and integration for new scientific discoveries.

All of these targeted programs and more come together under the virtual umbrella of the WDS-UCB/NSIDC. Active participation in the WDS community and connections to the many aligned WDS activities and systems are key to advancing our common vision.

1105 - POSTER PRESENTATIONS

P-1105-01

WDC - Solar Activity/BASS2000

J. Aboudarham (1) ; X. Bonnin (1)
(1) Observatoire de Paris, LESIA - OV Paris, Meudon, France

The understanding of space weather, solar-terrestrial relationship as well as the possible correlation with Earth's climate and solar activity is related to the possibility to study long-term behaviors. World Data Centre for Solar Activity BASS2000 (http://bass2000.obspm.fr) provides added-values on solar activity that can be used for such studies. It provides daily observations of the Sun for about 20 years, and older images, starting in 1919 are currently digitalized.

Moreover, in collaboration with the European HELIO project, a features catalogue has been developed giving detailed information on various solar and heliospheric features (filaments, prominences, sunspots, active regions, coronal holes, radio sources, type III bursts) for near 20 years also for some of them. And previous data have been digitalized from tables obtained from the Synoptic Maps of Solar Activity since 1919. When the insertion of those data in the features catalogue will be done, nearly one century of data will be available, providing the longest time signature of Solar activity, with around 8 solar cycles available.

The role of the GCOS Reference Upper-Air Network (GRUAN) in climate research

G. Bodeker (1) ; M. Sommer (2) ; R. Dirksen, (2) ; P. Thorne, (3)
(1) Bodeker Scientific, Alexandra, New Zealand; (2) Deutscher Wetterdienst, Lindenberg, Germany; (3) Maynooth University, Department of geography, Maynooth, Ireland

Measurements of primary state variables of the troposphere and stratosphere (primarily temperature, water vapour and pressure) are typically made to provide the input required by numerical weather prediction models. These same measurements then also constitute the primary source for meteorological reanalyses and climate analyses. The balloon-borne, ground-based and satellite-based systems used to make these measurements often undergo changes in instrumentation, data processing methods, retrieval techniques, and calibration. These changes are often poorly documented and very seldom are measurement series reprocessed to ensure long-term homogeneity of the climate data record. Such unphysical discontinuities in measurement can lead to deterioration of the quality of meteorological reanalyses. To address this specific deficiency of the global climate monitoring network, WMO and GCOS called for the establishment of a new state-of-the-art global network of high quality measurements of essential climate variables in the upper atmosphere, through the 2004 GCOS Implementation Plan (GCOS-92). The establishment of GRUAN (GCOS Reference Upper-Air Network) is now underway and sites are providing reference quality measurements that adhere to GRUAN operating protocols.

This presentation will provide an overview of the achievements of GRUAN to date as summarized in Bodeker et al. (in press 2015). It highlights:

- the protocols that have been established to ensure that measurements are of reference quality;
- what measurement systems are (and will be) operating at GRUAN sites;
- what data products are expected to flow from those systems;
- the data currently flowing from GRUAN sites, technical advancements within GRUAN to meet the needs of user of GRUAN data products; and
- research that has been conducted in support of GRUAN operations.

A network expansion workshop held in June 2012 provided a scientific context for the expansion of GRUAN and this presentation will include an update on how the outcomes of that workshop have guided GRUAN expansion to date. The goal of GRUAN is not only to produce long-term, carefully calibrated measurements with well-defined measurement uncertainties, but to also produce high quality data suitable for focussed process studies. How GRUAN balances operational and research goals will be included in the presentation. A key user of GRUAN data is the satellite calibration and validation community. Progress within GRUAN to meet the needs of this community will also be addressed. The presentation will finish with an overview of the challenges that GRUAN faces and plans for overcoming those challenges.

France; (7) University of Bern, Institute of applied physics, Bern, Switzerland; (8) LATMOS-IPSL, Guyancourt, France; (9) CNRS and Université de Versailles Saint Quentin, Lsce, Gif Sur Yvette, France; (10) IASB / BIRA, Institut d'aéronomie spatiale de belgique, Brussels, Belgium

Observatories of the climate system are essential to assess future climate predictions that are central and fundamental requirements for determining future mitigation strategies. Such observing platforms are very few ones in the tropical southern hemisphere. CNRS, Université de La Réunion, Région Réunion and the European FEDER program support together the construction of a high-altitude observatory which is operational since October 2012 in La Réunion (South West Indian Ocean, 2160 m asl, latitude 21°S, longitude 55°E). The Maïdo observatory takes over from its predecessor programs at sea level over the island who started long-term observation data of atmospheric chemical composition since 1994. The Maïdo observatory is an ideal platform to sample the atmosphere with different techniques (in-situ analysers, radiosounding, passive and active remote sensing) and to record surface measurements and vertical profiles from ground to the mesosphere over a subtropical latitude band poorly sampled by other international programs. The Maïdo observatory hosts lidars, one UV spectrometer, one radiosonding station, FTIR spectrometers, microwave radiometers, one lightning antenna, cameras, one GNSS station, microbarometers, etc. These devices sample many atmospheric parameters (e.g., meteorological parameters, reactive and greenhouse gases, aerosols, lightning and transient luminous events, infrasounds, etc). Part of this very extensive range of instruments is approved and belongs to international networks like NDACC (Network for the Detection of Atmospheric Composition Change), SHADOZ (Southern Hemisphere ADditional OZonesondes), TCCON (Total Carbon Column Observing Network), and WWLLN (World Wide Lightning Location Network). In-situ analysers regroup measurements of reactive and greenhouse gases, and aerosols measurements approved by or applying to networks like GAW/WMO (Global Atmospheric Watching / World Meteorological Organization), ICOS (Integrated Carbon Observing System). The Maïdo observatory is currently the only way to provide regular remote and in-situ atmospheric observations at subtropical latitudes and at high resolutions (seconds in time, few tenths of meters vertically) over a marine-remote region poorly sampled by other programs. It provides data for users in science and policy including air quality forecasting, verification of CO2 emissions and Kyoto monitoring, numerical weather prediction, and validation of global chemical transport model, global climate chemical model and satellite products. Since its participation in on-going European projects (NORS, ACTRIS-2, ARISE-2), and thanks to the start of delivery of data in near real time, the Maïdo observatory will largely contribute to the Copernicus Atmosphere Monitoring Services (CAMS). The Maïdo observatory is open to transnational access thanks to its participation in european programmes like ACTRIS-2 and ENVRIplus. This presentation will give an overview of results achieved so far and a number of highlights to illustrate the promise Maïdo observatory data hold for the future, allowing new applications and analysis for a broad community of users.

P-1105-04

Satellite-derived aerosol climate data records in the ESA Aerosol_cci project

G. De Leeuw (1) ; T. Holzer-Popp (2) ; S. Pinnock, (3) ; G. De Leeuw (4)

(1) FMI & UHEL, Climate Research / Physics, Helsinki, Finland; (2) DLR German Remote Sensing Data Center (DFD), Oberpfaffenhofen, Germany; (3) European Space Agency (ECSAT), Esa climate office, Harwell, Oxfordshire, United Kingdom; (4) fmi, Climate research, Helsinki, Finland

Within the ESA Climate Change Initiative (CCI) project Aerosol_cci (Phase 1: 2010 -2014; Phase 2: 2014-2017) intensive work has been conducted to improve algorithms for the retrieval of aerosol information from European sensors ATSR-2 (ERS-2), AATSR (3 algorithms), MERIS (3 algorithms), synergetic AATSR/SCIAMACHY, GOMOS (all on ENVISAT), PARASOL and OMI (EOS-Aura) (both part of NASA's A-Train). Whereas OMI and GOMOS were used to derive absorbing aerosol index and stratospheric extinction profiles, respectively, Aerosol Optical Depth (AOD) and Ångström coefficient were retrieved from the other sensors. The cooperation between the project partners, including both retrieval teams and independent validation teams, has resulted in a strong improvement of most algorithms. In particular the AATSR retrieved AOD is qualitatively similar to that from MODIS, usually taken as the standard, MISR and SeaWiFS. This conclusion has been reached by several different ways of validation of the L2 and L3 products. Using AERONET sun photometer data as the common ground-truth both 'traditional' statistical techniques and a 'scoring' technique based on spatial and temporal correlations were applied. Quantitatively, the limited AATSR swath width of 512km results in a smaller amount of data. Nevertheless, the assimilation of AATSR-retrieved AOD, together with MODIS data, contributes to improving ECMWF / MACC climate model results. In addition to the multi-spectral AOD, and thus the Ångström Exponent, also a per-pixel uncertainty is provided and validated. By the end of Aerosol_cci Phase 1 the ATSR algorithms have been applied to both ATSR-2 and AATSR resulting in an AOD time series of 17 years dating back to 1995.

In phase 2 this work is continued with a focus on the further improvement of the ATSR algorithms as well as those for the other instruments and algorithms, mentioned above, which in phase 1 were considered less mature. The first efforts are on the further characterization of the uncertainties and on better understanding of the cloud screening in the various algorithms. Other efforts will focus on surface treatment and possible improvement of aerosol models used in the retrieval. A yearly re-processing of the full 17-year global ATSR-2/AATSR data set with three different algorithms is planned to evaluate the effect of different changes and to monitor further improvement. A new focus in phase 2 is the production of a full-mission dataset of dust AOD from IASI with four different algorithms, which are based on very different retrieval techniques. A major task within the project is the first inter-comparison of those IASI dust retrieval algorithms on the basis of a large set of observations. For this purpose, one year of IASI observations (2013) over the major dust belt of the Northern hemisphere, including the Northern Atlantic Ocean, the Sahara desert, the Arabian Peninsula as well as the Central Asian desert regions, will be provided from all four algorithms and similar retrieval output (visible and infrared AOD, AOD uncertainty, retrieval quality, cloud flags) is generated in order to facilitate the comparison of results. Another new aspect is the production of a diagnostic time series over four regions in Africa, Asia and North America where other reference data are sparse, from POLDER (on ADEOS1 and 2) and PARASOL data. The application of the multi-pixel GRASP algorithm to data from these instruments, which combine multiple wavelengths and multiple viewing angles with polarization information is expected to provide an independent data set as reference for retrieval products from other instruments with less optimum characteristics for aerosol retrieval.

An important aspect is the use of the climate data records (CDRs) produced in the Aerosol_cci project and the interaction with the user community to further improve the products. To this end representatives of different user communities are tasked with applications such as trend analysis, use of the CDRs in climate modeling, studies on aerosol-cloud interactions and stratospheric chemistry. The presentation will summarize the concept and status of the Aerosol_cci project in both phases and discuss in particular the achievements regarding the 17 year ATSR time series and its significance for climate studies in different parts of the world.

P-1105-05

Expanding the Network of Precise Seawater Temperature Measurements for Fijian Coral Reefs

A. De Ramon N'yeurt (1) ; C. Whippy-Morris (2)

(1) The University of the South Pacific, Pacific Center for Environment and Sustainable Development, Suva, Fiji; (2) The University of the South Pacific, Institute of marine studies, Suva, Fiji

As part of the Pacific-wide ReefTEMPS Monitoring Network, the University of the South Pacific in collaboration with the South Pacific Integrated Observatory for the Environment and Terrestrial and Marine Biodiversity (GOPS) and the Institut de Recherche pour le Developpement (IRD), deployed for the first time high-precision (+/- 0.002°C) SBE-56 thermistors in Fiji waters since November 2012,

in order to continuously monitor shallow (-10 to -16 m) seawater temperature for use in climate and tropical cyclone prediction models. The shallow water thermistors monitor temperature on a 600-second sampling interval and are rotated every 6 to 10 months, with the data being uploaded on the GOPS/ReefTEMPS data portal for free use by researchers and students. Currently the Fiji monitoring network consists of 10 sites (both in the lagoon and outer reef slope) spanning the northermost isolated island of Rotuma to Kadavu Island in the south. Futher shallow-water sites to be deployed this year (including the southernmost Ceva-i-Ra reef) should bring the total to 14. To date, some 13 datasets representing over 100 months of continuous seawater temperature monitoring for Fiji have been obtained in the context of this ongoing project. Preliminary analysis of the data has shown that the highest seawater temperatures occur in the months of February and March, with episodes that can last several days above 29°C, creating favourable conditions for tropical cyclone generation and also heightening the risk of major coral bleaching events. Such in-situ data is also essential to ground-validate data from the Satellite Virtual Station time series graphs of sea surface temperature (SST) and Coral Bleaching Degree Heating Weeks (DHW) provided by the US National Oceanographic and Atmospheric Administration (NOAA) Coral Reef Watch Satellite Virtual Station in Fiji (BEFJ1 -18.5 ° lat, 178.5 ° lon). Over the course of 2015, the monitoring network will be further expanded in depth, with a line of thermistors deployed at -55, -75 and -90 m to measure rapid temperature variations, helping to monitor ENSO effect on the thermocline depth in coastal areas, with implications for the distribution of fish and marine invertebrates and the detection of seasonal upwelling zones of cooler waters that could mitigate coral bleaching. The deeper sensors, with sampling intervals of 30 to 60 seconds, will also help to monitor rapid variations in temperature linked to internal waves in Fijian coastal areas, with implications for the understanding of the deep transfer of mass, momentum and heat which is critical for developing more accurate climate models. This would be the first time such a study is carried out in the Southern Pacific Ocean.

Monitoring the Climate of the Upper Troposphere and Lower Stratosphere with Radio Occultation Data

U. Foelsche (1) ; B. Scherllin-Pirscher (2) ; J. Danzer, (2) ; F. Ladstädter (2) ; AK. Steiner (3) ; G. Kirchengast (2)

(1) University of Graz, Institute for Geophysics, Astrophysics, and Meteorology, Graz, Austria; (2) University of Graz, Wegener Center for Climate and Global Change, Graz, Austria; (3) Wegener Center for Climate and Global Change, University of Graz, Graz, Austria

The Radio Occultation (RO) technique has originally been developed in the 1960s for the study of planetary atmospheres and ionospheres. Accurate RO measurements of the Earth's atmosphere became feasible in the 1990s, with the precise radio signals of the GPS satellite system (guaranteed by on-board atomic clocks). A few hundred times per day, a satellite in low Earth orbit (LEO) sees one of the GPS satellites setting or rising behind the Earth's horizon. In this "occultation" geometry, the GPS signals have to pass through the Earth's atmosphere and they are characteristically influenced (slowed and bent), depending on the density of the atmosphere. The respective motion of the satellites provides a scan through the atmosphere. Accurate measurements of the change in the GPS signal (onboard the LEO satellite) therefore allow to reconstruct the atmospheric density and, subsequently, profiles of pressure as well as temperature. RO measurements can be performed during day and night, over oceans and land, and even inside clouds. During the last few years, RO measurements have been increasingly used by weather centers around the globe, and they a surprisingly large positive impact on the quality of atmospheric analyses (which are used as starting points for weather forecasts).

RO data a very well suited for climate applications, since they do not require external calibration and only short-term measurement stability over the occultation event duration (1 - 2 min), which is provided by the atomic clocks onboard the GPS satellites. With this "self-calibration", it is possible to combine data from different sensors and different occultation missions without need for inter-calibration and overlap (which is extremely hard to achieve for conventional satellite data).

Using the same retrieval for all datasets we obtained monthly refractivity and temperature climate records from multiple radio occultation satellites, which are consistent within 0.05 % and 0.05 K in almost any case (taking global averages over the altitude range 10 km to 30 km). Longer-term average deviations are even smaller. Even though the RO record is still comparatively short, its high quality already allows to see statistically significant temperature trends in the lower stratosphere.

P-1105-07

Aerosol optical properties and dynamic variability of climatic seasons in west Africa: Case study of Ouagadougou

B. Korgo (1) ; JC. Roger (2) ; J. Bathiebo (3)

(1) University of Ouagadougou, Physique, Ouagadougou, Burkina Faso; (2) University of Maryland, Geography, Washington, United States of America; (3) University of Ouagadougou, Physics, Ouagadougou, Burkina Faso

We present in this paper a climatological study of the optical properties of the atmosphere in West Africa. Using the measurement and photometric inversions data of AERONET in Ouagadougou, we analyze the main optical characteristics such as optical thickness, Angstrom exponent, the single scattering albedo and the asymmetry factor. These properties give quite varied information about the size and chemical nature of atmospheric aerosols in West Africa, particularly in the Sahel region. A study of different variabilities of these properties on a monthly and yearly scale, shows a strong connection with the seasonal succession of dry period marked by the predominance of harmattan winds from the Sahara Desert, laden with dust and wet period characterized by the thrust of the monsoon flow laden with moisture, specific to this part of the world. The spatial and temporal evolution of these atmospheric variables coupled with the dynamics of West African climate allows monitoring of the ascent to the north of the intertropical front marking the beginning of the wet season and its come back to the south at the end of this season. An appropriate positioning of AERONET photometric measurements points can allow a long-term monitoring at the regional level of the beginning, the end and the length of seasons and as such appears as a real tool for monitoring climate change in West Africa.

P-1105-08

Geospatial land use analysis and its relation to the climate change

M. Lavreniuk (1) ; A. Shelestov (2) ; N. Kussul (1) ; S. Skakun (3)

(1) Space research institute NASU-SSAU, Kyiv, Ukraine; (2) National University of Life and Environmental Sciences of Ukraine, Kyiv, Ukraine; (3) Integration-Plus Ltd, Kyiv, Ukraine

Land use analysis plays an important role in studying and understanding processes in ecosystems and solving many applied problems based on satellite monitoring. In particular, it allows to improve the accuracy of classification and areas estimation and to analyze climate change and its impact on agricultural production and whole biosphere. Since the 1980s there are many land use datasets based on satellite images, but they had low spatial resolution and accuracy. Also, in 2013-2014 years, several global maps have been made available, but they are not accurate enough at regional level. Low-resolution maps underestimate or overestimate certain land cover types. Therefore, creation of global and regional land cover maps based on high-resolution satellite images (such as Landsat series at 30 m) is an extremely important task. In this study, we produced land cover maps for the whole territory of Ukraine based on the Landsat-4/5/7 images for three decades: 1990s, 2000s and 2010s. These maps allow estimation of the general trends of land cover/use in Ukraine and discovering how geospatial land use influence on the climate change. This paper discusses methodological aspects to obtain a retrospective maps of land cover based on Landsat images at regional scale, including all preprocessing steps for satellite imagery, formation of training and test sets, classification method and result analysis.

Training (50%) and test (50%) sets consist of six main land cover classes: artificial surface, cropland, grassland, forest, bare land and water. We formed sets using a photo

interpretation method with uniform spatial distribution over the target territory and proportional representation of all classes. Images contained six spectral bands and three bands with shadow, cloud and cloud contours masks. We selected images with less than 50% of cloud cover for classification. First, we restored cloudy pixels from time-series of images using self-organizing Kohonen maps (SOMs). After that, we provided classification based on the time-series of restored images available for the certain year [1]. Classification was done using an ensemble of neural networks, namely multilayer perceptrons (MLPs) and such an approach have been provided better result than single neural network. After classification, each neural network gave a posteriori probability of the input pixel belonging to each class. In an ensemble, we estimated the average a posteriori probability from all networks and assign to the pixel class with the highest probability.

We estimated the accuracy of classification on independent test set. The overall classification accuracy achieved in the study was approximately 95%. Accuracies for each individual class were more than 70%. The lowest accuracy was for grassland since it is difficult to separate grassland from cropland. At the same time, we compare the obtained areas and official statistics for each oblast and for the whole territory of Ukraine for each time period (1990, 2000, 2010). In addition, we compared the accuracy of our classification for Ukraine with global land cover map GlobeLand30-2010 at 30 m resolution. The overall classification accuracy for Ukraine was 5% higher than GlobeLand30-2010. Accuracy of grassland classification was +10% (producer accuracy) and +45% (user accuracy) better than GlobeLand30-2010.

This paper presented a retrospective land cover mapping methodology for the territory of Ukraine based on Landsat data at 30 m resolution. The proposed methodology involved classification of multi-temporal satellite images with neural networks on previously restored cloudy pixels. The map was produced for the whole territory of Ukraine. The use of the proposed approached allowed us to achieve overall classification accuracy of 95% for three different time periods and improve quality of maps comparing to other land cover maps available for Ukraine, namely GlobeLand30-2010. At the presentation the results of climate changes influence on land use will be discussed in more detail.

P-1105-09

The BIOMASS satellite mission: quantifying global biomass, an essential variable of the climate system

T. Le Toan (1) ; P. Ciais (2) ; S. Quegan (3) ; K. Scipal (4)
(1) CESBIO, Toulouse, France; (2) IPSL, Lsce, Gif sur Yvette, France; (3) University of Sheffield, Sheffield, United Kingdom; (4) ESA , Estec, Noordwijk, Netherlands

Quantifying the global carbon cycle is essential to understanding many of the changes taking place in the Earth system and improving future projections. There is strong evidence that over the last 50 years, the terrestrial biosphere has acted as a net carbon sink, removing from the atmosphere approximately one third of the CO2 emitted by fossil fuel combustion. However, the status, dynamics and evolution of the terrestrial biosphere are the least understood and most uncertain element in the carbon cycle. Coupling between the terrestrial carbon cycle and climate has been identified by the IPCC as one of the major areas of uncertainties in the distribution of carbon stocks and carbon exchange, in the estimates of carbon emissions due to forest disturbances, and in the uptake of carbon through forest growth. A fundamental parameter characterising the spatial distribution of carbon in the biosphere is biomass, and forest comprise~80% of the terrestrial above ground biomass. Most of the biomass is in tropical forest that are projected by models to be vulnerable to drought in the future.

Because of its importance for climate, biomass is identified by the UNFCCC as an Essential Climate Variable needed to reduce uncertainties in our knowledge of the climate system (GCOS, 2010). Furthermore, sequestration of carbon in forest biomass is a critical mechanism for mitigating climate change, as recognised by REDD+ initiatives, which use market and financial incentives to reduce the emissions of GHG from deforestation and forest degradation.

The BIOMASS mission is the Seventh ESA Earth Explorer mission, selected in May 2013, for a launch in 2020. The primary aim of the BIOMASS mission is to determine, for the first time and in a consistent manner, the global distribution of above-ground forest biomass (AGB) and its changes in order to provide greatly improved quantification of the size and distribution of the terrestrial carbon pool, and much improved estimates of terrestrial carbon fluxes. In particular, by monitoring and quantifying disturbances and growth in forests, BIOMASS will yield new knowledge about the size and location of terrestrial carbon sources and sinks, and how forest disturbance trigger loss of biomass and subsequent forest regeneration.

Biomass will measure and map forest carbon stock, as well as forest height, over tropical, temperate and boreal forests at a spatial resolution of around 200 m every 6 months throughout the five years of the mission. However, the particular focus is on the carbon-rich dense tropical forests which contribute by far the largest current stock of biomass, but also the largest proportion of carbon emissions from deforestation and forest degradation. By using a long wavelength Synthetic Aperture Radar (SAR at P-band), BIOMASS allows high values of AGB in tropical forests to be measured.

The combination of three measurement techniques, namely polarimetric SAR, polarimetric interferometric SAR and tomographic SAR all using the same sensor, will significantly reduce the uncertainties in biomass retrievals and contribute to meeting the target of 20% accuracy in AGB at a resolution of 200 m. The spatial consistency of these products together with their provision as time series, means that they will contribute significantly to improving the accuracy of the Land Use Change flux and better quantifying dynamic spatial processes in the world's forests. These BIOMASS products can also be used as unbiased reference data for national reporting for initiatives such as REDD+.

Comparing BIOMASS data with biomass calculated by carbon models, or assimilating biomass in those models, will provide a way of testing the models and also give indications on the sources of discrepancy. Comparison of existing models indicates that they are very dissimilar regarding the absolute magnitude of biomass and its spatial distribution, and that a large part of the misrepresentation of biomass comes from the lack of considerations of disturbances and land use change and incorrect modeling ecosystem processes such as mortality.

The paper will present an overview of the BIOMASS mission, and will discuss the use of BIOMASS data to improve forest productivity modeling and to allow forcing of Dynamic Vegetation Model simulations under future climatic scenarios.

P-1105-10

The Pacific Islands Global Climate Observing System (PI GCOS): Where to Next?

PF. Lefale (1) ; HJ. Diamond, (2)
(1) Bodeker Scientific, Wellington, New Zealand; (2) Victoria University of Wellington, Geography department, Wellington, New Zealand

The Tropical Western Pacific (TWP) is the 'ground zero' engine of the global climate system. It is home to some of the largest natural drivers of the climate system; the biggest ocean on the planet, including the El Nino Southern Oscillation (ENSO), the Pacific Decadal Oscillation (PDO). Despite this, the TWP is one of the least observed and monitored regions of the world. Yet, the needs for climate system monitoring, climate change detection and monitoring the impacts of and the response to climate change, especially marine ecosystem, ocean acidification and mean sea level rise, and research toward improved understanding, modelling and prediction of the climate system are fundamental in understanding the properties and evolution of the earth's climate system.

The Pacific Islands-Global Climate Observing System (PI-GCOS) is one of only a few international-sponsored regional programs established in the early 2000s to assist

Pacific Islands and the international scientific community to observe and monitor the TWP region. The PI GCOS program started in Apia, Samoa, in 2000. It is a sub-program of the international GCOS aimed specifically at meeting climate and related observing needs of Pacific Islands. The outcomes of the Apia GCOS workshop, combined with the findings and recommendations of the Secretariat of the Pacific Regional Environmental Program (SPREP)/World Meteorological Organization (WMO) led Pacific Meteorological Services Needs Analysis Project (PMSNAP) report in 2000, provided the foundation for the development of the PI-GCOS Program. As a result, a PI GCOS Action Plan (Salinger et al., 2002) was developed to help establish and guide the program by identifying GCOS requirements in the region and outline an approach to address these needs in a short strategy document (see http://www.wmo.int/pages/prog/gcos/documents/PI-GCOS AP.pdf). A regional PI GCOS Officer was hired and hosted by the SPREP in Apia, Samoa from 2004 to 2012 to manage the program. Unfortunately, due to a lack of sustained resources, the program was only active until 2012 at which point it went dormant.

This presentation will summarise key preliminary findings & recommendations of the Review of the PI GCOS ("the Review") that is currently underway to look at resurrecting the program on behalf of the region as part of a formal bilateral climate activity between New Zealand and the United States agreed to in September 2014. The Review assesses the balance and relevance of the PI GCOS, its achievements, relations between PI GCOS and partner organizations and Members, its functions and governance mechanisms, and vision and future plans. The Review arises from the realization that there is an urgent need to re-establish the PI GCOS Program in light of the increasing demand for climate and related services in the Pacific Islands and internationally. The need for improved climate observations in the Pacific region has already been identified and if efforts such as the delivery of climate monitoring, research and services in the Pacific through the UNFCCC, the IPCC and Global Framework for Climate Services (GFCS) are to be successful, then re-establishing the PI GCOS is an essential pre-requisite.

Tipping point analysis of atmospheric oxygen concentration

V. Livina (1) ; V. Teresa (2) ; A. Forbes (1)

(1) National Physical Laboratory, Teddington, United Kingdom; (2) John Innes Centre, Norwich, United Kingdom

We apply tipping point analysis to nine observational oxygen concentration records around the globe, analyse their dynamics and perform projections under possible future scenarios leading to oxygen deficiency in the atmosphere. The analysis is based on statistical physics framework with stochastic modelling, where we represent the observed data as a composition of deterministic and stochastic components estimated from the observed data using Bayesian and wavelet techniques.

P-1105-12

OneGeology - A distributed data system that enables access to up-to-date global geoscience data

K. Marko (1) ; D. Tim (2) ; F. Robida (3) ; H. Matt (2) ; A. Lee (4)

(1) OneGeology, Keyworth, United Kingdom; (2) BGS, Keyworth, United Kingdom; (3) BRGM, Orleans, France; (4) Arizona Geological Survey, Tucson, United States of America

OneGeology is an initiative of Geological Survey Organisations (GSO) around the globe that dates back to Brighton, UK in 2007. Since then OneGeology has been a leader in developing geological online map data using a new international standard - a geological exchange language known as the 'GeoSciML' (currently version 3.2 exists, which enables instant interoperability of the data). Increased use of this new language allows geological data to be shared and integrated across the planet with other organisations. One of very important goals of OneGeology was a transfer of valuable know-how to the developing world, hence shortening the digital learning curve. In autumn 2013 OneGeology was transformed into a Consortium with a clearly defined governance structure, making its structure more official, its operability more flexible and its membership more open where in addition to GSO also to other type of organisations that manage geoscience data can join and contribute. The next stage of the OneGeology initiative will hence be focused into increasing the openness and richness of that data from individual countries to create a multi-thematic global geological data resource on the rocks beneath our feet. Authoritative information on hazards and minerals will help to prevent natural disasters, explore for resources (water, minerals and energy) and identify risks to human health on a planetary scale. With this new stage also renewed OneGeology objectives were defined and these are 1) to be the provider of geosciences data globally, 2) to ensure exchange of know-how and skills so all can participate, and 3) to use the global profile of 1G to increase awareness of the geosciences and their relevance among professional and general public. We live in a digital world that enables prompt access to vast amounts of open access data. Understanding our world, the geology beneath our feet and environmental challenges related to geology calls for accessibility of geoscience data and OneGeology Portal (portal.onegeology.org) is the place to find them.

Getting Back to the Source: A review of Earth science data citation and access

M. Parsons (1)

(1) Research Data Alliance, Boulder, France

Creating a great data set can be a life's work (consider Charles Keeling). Yet, scientists do not receive much recognition for creating rigorous, useful data. At the same time, in a post "climategate" world there is increased scrutiny on science and a greater need than ever to adhere to scientific principles of transparency and reproducibility. In this sense it is clear that scientific assertions must be backed up by precise pointers to the actual evidence used. In many cases this should take the form of a data citation. Indeed the IPCC has increasingly rigorous data citation requirements for its assessment.

The concept of data citation has gained significant traction in recent years. This is most apparent in the Joint Declaration of Data Citation Principles. Some communities such as DataVerse, DataCite, and the Earth Science Information Partners have developed specific guidelines on how to actually cite data. Challenges remain, however, on how to precisely cite specific subsets of very dynamic data. Moreover, there is still some confusion on the purposes of data citation.

This presentation will review the current state of the art in data citation with a special emphasis on new developments coming out of the Research Data Alliance, Force11, and elsewhere. It will make concrete recommendations on the purposes and approaches of data citation, especially in the context of climate research and assertions.

ICOS Atmsopheric Thematic Center

L. Rivier, (1) ; L. Hazan (1) ; O. Laurent, (2) ; T. Laurila (3) ; M. Ramonet (4) ; J. Tarniewicz (1) ; C. Yver-Kwok, (2) ; S. Karri (3) ; H. Aaltonen (3) ; O. Jossoud (1) ; A. Guemri (1) ; C. Garrec (1) ; C. Milcent (1) ; A. Abbaris (1) ; J. Helle, (5) ; C. Philippon (1) ; S. Delalande (1) ; N. Kachroudi (1) ; S. Ars (1)

(1) LSCE, Gif sur Yvette, France; (2) LSCE, Gif-sur-Yvette, France; (3) FMI, Helsinki, Finland; (4) CNRS and Université de Versailles Saint Quentin, Lsce, Gif Sur Yvette, France; (5) LSCE, Cea/cnrs/uvsq, Gif-sur-Yvette, France

ICOS is a recently-launched, world-class research infrastructure dedicated to the monitoring and improved understanding of carbon sources and sinks. It consists of complementary, harmonized networks of long-term monitoring stations focusing on Europe and adjacent regions. The ICOS networks will comprise about 40 operational atmospheric stations (measuring atmospheric composition in greenhouse gases and other core parameters), 40 ecosystem stations (measuring fluxes from ecosystems) and about 20 oceanic measurement platforms.

The networks are coordinated through a set of central facilities: three thematic centres respectively for atmospheric, ecosystem and ocean data, and a central analytical lab.The Atmospheric Thematic Center (ATC) has

two main functions:

1.Operate the atmospheric data processing chains, going from data transmission from stations to the routine delivery of quality checked data-stream

2.Carry out regular measurement technology survey, analysis and enable development of new sensors and their testing prior to field deployment in ICOS

The presentation will describe state of the art of atmospheric GHG measurement and data processing with a special focus on quality assessment. It will also present new measurement technique, like isotopic measurement, that can attribute GHG concentration changes to different emission sources.

P-1105-15

Steps toward effective multi-disciplinary research data management systems

D. Schade (1)

(1) National Research Council Canada, Canadian Astronomy Data Centre, Victoria, BC,, France

Astronomy is often viewed as a discipline whose data management needs are well taken care of whereas a great many other research disciplines (the "long tail") are suffering from the absence of good data management systems. Technology and data management practice evolve rapidly and I would argue that no area of research, including astronomy, has any real degree of security for the future of its data collections. Nevertheless, astronomy has a long history of digital data handling and thus has considerable experience and expertise that should be shared with other fields. It is important to acknowledge that astronomy is only one of many disciplines that could collectively share experience with other, less "well-served" communities. It is also important to recognize that we all have much to learn from one another and that interaction with "long tail" research communities will result in better data management practices for astronomy.

Astronomy was part of the "long-tail" or research data 25 years ago. It's data collections were small, heterogeneous, lacked common standards, and were not interoperable. These properties of astronomy data management have changed dramatically (although we still face many challenges) and they have changed because of the hard work of dedicated cross-disciplinary teams of scientists and technologists. But our field has some demonstrable successes to our credit and has learned some profound lessons.

The central problem in creating multi-disciplinary data management systems is the development of Common Data Models that cross disciplinary boundaries. That means managing metadata in a way that supports the use cases of the multi-disciplinary research communities. This is true for all fields, including those that address climate change. The reality of astronomy data is that it is still produced in formats that represent thousands of "native data models" from thousands of different instruments. (A "data model", in our vocabulary, is the structure that carries the meaning of the data and metadata.) The challenge is to develop a data model that supports the transformation of a large set of heterogenous native data models into a Common Data Model. The Common Data Model (CDM) supports the data management functions (curation, discovery, data access, data security) spanning diverse data collections.

This is the same problem that we face in creating multi-disciplinary data management systems. The process for solving the problem will be very similar. Collect research use cases and define requirements. Identify the metadata elements that are required to satisfy those requirements. Analyse where, in the native data models, those elements can be sourced or which elements can be transformed to produce the needed elements. It is true that we have diverse ways of representing even fundamental quantities like time and place (astronomy faces the same problem itself) but these can be reconciled.

Two points are worth mentioning with respect to Common Data Models. First, there exists no ideal, complete, and all-encompassing Common Data Model. Second, there is no "lossless" Common Data Model. Compromises are involved and loss of information may take place. A Common Data Model is implemented for the purpose of unifying diverse data collections. At the Canadian Astronomy Data Centre we ended 25 years of creating silos for each data collection by integrating 119 native data models into a single common model. Now there is a single path (shared by all interfaces) to using our data collections. The next step is to move into other research domains by building significant collaborations with other data management communities.

P-1105-16

Current status and stratigies of biodiversity data integration in Taiwan

KT. Shao (1)

(1) Biodiversity Research Center, Academia Sinica, Taipei, France

The integration of Taiwan's biodiversity databases started in 2001, the same year that the Ministry of Science & Technology launched the National Digital Archives Program, the Executive Yuan began the Biodiversity Promotion Plan, and Taiwan joined GBIF as an Associate Participant. Taiwan, hence, embarked on a decade of integrating biodiversity data. Afterward, the "Catalog of Life in Taiwan" (TaiCOL) [57,000+ native species], "Taiwan's node of GBIF" (TaiBIF) [2.8 M+ georeferenced distributional data], the "Cryobanking and Barcode of Life for Wildlife Genetic Material in Taiwan" (TaiBOL) [3,000 species with 12,000 barcode] and "Taiwan Encyclopedia of Life" (TaiEOL) [18,000+ species pages] are established, integrated and open to public access. The databases aim to promote the collection and integration of national biodiversity data and should be useful for future climate change researches. These databases intimately collaborate with their corresponding global databases of COL, GBIF, BOL and EOL, respectively. Raw data, especially those of ecological distribution generated by different government agencies or NGOs, are nevertheless still dispersed due to assorted reasons. Most people agree that it is imperative to integrate databases, but many researchers are unwilling to invest in database building — a kind of academic services — under the current academic evaluation system. Thus a cross-agency committee of GBIF / Chinese, Taipei was established in Academia Sinica in 2008 to formulate policies on data collection and integration, and the mechanism to make data available to the public. Any commissioned project was hereafter asked to include these policy requirements in the contract. Furthermore, a new project to build the "National Biodiversity Monitoring and Reporting System" (TaiBON) will be initiated soon which will integrate all the long-term biodiversity monitoring and bioindicator data from various agencies in Taiwan as well as collaborate with AP-BON and GEO BON.

P-1105-17

Climate change revealed from mass balance of mountain glaciers and polar ice sheets - GLACIOCLIM, the French Glaciers Observatory

D. Six (1) ; C. Vincent (2) ; A. Rabatel (3) ; V. Favier (1) ; P. Wagnon (4)

(1) LGGE - CNRS/UJF, Saint-Martin d'Hères, France; (2) LGGE - CNRS/UJF, Saint-Martin d'Heres , France; (3) UJF, Lgge, Grenoble, France; (4) LTHE - IRD, Saint Martin d'Heres , France

Mountain glaciers are widely recognized as excellent indicators of climate change over recent centuries (e.g. IPCC, 2013). Glacier mass balance variations are a useful tool to assess climate changes over the 20th and 21th centuries and anticipate future challenges related to water resources and sea level rise.

A multi-level monitoring combining in-situ and remotely-sensed measurements within different climate regions constitutes the strategy recommended by the Global Terrestrial Network for Glaciers (GTN-G) supported by the United Nations Framework Convention on Climate Change (UNFCC). It should provide the basic data sets required for integrative studies and assessments of the distribution and changes of glaciers and ice caps.

In this context, the French national observatory of glaciers "GLACIOCLIM", supported by INSU, IRD, IPEV and University of Grenoble in collaboration with local partners, has been developing such a strategy for several decades

on glaciers in the French Alps, the tropical Andes, the Antarctic and the Himalayas. The policy supported by GLACIOCLIM in terms of data sharing relies on: (1) free access through an interactive database which has been recently redesigned; (2) a contribution to the World Glacier Monitoring Service database, sustained by a MoU; and (3) a contribution to the GLIMS initiative for multi-temporal glacier inventories. Our monitoring strategy is based on a comprehensive, consistent set of data, including glaciological measurements (mass balance, ice velocity, length and thickness variations), along with hydrological and meteorological measurements. Contrary to the length variations which result from complex ice flow dynamics, mass balance fluctuations are direct indicators as they record solid precipitation via accumulation and surface energy fluxes via ablation. Given that most mountainous glaciers are temperate (i.e. close to the pressure melting point), the excess energy flux at the glacier surface during the ablation season serves mainly for melting. Consequently, it is necessary to measure both winter and summer mass balance terms over long periods to investigate long-term climate trends. The full network then provides the opportunity to thoroughly analyze the relationships between surface mass balance and meteorological variables on selected glaciers in the world.

Most of the glaciers in the world have been decreasing over the last decades and ice temperature measurements in boreholes at very high altitudes provide a clear evidence of atmospheric warming. The goal of this presentation is to analyze the climate – glacier relationships and to provide the cause of this decrease in selected mountainous regions (Alps, Himalayas and Andes) based on in-situ measurements, remote sensing data and results from simple to complex models. The surprising paradox of East Antarctica, where surface mass balance changes are still limited will also be justified in view of data from the GLACIOCLIM observatory.

P-1105-18

Observing Climate Variability and Change with GPS Radio Occultation

AK. Steiner (1) ; B. Scherllin-Pirscher (1) ; F. Ladstädter (1) ; L. Brunner (1) ; M. Schwärz (1) ; R. Biondi (1) ; J. Fritzer (1) ; J. Schwarz (1) ; U. Foelsche (2) ; G. Kirchengast (1)

(1) Wegener Center for Climate and Global Change, University of Graz, Graz, Austria; (2) Institute for Geophysics, Astrophysics, and Meteorology/Institute of Physics, University of Graz, Graz, Austria

Overall agreement on global warming of the troposphere and cooling of the stratosphere exists from conventional observations. However, uncertainty in trend rates and their vertical structure limits the ability to draw robust and consistent inferences about long-term trends, a key issue as stated in the recent report of the Intergovernmental Panel on Climate Change. Monitoring atmospheric variability and climate change requires climate data records which are continuous and homogeneous, long-term stable, and traceable to standards of the international system of units (SI). The uncertainty of essential climate variables, such as temperature, must be smaller than the signals expected from long-term change.

Radio Occultation (RO) observations based on Global Positioning System (GPS) signals meet these requirements. The traceability to fundamental time standards with precise atomic clocks assures a long-term stable and consistent data record with global coverage and all-weather utility. RO data are available from 2001 onwards. Information on error characteristics is provided as well. Data products comprise vertical profiles and gridded climatological fields of key atmospheric variables including bending angle, refractivity, pressure, geopotential height, temperature, and specific humidity. Derived quantities such as tropopause parameters or geostrophic winds are also available. Highest quality and vertical resolution (about 0.5 km to 1.5 km) is delivered over the upper troposphere and lower stratosphere, offering the distinct advantage to assess the vertical thermodynamic structure.

We present an overview on the accomplishments and diverse applications of the RO record for monitoring climate variability and climate change in the atmosphere. Results show the ability of RO to capture the El Niño-Southern Oscillation (ENSO), Quasi-Biennial Oscillation (QBO), atmospheric waves and thermal tides, and extreme weather events such as tropical cyclones with unprecedented vertical resolution. Despite of the relatively short RO record, its utility for climate change detection is demonstrated as a global climate observing system. Current and future challenges are discussed for the establishment of an RO climate data record, which will contribute to improving our knowledge on atmospheric structure and trends.

Reliable predictions of the future climate using climate models are central and fundamental requirements for determining future mitigation strategies. The use of commercial aircraft allows the collection of highly relevant observations on a scale and in sheer quantity impossible to achieve using research aircraft, and at altitudes where other measurement methods (e.g., satellites) fall short. It has been extensively demonstrated by 3 ongoing international projects in Europe and Japan now that commercial aircraft are ideal platforms to record vertical profiles from ground to 12 km to the tropopause region over areas never or poorly sampled by other programs (e.g. surface or radio soundings network) and to sample the atmosphere between 9 and 12 km at high horizontal and vertical resolution corresponding to the critical upper troposphere / lower stratosphere (UT/LS) region at mid-latitudes, where most long-range aircraft fly. The European Research Infrastructure IAGOS (In-service Aircraft for a Global Observing System; www.iagos.org) operates a global-scale monitoring system for atmospheric composition, aerosols and clouds by using Airbus A340 and/or A330 long-range aircraft performing regular intercontinental flights. Today's participating airlines, Lufthansa, Air France, China Airlines, Cathay Pacific and Iberia, ensure global-scale coverage by the infrastructure (see map of the flight on htt://www.iagos.fr), which is designed for a lifetime of at least 20 years. IAGOS complements the global observing system in addition to ground-based networks, dedicated research campaigns, satellites, balloons, and ships. The infrastructure builds on the heritage of former research projects MOZAIC (Measurement of Ozone and Water Vapour on Airbus In-service Aircraft; http://www.iagos.fr/mozaic) and CARIBIC (Civil Aircraft for the Regular Investigation of the Atmosphere Based on an Instrument Container; http://www.caribic-atmospheric.com). IAGOS is now the European Research Infrastructure combining and coordinating these two different and complementary approaches/methodologies which comprise (i) IAGOS-core based on MOZAIC (a fleet of 15 to 20 aircraft flying a reduced set of automatic instruments) and (ii) IAGOS-CARIBIC based on CARIBIC (1 aircraft flying a 1.5 ton laboratory with 16 instruments deployed once a month for 4 flights). IAGOS combines research centres, universities, national weather services, airline operators and aviation industry. It provides data for users in science and policy including air quality forecasting, verification of CO2 emissions and Kyoto monitoring, numerical weather prediction, and validation of global chemical transport model, global climate chemical model and satellite products. Since its participation in the on-going MACC projects (http://www.iagos.fr/macc), and demonstration

and delivery of core data in near real time (NRT) and soon in real time for a subset of information, IAGOS is considered a major contributor to the in-situ component of Copernicus Atmosphere Monitoring Services (CAMS). The IAGOS infrastructure is currently the only approach to providing regular in-situ observations in the UT/LS over mid-latitudes at high spatial resolution (4 seconds or 1 km horizontally) and vertical profiles (4 seconds or 30 meters vertically) of reactive gases, greenhouse gases, and aerosol concentration in the troposphere over continental sites, never or sparsely sampled by other programs, (e.g. in Africa, South East Asia, and South America). In combination with its predecessor programs MOZAIC and CARIBIC, IAGOS has been providing long-term observational data of atmospheric chemical composition in the UT/LS since 1994 with to date 20 year time series of temperature, H2O and O3, and 9-15 years of aerosol, CO, NOy, CO2, CH4, N2O, SF6, Hg, acetone, ~30 HFCs, ~20 NMHC data. This presentation will give an overview of the original results achieved so far and a number of highlights to illustrate the promise IAGOS data hold for the future (new measured compounds along with near real time and real time transmission of data), taking full advantage of coupled chemistry-dynamics atmospheric models, allowing new applications and analysis for a broad community of users. One of the most striking examples we will highlight concerns evaluation of forecast runs with IAGOS NRT data as proposed in the frame of CAMS.

P-1105-20

Toward improved metadata catalogue services for WDS members in China

J. Wang (1)
(1) Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China

There are about 9 regular members of WDS in China, which covers multi-disciplines, such as geography and environment, space, astronomy, ocean, polar, microbe, and so on. It is difficult to provide uniform metadata catalogue services and update the related information dynamically. Face to this problem, WDS China family design and build the clearing house for metadata inter-operability. It includes three important part, i.e., metadata standard, data update mechanism, clearing house portal. A uniform metadata exchange standard is designed for WDS members in China. In order to advance the data and metadata services quality, an integrated data and metadata update mechanism are proposed based on the review and training mechanism supported by WDS China secretary office. Finally, a new clearing house portal is provided which can be accessed by WDS portal directly.

P-1105-21

60-year Database of Cosmic-Ray Neutron Fluxes held by the WDC for Cosmic Rays

T. Watanabe (1)
(1) National Institute of Information and Communications Technology, Integrated Science Data System Research Laboratory, Koganei, Tokyo, Japan

It has been suggested by a number of authors that fluctuations in the cosmic-ray, which are known to be caused by changes in solar activity with the time scale of eleven years or longer, could play a role in climate change. The World Data Center (WDC) for Cosmic Rays of Solar-Terrestrial Environment Laboratory, Nagoya University, is almost unique data center providing with pressure-corrected and scale-adjusted one-hour fluxes of cosmic-ray, supplied by ground-based stations (about 50 at present) distributed in a wide range of the longitude and the latitude, including polar and equatorial regions. Quality controlled data since 1953 in unified formats are opened through the Web page whose ULR is given below. Beside of well-known "11-year" solar-cycle variations of the cosmic-ray flux, appearing in the opposite sense of the variations of sunspot number, a weak increasing trend can be recognized in this several solar cycles, reflecting a weakening tendency of the solar activity. Although a weak inverse correlation is seen between the cosmic-ray flux and the global temperature in 1953-2006, the correlation analysis is strongly affected by the global cooling presumably caused by two major volcanic eruptions (El Chichon in 1982, and Pinatubo in 1991). Both eruptions were "accidentally" taken place in two subsequent solar-cycle maxima.

http://center.stelab.nagoya-u.ac.jp/WDCCR/.

1106 - The Earth's energy imbalance and exchanges at the atmosphere-ocean interface: from fundamental research to societal concern

ORAL PRESENTATIONS

K-1106-01

Earth's energy imbalance: current knowledge and future challenges

M. Palmer (1)
(1) Met Office, Hadley Centre, Exeter, United Kingdom

Anthropogenic climate change arises from the accumulation of excess solar energy in the Earth system through increases in heat-trapping greenhouse gases associated with human activities. The various aspects of observed climate change (surface temperature rise, increased rainfall rates, loss of glaciers, global sea level rise, changes in climatic extremes) are all symptoms of this accumulation of energy, of which > 90% is manifested in increased ocean heat storage. The rate of climate change is defined by Earth's energy imbalance (EEI) and this represents the most fundamental quantity for monitoring ongoing global warming.

Ultimately, the impacts of climate change will be determined by the future evolution of EEI and how this additional energy interacts with the flows of energy within the Earth system. In this talk, I will outline the scientific motivation for better monitoring of EEI and review the recent progress that has been made through improved Earth system observations. I will discuss the future challenges in improving our estimates of this critical aspect of global change and advocate for EEI and ocean heat storage becoming central to both our thinking and communication on climate change.

K-1106-02

SOLAS, a decade of international research at the air-sea interface: main accomplishments and future goals

C. Guieu (1)
(1) CNRS-UPMC, Villefranche sur mer, France

The surface ocean and lower atmosphere domain is a complex, highly dynamic component of the Earth system. Air-sea fluxes of biogeochemically-active materials and energy exert a major impact on global biogeochemistry and climate. Some of the largest uncertainties in projecting future global environmental trends are attributable to an insufficient understanding of the physical and biogeochemical interactions and feedbacks between the ocean and atmosphere (IPCC, 2013).

The overarching goal of SOLAS (Surface Ocean-Lower Atmosphere Study) international program launched in 2004, is to achieve a quantitative understanding of the key biogeochemical-physical interactions and feedbacks between the ocean and atmosphere, and how this coupled

system affects and is affected by global change. Our understanding of the exchanges of energy, gases and particles at the atmosphere-ocean interface has advanced over the past decade but there are still large uncertainties to adequately parameterize fundamental controlling processes as identified in the new research strategies of the international SOLAS group (Law et al., 2013). In this context, the scientific questions driving SOLAS research are highly challenging, inherently multidisciplinary, and broad in scope. They include: (1) What controls the ocean/atmosphere exchange of climate-relevant gases and particles? (2) How does the atmospheric deposition of materials impact ocean biogeochemistry? (3) What are the links between ocean biology, aerosols, and clouds? (4) What are the biogeochemical controls on emissions of highly reactive gases that impact atmospheric photochemistry and stratospheric ozone?

Climate mitigation policies based on greenhouse gas budgets must take into account the role of ocean-atmosphere fluxes for future projections. In that context, several of the geoengineering schemes currently debated for climate mitigation are directly linked to the ocean-atmosphere system, including ocean iron fertilization, sea spray generators, ocean foams, and modification of the ocean upwelling. Informed assessment of their feasibility, efficacy and potentially unintended effects will derive from SOLAS science.

This presentation will overview the SOLAS 2004-2014 goals and main accomplishments and present the SOLAS 2015-2025 rationale and scientific scope.

O-1106-01

Origin of the Recent Tropical Atlantic SST warming: the role of ocean dynamics?

J. Servain, (1) ; G. Caniaux (2) ; A. Hounsou-Gbo (3) ; Y. Kouadio (4) ; M. Mcphaden (5) ; M. Araujo (3)
(1) IRD/UMR-182, Locean, Paris, France; (2) CNRM/GAME (Météo-France/CNRS), TOULOUSE, France; (3) Universidade de Pernambouco, Departamento de oceanografia, Recife, Brazil; (4) University Felix Houphouet Boigny – Cocody – Abidjan, Physic, Abidjan, Ivory Coast; (5) NOAA, Pmel, Seattle, United States of America

During the last decades, the sea surface temperatures (SSTs) of the whole tropical Atlantic has substantially increased. Since the 1960s, the mean SST series of the tropical Atlantic [30°N-20°S, 60°W-15°E] has gained some 0.8°C. Moreover, when considering the main break points which affect the time series, the most significant trend occurred since 1995, at a rate of 0.25°C per decade for the whole basin. When regionalyzed, the most severe warming affects the north-western part of the basin with values up to 1°C, as well as the coastal upwelling regions offshore Africa. Surprisingly the trade wind system, that drives the equatorial upwellings, strengthened since the 1960s and specially since the 1980s. These changes has been established by considering various independent observational data sets, allowing to prove the robustness of the results.

The origin of the SST change has been investigated by analyzing the changes of the air-sea surface fluxes and of the water column by considering integral quantities like sea level anomalies and upper level heat contents. It appears that the SST warming is not directly related to the local surface heat fluxes, which tend to increase the ocean heat loss. This implies that the signal is not coming from the atmosphere but rather from the ocean itself, i.e. due to recent changes in the ocean dynamics. Moreover, lagged correlation patterns between heat content and SSTs, suggest the existence of a relationship between the SST warming and the circulation in the northern tropical Atlantic. Finally, several hypotheses are presented to conciliate both the strengthening of the wind-stress, the SST and upper-water warming, as well as the break point dates which affect the trends.

O-1106-02

Oceanic biotic components, production mechanism of organic aerosol in Marine Boundary Layer ans cloud-climate system

MC. Facchini (1) ; CD. O'dowd (2) ; R. Danovaro (3)
(1) National Research Council (CNR), Institute of Atmospheric Sciences and Climate (ISAC), Bologna , France; (2) National University of Ireland Galway, School of physics and centre for climate & air pollution studies, ryan institute, Galway, Ireland; (3) Polytechnic University of Marche, Department of life and environmental sciences, Ancona, Italy

Studies performed during the past years strongly suggest that biogenic organic compounds play an important role in submicron marine aerosol chemical composition over biologically productive, high latitude, marine regions, in both hemispheres and new biogenic oceanic sources of primary and secondary origin of OA were revealed. We discuss on the global importance of biogenic OA marine sources and their high spatial and temporal variability and the complex interaction with gaseous biogenic precursors and oceanic biotic components (Phytoplankton, viruses and bacteria). Submicron marine organic aerosol are a complex mixture of biogenic materials transferred from the ocean surface by the sea spray or by oxidative gas to particle conversion of volatile organics emitted by decomposition processes of oceanic dissolved organic carbon. The role of marine biota on the evolution of plankton bloom and on the partitioning of oceanic organic carbon in POC and DOC reservoirs and transfer mechanisms into MBL will be discussed.

1106-POSTER PRESENTATIONS

P-1106-01

Comparative assessment of surface fluxes from different sources: a framework based on probability distributions

S. Gulev (1)
(1) RAS Institute for Oceanology, SAIL, Moscow, Russia

Surface turbulent heat fluxes from modern era and first generation reanalyses (NCEP-DOE, ERA-Interim, MERRA NCEP-CFSR, JRA) as well as from satellite products (SEAFLUX, IFREMER, HOAPS) were intercompared using framework of probability distributions for sensible and latent heat fluxes. For approximation of probability distributions and estimation of extreme flux values Modified Fisher-Tippett (MFT) distribution has been used. Besides mean flux values, consideration is given to the comparative analysis of (i) parameters of the MFT probability density functions (scale and location), (ii) extreme flux values corresponding high order percentiles of fluxes (e.g. 99th and higher) and (iii) fractional contribution of extreme surface flux events in the total surface turbulent fluxes integrated over months and seasons. The latter was estimated using both fractional distribution derived from MFT and empirical estimates based upon occurrence histograms. The strongest differences in the parameters of probability distributions of surface fluxes and extreme surface flux values between different reanalyses are found in the western boundary current extension regions and high latitudes, while the highest differences in the fractional contributions of surface fluxes may occur in mid ocean regions being closely associated with atmospheric synoptic dynamics. Generally, satellite surface flux products demonstrate relatively stronger extreme fluxes compared to reanalyses, even in the Northern Hemisphere midlatitudes where data assimilation input in reanalyses is quite dense compared to the Southern Ocean regions. Our assessment also discriminated different reanalyses and satellite products with respect to their ability to quantify the role of extreme surface turbulent fluxes in forming ocean heat release in different regions.

P-1106-02

The New Planetary Energetic Budget, the New Climate and the New Water Cycle in the North Atlantic Ocean and its edges

MS. Karrouk (1)
(1) University Hassan II, Climatology Research Centre (CEREC), Geography, Climatology, Casablanca, Morocco

Global warming has now reached the energetic phase of H2O's return to the ground after the saturation of the atmosphere in evaporation since the 80s and 90s of the last century, which were characterized by severe droughts, mainly in Africa.

This phase is the result of the accumulation of thermal energy exchanges in the Earth-Ocean-Atmosphere system that resulted in the thrust reversal of the energy balance toward the poles. This situation is characterized by a new thermal distribution: above the ocean, the situation is more in surplus compared to the mainland, or even opposite when the balance is negative on the land, and in the atmosphere, warm thermal advection easily reach the North Pole (planetary crests), as well as cold advection push deep into North Africa and the Gulf of Mexico (planetary valleys).

This «New Ground Energy Balance» establishes a «New Meridian Atmospheric Circulation (MAC)» with an undulating character throughout the year, including the winter characterized by intense latitudinal very active energy exchanges between the surplus areas (tropical) and the deficit (polar) on the one hand, and the atmosphere, the ocean and the continent on the other.

The excess radiation balance increases the potential evaporation of the atmosphere and provides a new geographical distribution of H2O worldwide: the excess water vapor is easily converted by cold advection (polar vortex) to heavy rains that cause floods or snow storms that paralyze the normal functioning of human activities, which creates many difficulties for users and leaves damage and casualties, but ensures water availability missing since a long time in many parts of the world, in Africa, Europe and America.

The new thermal distribution reorganizes the geography of atmospheric pressure: the ocean energy concentration is transmitted directly to the atmosphere, and the excess torque is pushed northward. The Azores anticyclone is strengthened and is a global lock by the Atlantic ridge at Greenland, which imposes on the jet stream a positive ripple, very strongly marked poleward, bringing cosmic cold advection of polar air masses winter over from Europe to North Africa. Hence the enormous meridian heat exchanges north-south, and south-north.

This new spatial thermal provision therefore imposes on the jet-stream a positive ripple on the North Atlantic (Greenland) and eastern Pacific (Alaska); this is the cause of the heat and drought of California, followed by negative waves in eastern US, and Europe.

This is the «New Atmospheric Circulation» predominantly «Meridian», due to the «New Climate» caused by global warming.

Combining satellite data, atmospheric reanalyses and climate model simulations, variability in the net downward radiative flux imbalance at the top of Earth's atmosphere (N) are reconstructed and linked to recent climate change. Over the period 1985-2012 we estimate N=0.47±0.54 Wm−2 (uncertainties at 90% confidence level). Variability relates primarily to the eruption of Mt. Pinatubo in 1991 and El Niño Southernn Oscillation with good agreement (r~0.6) between the monthly reconstruction and atmospheric simulations using prescribed sea surface temperature and radiative forcings. Combining with a simple energy balance climate model we argue that increased ocean heat uptake below the mixed layer is required to reconcile changes in N and surface temperature since 1985.

The surface net fluxes can be estimated based upon the reconstructed N and the atmospheric energy tendencies and transports from the ERA-Interim reanalysis. The energy divergences over the oceans are adjusted to remove an unphysical residual global mean atmospheric energy divergence. The estimated net surface energy fluxes are compared with reanalysis and atmospheric model simulations. The spatial correlation coefficients of multi-annual means between the estimations made here and other data sets are all around 0.9. There are good agreements in area mean anomaly variability over the global ocean. The inter-hemispheric heating differences and precipitation biases are also discussed.

Uncoupling the ocean and sea-ice from the atmosphere: Challenges of Coordinated Ocean-ice Reference Experiments (COREs)

AM. Treguier (1) ; G. Danabasoglu (2) ; S. Marsland (3) ; S. Griffies (4) ; W. Omdp Members (5)

(1) CNRS, LPO, IUEM, Plouzane, France; (2) NCAR, Boulder, United States of America; (3) CSIRO, Melbourne, Australia; (4) NOAA - GFDL, Princeton, United States of America; (5) CLIVAR ICGPO, State oceanographic administration first institute of oceanography, Qingdao, China

Earth system models are complex, and the interactions and nonlinear feedbacks between their different components are poorly understood. Climate predictions benefit from an independent validation of each component model, before coupling them together. Atmospheric Model Intercomparison Projects, which involve forcing the atmospheric models with observed sea surface temperatures (SST) and sea-ice cover, have existed since the early days of IPCC. In contrast, a similar exercise for ocean - sea-ice models has been difficult to implement, because there are long time scale interactions between the ocean-ice-atmosphere system and there are large uncertainties in observations within the atmospheric boundary layer.

Under the umbrella of the World Climate Research Program's (WCRP) Climate and Ocean Variability, Predictability and Change (CLIVAR) Project, the Ocean Model Development Panel (OMDP) has worked for over a decade to develop a meaningful validation of ocean - sea-ice models for our present climate and has produced a common protocol: Coordinated Ocean-ice Reference Experiments (COREs). CORE consists of running ocean - sea-ice coupled models with a fixed atmospheric state (observed air temperature, humidity, boundary layer winds, downward radiation, precipitation, and river runoff). This atmospheric state has been obtained in such a way to produce realistic globally averaged heat and freshwater fluxes when combined with observed SST. Existing atmospheric reanalysis products such as NCEP or ERA are not yet suitable for this purpose without corrections. Prescribing the air temperature, rather than heat flux, is necessary in order to allow the feedbacks between the evolving SSTs and the air-sea heat fluxes: this feedback is essential to ensure the stability of the ocean-ice system.

The main challenge in the CORE framework stems from the lack of sufficient feedbacks in the water cycle. If evaporation increases over the ocean, the extra water is likely to return to the ocean as rain or runoff on long time scales. Because this nonlocal feedback is neglected when the atmospheric state is fixed, it has been necessary to introduce an arbitrary relaxation of the surface salinity to observations. In part due to this salinity forcing, CORE simulations subject to the same atmospheric state exhibit very different large scale ocean circulations: this finding underlines our limited capacity to fully validate the ocean - sea-ice components of earth system models used for climate scenarios, independently of the atmosphere. Nevertheless, a recent suite of CORE experiments carried out with over 20 different models brings new insights into the reproducibility and robustness of essential climate variables such as regional sea level patterns and the North Atlantic overturning circulation.

Measuring Earth's polar ice sheets from space

A. Shepherd (1) ; E. Ivins, (2)
(1) University of Leeds, School of earth and environment, Leeds, United Kingdom; (2) Caltech, Pasadena, United States of America

Earth's ice responds rapidly to climate forcing, and satellite observations have become an essential tool with which to measure and understand these changes. Although considerable progress has been made in quantifying recent fluctuations in ice sheet mass balance, significant challenges remain in attempting to predict future ice sheet losses. This is because past changes have been too small to reliably judge the performance of the ice sheet models upon which predictions are currently based. In consequence, there is a continued need for satellite-based observations of the polar ice sheets – both to inform the development of ice sheet models, and to deliver synoptic assessments of their contribution to contemporary sea level rise.

There are three popular satellite-based techniques for estimating the sea level contribution due losses from the polar ice sheets; satellite altimetry can measure changes in ice sheet volume; satellite interferometry can measure outlet glacier discharge, and satellite gravimetry can measure fluctuations in ice sheet mass. Although all three approaches are technically sound, in the past there has been poor agreement between independent assessments. The Ice Sheet Mass Balance Inter-Comparison Exercise (IMBIE) was established in 2011 as a joint initiative of the European Space Agency (ESA) and the US National Aeronautics and Space Administration (NASA) as an attempt to resolve the apparent disagreement between geodetic estimates of ice sheet mass balance. Within IMBIE, estimates of ice sheet mass balance are developed from all three geodetic techniques using a common spatial and temporal reference frame and a common appreciation of the contributions due to external signals. The project brings together the laboratories and space agencies that have been instrumental in developing independent estimates of ice sheet mass balance to date.

In 2012, the first IMBIE assessment was delivered. It included 19-years of satellite radar altimeter data, 5-years of satellite laser altimeter data, 18 years of satellite radar interferometer data, 7-years of satellite gravimetry data, 32-years of surface mass balance model predictions, and predictions from a suite of post glacial rebound models. Since then, further changes have occurred in Antarctica and Greenland, and the record of satellite observations has been extended through continued operation of existing missions, such as GRACE, and through the availability of measurements from new sensors, including CryoSat-2 and Sentinel-1a.

This presentation will review the latest satellite measurements of Antarctica and Greenland, and will outline progress towards a second ice sheet mass balance inter-comparison exercise.

K-1107-02

Polar ice sheets and sea-level rise: threats and uncertainties

G. Durand (1)
(1) LGGE / CNRS, St Martin d'Hères, France

During the last 20 years, the Greenland and Antarctic ice sheets have been loosing mass with an increasing rate. They now significantly contribute to sea-level rise and will most probably continue in the foreseeable future. Their potential total contribution is tremendous as ice sheets contain tens of meters of sea level equivalent. However, the rate of their coming outflow remains speculative. In particular both ice sheets may exhibit some instability processes that could be initiated once oceanic or atmospheric perturbations exceed a given threshold. Once engaged in such instabilities, ice sheet mass loss is self-entertained and large regions may collapse. This lecture will describe the essential processes at the origin of the observed ice sheets' imbalance, our current knowledge on potential tipping points and highlight the main reasons of the uncertainties in the projection of ice sheets' contribution to sea level.

O-1107-01

Present-day sea level rise

A. Cazenave (1)
(1) CNES, LEGOS, Toulouse, France

We review most recent progress realized in measuring global mean sea level (GMSL) over recent decades and satellite altimetry era (starting in 1993), as well as in understanding the causes of the observed rise (i.e., ocean thermal expansion, land ice loss and terrestrial water storage change). The IPCC 5th Assessment Report revisited the sea level budget for the last few decades and came to rather good agreement between observed GMSL rise and sum of climate and non-climate contributions. Over the satellite altimetry era, GMSL rise (of 3.2 mm/yr) is reasonably well explained by ocean thermal expansion (contributing ~ 37%) and land ice loss from glaciers and ice sheets (contributing ~ 55%). Terrestrial water storage change (mostly due to ground water pumping) is supposed to explain the remaining, but this component is quite uncertain. For about 10 years, new observing systems from space and in situ (e.g., GRACE space gravimetry, Argo profiling floats) allow improved estimates of the various contributions to sea level rise, in particular direct estimate of ocean mass change. These observations indicate that over 2005-2013, ocean thermal expansion rose less rapidly than during the 1990s (with a contribution of only 28%) while the ocean mass increase now explains ~ 66% of the GMSL rise. This mostly results from ice mass loss acceleration from the ice sheets. This improved sea level budget approach allows us to put constraints on the contribution of the deep ocean (not seen by Argo) and its role in the current 'hiatus'.

O-1107-02

Projections of sea level change

J. Gregory (1)
(1) NCAS, University of Reading and Met Office Hadley Centre, Reading, United Kingdom

It is very likely that the rate of global mean sea level rise (GMSLR) during the 21st century will exceed the rate during 1971-2010, due to increases in ocean warming and loss of mass from glaciers and ice sheets. Ocean thermal expansion is the largest contributor to projections of GMSLR during the 21st century. For a given scenario, there is a substantial spread in climate model projections of thermal expansion, and in the geographical pattern of sea level change due to ocean density and circulation change. Larger uncertainty in projections of GMSLR comes from the land-ice contributions, especially ice-sheet dynamical change. These contributions also influence regional sea-level change, through their effect on gravity and the solid Earth. GMSLR by 2100 is likely to be in the range 0.28-0.61 m above the 1986-2005 mean under a scenario of strong mitigation (RCP2.6), and 0.52-0.98 m under a scenario of high emissions (RCP8.5). Unlike surface temperature change, GMSLR depends on the pathway of CO2 emissions, not only on the total; earlier emissions of the same total lead to greater GMSLR. By the end of the century, the rate of GMSLR under RCP2.6 could stabilise at rates similar to those of the early 21st century, while under RCP8.5 it could approach the average rates that occurred during the last deglaciation. It is very likely that regional sea level rise will be positive over about 95% of the world ocean, and about 70% of the global coastlines are projected to experience a relative sea level change within 20% of the global mean. Based on current understanding, only the collapse of marine-based sectors of the Antarctic ice sheet, if initiated, could cause GMSLR above the likely ranges during this century, but GMSLR

will continue for many subsequent centuries, because of the long timescales of ice-sheet change and deep-ocean warming, and could be partly irreversible.

Two Decades of Global and Regional Sea Level Observations from the ESA Climate Change Initiative Sea Level Project

M. Ablain, (1) ; JF. Legeais (2) ; A. Cazenave (3) ; B. Meyssignac (4) ; G. Larnicol, (1) ; J. Benveniste, (5)
(1) CLS, DOS, PMC, Ramonville St Agne, France; (2) CLS, Space Oceanography Division, Ramonville St Agne, France; (3) CNRS-CNES, Laboratoire d'études en géophysique et océanographie spatiales, Toulouse, France; (4) CNES, Legos, Toulouse, France; (5) ESA, Esrin, Frascati, Italy

Sea level is a very sensitive index of climate change and variability. Sea level integrates the ocean warming, mountain glaciers and ice sheet melting. Understanding the sea level variability and changes implies an accurate monitoring of the sea level variable at climate scales, in addition to understanding the ocean variability and the exchanges between ocean, land, cryosphere, and atmosphere. That is why Sea Level is one of the Essential Climate Variables (ECV) selected in the frame of the ESA Climate Change Initiative (CCI) program. It aims at providing long-term monitoring of the sea level ECV with regular updates, as required for climate studies. After a first phase (2011-2013), the program has started in 2014 a second phase of 3 years. The objectives of this second phase are to involve the climate research community, to refine their needs and collect their feedbacks on product quality, to develop, test and select the best algorithms and standards to generate an updated climate time series and to produce and validate the Sea Level ECV product. This will better answer the climate user needs by improving the quality of the Sea Level products and maintain a sustain service for an up-to-date production. To this extent, the ECV time series has been extended and it now covers the period 1993-2013.

We will firstly present the main achievements of the ESA CCI Sea Level Project. On the one hand, the major steps required to produce the 21 years climate time series are briefly described: collect and refine the user requirements, development of adapted algorithms for climate applications and specification of the production system. On the other hand, the product characteristics are described as well as the results from product validation, performed by several groups of the ocean and climate modeling community. At last, the work plan and key challenges of the second phase of the project are described.

Error characterization of global Mean Sea Level time series deduced from TOPEX, Jason-1 and Jason-2 altimeter missions

M. Ablain, (1) ; L. Zawadzki, (1) ; P. Prandi, (1)
(1) CLS, DOS, PMC, Ramonville St Agne, France

With the satellite altimetry missions, the global mean sea level (GMSL) has been calculated on a continual basis since January 1993. 'Verification' phases, during which the satellites follow each other in close succession (TOPEX/Poseidon--Jason-1, then Jason-1--Jason-2), help to link up these different missions by precisely determining any bias between them. The global mean sea level (MSL) deduced from these 3 altimetric missions provides a global rate of 3.2 mm from 1993 to 2013 applying the post glacial rebound (MSL AVISO website http://www.jason.oceanobs.com/msl).

Within the ESA Climate Change Initiative program, the users requirements have been collected and for the users of the Sea Level ECV, it is crucial to know as much as possible the errors impacting the MSL calculation in order to analyze the MSL variations and in fine to interpret correctly the geophysical mechanisms underlying these variations. The characterization of these errors was performed over the whole altimetric period separating several time scales as the long-term evolution (mean sea level trend), but also the inter-annual and periodic signals.

However, it will also be very useful to provide the confidence envelop (or error envelop) of the global MSL time series in order to know the exact error level at each time step. In this paper, we propose to describe in details the approach developed to compute this confidence envelop. We will also present the results obtained and how to interpret them.

P-1107-03

Altimeter sea level rise assessment with tide gauge measurements

M. Ablain, (1) ; P. Prandi, (1) ; G. Valladeau, (1)
(1) CLS, DOS, PMC, Ramonville St Agne, France

Since the first altimeter missions and the improvements performed in the accuracy of sea surface height measurements from 1992 onwards, the importance of global quality assessment of altimeter data has been increasing. Global CalVal studies usually assess this performance by the analysis of internal consistency and cross-comparison between all missions. The overall quality assessment of altimeter data can be performed by analyzing their internal consistency and the cross-comparison between all missions.

As a complementary approach, tide gauge measurements are used as an external and independent reference to enable further quality assessment of the altimeter sea level and provide a better estimate of the multiple altimeter performances. In this way, both altimeter and tide gauge observations, dedicated to climate applications, require a rigorous quality control. The tide gauge time series considered in this study derive from several networks (GLOSS/CLIVAR, PSMSL, REFMAR) and provide sea-level heights with a physical content comparable with altimetry sea level estimates.

Concerning altimeter data, the long-term drift assessment can be evaluated thanks to a widespread network of tide gauges. Thus, in-situ measurements are compared with altimeter sea level for the main altimeter missions. If altimeter time series are long enough, tide gauge data provide a relevant estimation of the global Mean Sea Level (MSL) drift calculated for all the missions. Moreover, comparisons with sea level products merging all the altimeter missions together have also been performed using several datasets, among which the AVISO delayed-time Sea Level Anomaly grids.

P-1107-04

Probabilistic surface reconstruction of coastal sea level rise during the twentieth century

G. Choblet (1) ; H. Laurent (2) ; T. Bodin (3)
(1) CNRS – Université de Nantes, Laboratoire de Planétologie et Géodynamique, Nantes, France; (2) CNRS – Université Joseph Fourier, Isterre, Grenoble, France; (3) UC Berkeley, Earth and planetary science, Berkeley, United States of America

We present a new surface reconstruction procedure based on the Bayesian inference method for coastal relative sea level variation during the twentieth century. Average rates are computed from tide gauge records. Models based on a Voronoi tessellation adapt to the level of information which proves well suited to the strong heterogeneity of data. Each point of the reconstructed surface is defined through a probability density function, a format particularly well adapted to this climate-related datum. The resolution of reconstructed surfaces strongly varies among the six large regions considered and within a given region. Anomalous sea level variations recorded locally are shown to reflect either anthropogenic effects or well-identified fast tectonics. For a poor data coverage, these can cause a problematic distortion of the reconstructed surface. Europe, North America, Australia, and Africa present a single trend with a decreasing precision of the reconstructed surface as a function of resolution of the tide gauge record. The most prominent feature in Europe is the pronounced uplift of Fennoscandia. Coasts of United States have the best resolution in North America and present stronger rates of sea level rise on the Atlantic than their European counterparts. Australia (especially in

the North) and Africa are poorly resolved. Asia and South America depart clearly from this trend: a relatively uniform rise is obtained for Asia in spite of a good tide gauge record. Conversely, the reconstructed surface for South America presents an exceptional degree of roughness, at odds with a relatively poor record. Overall, this method not only offers a new assessment of sea level change (validating earlier results) but also quantifies the reliability of estimates.

We finally apply a similar procedure to GPS vertical data. First results on vertical ground motion which therefore allow the local evaluation of absolute sea-level rise during the twentieth century will be presented.

Climatic information from unexplored areas of East Antarctica: The French ITASE Contribution

V. Favier (1) ; L. Arnaud (1) ; G. Delaygue (1) ; M. Fily (1) ; H. Gallée (1) ; C. Genthon (1) ; B. Jourdain (1) ; G. Krinner (1) ; A. Landais (2) ; M. Legrand (1) ; ME. Le (1) ; O. Magand (1) ; V. Masson-Delmotte (2) ; B. Minster (2) ; G. Picard (1) ; S. Preunkert (1) ; F. Prié (2) ; F. Remy (3) ; J. Savarino (1)

(1) LGGE, Grenoble, France; (2) LSCE, Gif-sur-Yvette, France; (3) LEGOS, Toulouse, France

Antarctica is the largest ice reservoir on Earth. In the context of climate change, the surface mass balance (SMB) of Antarctica will play a major role in the evolution of sea level. Knowledge of the current variations of Antarctic SMB is thus a major challenge. However, for Antarctica the spatially averaged SMB is still poorly constrained because field data are sparse. The IPCC fifth assessment report (AR5) has highlighted this uncertainty as one of the main scientific challenges in climate science.

How the surface mass balance of Antarctica will change in the future?

In spite of decades of studies, an international effort is still necessary to reduce the important remaining uncertainties. Especially, large regions of Antarctica are still unexplored. Hence, scientific traverses have been designed in the framework of SCAR-ITASE program (International Trans-Antarctic Scientific Expeditions) to collect invaluable samples and observations in the field. In the context of ITASE project, the French glaciology community has launched a program to get new information on surface mass balance. During the 2009-10, 2011-2012 and 2013-14 summers, scientific traverses have been performed over large distances on the Antarctic plateau. However, the coast-to-plateau transition zone has been largely unexplored, whereas this is where most of future changes are expected to occur. Hence, a new traverse is planned in this area for the summer 2016-17. Using up-to-date techniques, we propose to collect information on snow physical properties to analyze the processes responsible for their spatial and temporal variations. A special attention will be paid on the way to use remote sensing data to infer the physical characteristics of snow. This knowledge is expected to allow us to interpret remote sensing signal in terms of surface mass balance. Getting information on how the origin and transport of moisture affect chemical and isotopic signals stored in firn and ice will also be a priority. This knowledge will help us to validate climate and surface mass balance models, which are used to forecast future surface mass balance. The goal of this presentation is to describe recent results obtained by the French ITASE community, and to describe its strategy for future research performed in Antarctica.

P-1107-06

Testing the sensitivity of the East Antarctic Ice Sheet to Southern Ocean dynamics: past changes and future implications

C. Fogwill (1) ; C. Turney, (1) ; K. Meissner, (1) ; N. Golledge, (2) ; P. Spence, (1) ; J. Roberts, (3) ; M. England (4) ; R. Jones, (5) ; L. Carter, (2)

(1) University of New South Wales, Climate Change Research Centre, Sydney, NSW, Australia; (2) Victoria University of Wellington, Antarctic research centre, Wellington, New Zealand; (3) Australian Antarctic Division, Institute of marine and atomospheric studies, Hobart, Australia; (4) The University of New South Wales, Climate change research centre, Sydney, Australia; (5) University of Exeter, Geography, Exeter, United Kingdom

The stability of Antarctic ice sheets and their potential contribution to sea level under projected future warming remains highly uncertain. The Last Interglacial (135,000-116,000 years ago) provides a potential analogue, with global temperatures 2°C higher and rates of sea-level rise >5.6 m ka−1, leading to sea levels 6.6-9.4 m higher than present. The source(s) of this sea-level rise remain fiercely debated.

Here we report a series of independent model simulations exploring the effects of migrating Southern Hemisphere Westerlies (SHWs) on Southern Ocean circulation and Antarctic ice-sheet dynamics. We suggest that southerly shifts in winds may have significantly impacted the sub-polar gyres, inducing pervasive warming (0.2-0.8°C in the upper 1,200 m) adjacent to sectors of the East Antarctic Ice Sheet (EAIS), which due to their geometries and connectivity to the Southern Ocean are highly sensitive to ocean forcing. We conclude that the EAIS potentially made a substantial, hitherto unsuspected, contribution to interglacial sea levels, and given 21st-century projections in the Southern Annular Mode and associated SHW migration, we highlight how pervasive circum-Antarctic warming may threaten EAIS stability.

P-1107-07

Uncertainties on the surface mass balance of Antarctica

C. Genthon (1) ; C. Palerme (1) ; H. Barral (2) ; C. Amory (2)

(1) CNRS, Laboratoire de Glaciologie et Géophysique de l'Environnement, Saint Martin d'Hères, France; (2) Université de Grenoble Alpes, Laboratoire de glaciologie et géophysique de l'environnement, Saint Martin d'Hères, France

On average, the ~12 106 km³ of the grounded Antarctic ice sheet accumulates ~15 cm of water equivalent per year at its surface. The main term in the surface mass balance equation is precipitation, mainly in the form of snowfall. Other terms include evaporation/frost deposition, melting and runoff to the oceans, and blowing snow effects. Climate models may or may not account for these terms, if they do with varying degrees of realism which can only be evaluated against past or present day observations. All climate models simulate precipitation and predict an increase of antarctic snowfall but disagree on the magnitude of the increase. A 20 % increase (everything else unchanged) would induce a ~1 mm/year moderation of sea-level rise due to other causes of sea-level change. Unfortunately, there are no in situ observations of antarctic snowfall that can be used to confidently assess model performance and sort out their reliability. Satellite data suggest that most models overestimate antarctic precipitation. Those models closest to the satellite data predict a larger precipitation increase and impact on sea-level. Blowing snow is a frequent phenomenon on the peripheral slopes of the antarctic ice sheet where catabatic winds blow, but none of the past IPCC climate models have accounted for this process and a possible contribution to surface mass balance change. There are few observations of antarctic blowing snow and those available suggest systematic model biases in blowing snow conditions. Although the current mean surface mass balance of Antarctica is relatively well know from glaciological measurements, there is a deficit of evaluation and validation of the independent components and thus of the physical processes which may be individually and differently altered in a changing climate.

P-1107-08

Avoided Sea Level Rise from thermal expansion for RCP4.5 versus RCP8.5

A. Hu (1) ; S. Bates, (1)

(1) National Center for Atmospheric Research, Boulder, CO, United States of America

Observational evidence shows that as the global mean temperature increases, the global mean sea level is also rising. The rising sea level could impose significant impacts on coastal communities, especially when this rising sea is compounded with storm surges. Here, by analyzing

results from two sets of ensemble simulations using the Community Earth System Model version 1, we study the potential avoided sea level rise over the 21st century on global and regional scales if a climate pathway of RCP4.5 is followed versus RCP8.5. Results show that the global mean sea level rise averaged over 2061-2080 due thermal expansion of sea water can be reduced by about 25% (~3.7 cm). Regionally, this avoided sea level rise can be marginal in some areas, such Melbourne, Australia (14cm vs. 13cm), and can be very large in others, such as New York (35cm vs. 25cm) due to regional changes in dynamical forcing.

P-1107-09

Analyses of altimetry errors using Argo and GRACE data

JF. Legeais (1) ; P. Prandi, (2) ; M. Ablain, (2) ; N. Picot (3)
(1) CLS, Space Oceanography Division, Ramonville St Agne, France; (2) CLS, Dos, pmc, Ramonville St Agne, France; (3) CNES, Toulouse, France

Since the first altimeter missions and the improvements performed in the accuracy of sea surface height measurements from 1992 onwards, the importance of global quality assessment of altimeter data has been increasing. Global Cal/Val studies are usually performed by the analysis of internal consistency and cross-comparison between all missions. In this study, the steric and mass contributions to the sea level provided by Argo profiling floats and the Gravity Recovery And Climate Experiment (GRACE) mission respectively are used as independent sources of comparison to analyze the altimetry errors.

Argo profiling floats are spread out over almost the global open ocean since 2004. However, they measure temperature and salinity vertical profiles, providing only the steric contribution to the total sea level content measured by altimeters. The missing mass contribution is derived from the GRACE data set from 2003 onwards.

The comparison is performed with the first objective of detecting global and regional altimeter mean sea level drifts. A second goal is to assess the impact of new altimeter standards (orbit, geophysical corrections, ground processing) and new versions of altimeter merged products such as the 2014 AVISO reprocessing or the Sea Level CCI data set. We also focus our work on sensitivity analyses of the method of comparison to various parameters. In particular, we determine to which extent the altimeter quality assessment is affected by a different pre-processing of altimeter data, a sub sampling of the Argo network and a change of the reference depth used to compute Argo dynamic heights.

P-1107-10

An upper limit of future sea-level rise

A. Levermann (1)
(1) Potsdam Institute for Climate Impact Research, Research Domain Sustainable Solutions, Potsdam, France

For coastal protection an upper limit of future sea-level rise is of much higher value than the likely range provided by the Intergovernmental Panel on Climate Change AR-5. Based on state-of-the-art process-based simulations and physical considerations, an upper limit for the global mean sea-level rise of the 21st century is presented. It is shown that this upper limit is consistent with the likely range provided by the IPCC-AR5, but far exceeds the upper value of this likely range. For practical purposes a full probability distribution is suggested which is both consistent with the IPCC-range and the upper limit estimate.

P-1107-11

Climate change impacts on Nef Glacier and repercussions on the hydrological regime of Nef River (Patagonia, Chile)

P. Lopez (1) ; B. Pouyaud, (2) ; P. Chevallier, (2) ; G. Casassa, (3) ; F. Espinoza, (4) ; J. Salas, (5) ; P. Nahuelcar, (5) ; J. O'kuinghttons, (5) ; L. Longuevergne (6)
(1) CNRS, University Rennes 1, Geosciences Rennes, Rennes, France; (2) Laboratoire Hydrosciences UMR 5569 (CNRS, IRD, Université de Montpellier), Montpellier, France; (3) Geoestudios Ltda and Universidad de Magallanes, Santiago and Punta Arenas, Chile; (4) Independent consultant, Coyhaique, Chile; (5) Dirección General de Aguas, Coyhaique, Chile; (6) CNRS, University Rennes 1, Geosciences rennes, Rennes, France

The Nef River, with its origin in the Nef Glacier, located on the Northern Patagonia Icefield (Chile), drains a glacierized basin of 800 km². In this study, fluctuations between 2005 and 2010 in the discharge of Nef River measured close to the Nef Glacier's front, were analyzed. Throughout the whole data series, the discharge follows a seasonal fluctuation with a mean discharge of 27.1 m3/s and 78.3 m3/s for the fall/winter and spring/summer season, respectively. During autumn, spring, and summer, several floods are related in terms of temperature peaks. The highest flood of the whole period (189 m3/s) was observed on 11 March 2009 and occurred as a result of a significant increased of the air temperature (from -0.9°C to +12.5°C) appeared during the 5 previous days to the flood triggering increase of glacier melting.

In order to quantify the Nef Glacier's melting (in function to the air temperature) during spring and summer seasons, a simplified degree-day method was applied for the 2007-2008 hydrological year (which is the only period without gaps on the data series). The glacier melt water contributed for 30% to the total discharge; meanwhile precipitation represents only a 7.2%.

In addition, we found that Glacial Lake Outburst Flood (GLOF) events occurred at Nef Norte Lake (a small proglacial lake originated on a lateral front of Nef Glacier) can contribute significantly to the total discharge of Nef River. Indeed, the surface area of the lake was monitored using SPOT 5 satellite images and DEMs. By 23th March 2008, the lake lost at least 25% of the surface measured in 13th March and the water level of the lake was 33.6 m lower (equivalent to 6*106 m3). This amount is therefore coherent with the increase of discharge of 25.5 m3/s recorded between 15th and 20st March 2008. In consequence, we suggest that a GLOF event was responsible of the 4th highest flood (156.8 m3/s) of the 2005 - 2010 period.

GLOF events, which increased their frequency in Patagonia during the last decade, are the clear evidence of constant glacier thinning as response to climate change. The ablation area of Nef Glacier thinned 1.8 m between 2001 and 2011.

These results confirm that a hydrological approach applied to the glacial runoffs can correctly estimate glacier melting coming from ablation area, which is largely unknown at basin scale in the Northern Patagonia Icefield.

P-1107-12

Recent acceleration of glacier retreat in the Northern Patagonia Icefield based on an updated decennial evolution

P. Lopez (1) ; G. Casassa, (2)
(1) Géosciences Rennes, Rennes, France; (2) Geoestudios Ltda and Universidad de Magallanes, Santiago and Punta Arenas, Chile

The glacier length fluctuations and the surface area evolution between 2001 and 2011 of 25 glaciers of the Northern Patagonia Icefield (NPI) were studied: the information extracted from the Landsat ETM+ satellite image of 11 March 2001 was compared to the measurements performed based on the Landsat ETM+ satellite image of 19 February 2011. From a global point of view, the majority of the studied glaciers thinned, retreated and lost surface between 2001 and 2011, only few glaciers (Leones, Nef, Pared Sur and Soler) located on the eastern side of the NPI have been stable. Glaciers located on the western side of the NPI suffered a stronger wasting compared to the glaciers located on the eastern side.

Between 2001 and 2011, a noteworthy retreat of 1.9 km was experienced by Gualas Glacier and by Reichert Glacier with 1.6 km, both located on the north-western side of the NPI. On the south-western side of the NPI, during the same decennia, Steffen Glacier experienced a remarkable retreat of 1.6 km as well. During the 2001-2011 period, Steffen Glacier more than doubled its rate of retreat (compared to the 1979-2001 period) and experienced the disintegration of its main front as well as a lateral tongue that retreated

3.1 km. The most significant retreat observed on the eastern side was experienced by Colonia Glacier (1 km).

Area loss was also relevant during the period 2001–2011. Overall, the icefield experienced a reduction of 50.6 km² which represents a 1.3% relative to the surface area calculated for 2001 year. The most remarkable surface reduction was observed for HPN-1 Glacier that lost 3.2% of its surface estimated in 2001, followed by Steffen Glacier (2.8%).

We suggest that the glacier shrinking observed in the NPI is controlled firstly by atmospheric warming, as it has been reported in this area. Nevertheless, updated climatic studies are needed in order to confirm this suggestion. If the detected past climate trends persist, in the future, glaciers of the NPI will continuous or even increase their rate of shrinking generating important consequences for this region like the production of Glacier Lake Outburst Flood events or the decrease of the melt-water runoff in the long-term future.

P-1107-13

Use of Differential SAR Interferometry for vertical ground motions monitoring in coastal cities

D. Raucoules (1) ; G. Woppelmann (2) ; G. Le Cozannet (1) ; M. De Michele (1)
(1) BRGM, ORLEANS, France; (2) LIENSS – univ la Rochelle, La Rochelle, France

Before the altimetry era, tide gauge are a unique source of information to evaluate past sea-level changes. However, they can be affected by vertical ground motions acting at different space scales. We use synthetic aperture radar techniques to assess these ground motions and their consequences for geodetic instruments such as Tide Gauge, GPS, Doris stations. Summarizing results obtained at Alexandria (Egypt; Woppelmann et al., 2013), Manila (Philippines; Raucoules et al., 2013) and Dakar (Senegal; Le Cozannet et al., subm.), we identify different situations in terms of data availability and ground motion context: - when strong ground motions affect the tide gauge, the technique can easily help rejecting tide gauges records from the database of reliable datasets (case of Manila) - however, when no ground motions can be observed using InSAR in the vicinity of geodetic instruments (Case of Alexandria and Dakar), it remains challenging to reach the accuracy required to confirm that tide gauge records are indeed suitable for monitoring sea level changes. To reach the required accuracy of this InSAR application, a large set of SAR data must have been acquired over the area. For future science application of Sentinel 1 in the field of geodesy underpinning sea level science, it will be necessary to define appropriate background missions covering coastal sites where key records have been aquired.

Sea level rise and Geoid: Factor analysis approach

A. Sadovski (1) ; H. Song, (2) ; G. Jeffress, (2)
(1) TexasA&M University-Corpus Christi, Corpus Christi, TX, United States of America; (2) Texas A&M University-Corpus Christi, Conrad blucher institute for surveying, Corpus Christi, United States of America

Sea levels are rising around the world, and this is a particular concern along most of the coasts of the United States. A 1989 EPA report shows that sea levels rose 5-6 inches more than the global average along the Mid-Atlantic and Gulf Coasts in the last century. The main reason for this is coastal land subsidence. This sea level rise is considered more as relative sea level rise than global sea level rise. Thus, instead of studying sea level rise globally, this paper describes a statistical approach by using factor analysis of regional sea level rates of change. Unlike physical models and semi-empirical models that attempt to approach how much and how fast sea levels are changing, this methodology allows for a discussion of the factor(s) that statistically affects sea level rates of change, and seeks patterns to explain spatial correlations.

Cartographers and geodesists, those who study the measurement of the size and shape of the earth, are interested in sea level as an elevation datum. This datum is called the geoid, which is defined as the equipotential gravity surface of the Earth, and theoretically best fits global mean sea level in ocean areas. Hence, the rate of change in mean sea level directly affects changes to the geoid and the elevation datum used as the reference for topographic mapping.

Many methods have been used in sea level rise modeling. These methods can be divided into two categories: physical models, based on the conservation of mass (global water mass and ice mass measurements), and semi-empirical models, studying measured rates of change of sea level and measured changes in global temperatures along with the error estimates of measurements to predict future trends. These two approaches are complementary. For example, no one really understands the dynamics of each and every glacier, so it is quite difficult to calculate melting glaciers from physical models, hence the use of semi-empirical methods described in the majority of studies of sea level rise. This paper introduces a different approach by using factor analysis of regional sea level rates of change as a statistical analysis tool. Instead of answering the question of how much and how fast sea levels are changing, this paper computes and discusses which mathematical factor statistically affects sea level rates of change and seeks patterns to explain spatial correlation. The paper also seeks to hypothesize that any insights into the factors influencing sea level change also apply to the changes to the geoid.

P-1107-15

Strategy and new statistical downscaling method for the on-line derivation of the Greenland ice sheet surface mass balance in a GCM

D. Salas Y Melia (1) ; M. Geyer (1) ; E. Brun (2) ; M. Dumont (3)
(1) CNRM-GAME (METEO-FRANCE/CNRS), GMGEC/ASTER, Toulouse, France; (2) ONERC, Paris, France; (3) CEN, Grenoble, France

Current CMIP5 (Coupled Model Intercomparison Project Phase 5) coupled Global Climate Models (GCMs) cannot realistically represent ice sheet/climate feedbacks. This is due to their coarse horizontal resolution, which hampers the correct representation of Surface Mass Balance (SMB) spatial variability, to weaknesses in the representation of physical processes at the ice sheetsurface and to the lack of interactive ice sheet models which are necessary torepresent the ice loss due to dynamics. As a contribution to the future inclusion of interactive ice sheet models in coupled GCMs, we discuss various potential methods. We present a downscaling method designed for the online derivation of the SMB field over the Greenland ice sheet (GrIS). This method uses statistical relationships between SMB and temperature variations which have been established from off-line simulations of the SMB performed on a high resolution grid with a detailed snowpack model. We used this technique to downscale 150 km horizontal resolution SMB output from the CNRM-CM5.1 GCM to a 15 km resolution grid. A comparison with output from the MAR regional model shows that the downscaling clearly improves the spatial distribution of the SMB, particularly along the GrIS margins, where steep topography gradients are not correctly represented at low-resolution. A simulation where CNRM-CM5.1 was nudged with ERA-Interim demonstrates the ability of the method to reproduce reasonably well the interannual variability of the total GrIS SMB from 1979 to 2012. From a technical point of view, the method is generic enough to be applied to outputs from other GCMs, though it cannot completely filter model biases, especially in the interior of the GrIS.

Sea-level change and projection for future flooding along the coast off Egypt

M. Shaltout (1)
(1) Faculty of Science, Alexandria University, Egypt., Physical Oceanography, Alexandria, Egypt

The current study analyses the recent changes in the daily satellite altimetry data along the southern Levantine sub-basin and cost off Egypt over the period 1993-2013. First,

the accuracy of using satellite altimetry data, represented by dynamical topography (DT) as a measure of coastal sea levels, is examined based on tide gauges observations. Second, daily and annual satellite altimetry data are related to five atmospheric/oceanic factors to evaluate their effect on DT changes. Third, the qualities of three realisations of the Geophysical Fluid Dynamics Laboratory (GFDL) global climate model (GCM) are examined by comparing these with the satellite altimetry dataset. Finally, the simulations that best describes the present satellite altimetry data are used to describe the uncertainties in projection of the sea level changes along the study area.

The results indicate that the satellite altimetry data represented by DT can be used to study coastal and deep sea level changes in the study area. Southern Levantine sub-basin sea level display a recent average sea level rise of 3.1 cm decade-1 and exhibits a significant annual sea level variation from -17 cm (deep water) to 8 cm (shallow water). The sea level variations are significantly affected by several factors such as and in order of importance: sea level variations west of Gibraltar Strait, steric sea level variations and sea surface temperature. The GCMs that most realistically describe the recent sea level over the study area is GFDL-CM3, outputs from this model are used to study the projected sea level along the study area for different emission scenarios. GFDL-CM3 model results indicate that the coast of Egypt will experience sea level rise in the current century. Uncertainty in the projected sea level rise over the studied area ranged from 4 to 22 cm rise by 2100 and was explained by three different sources of uncertainties, of which the emission assumed dominated. Comparing of uncertainty in the projected sea level rise with digital elevation data shows that the Egyptian Mediterranean coast will only become safe from flooded by the end of 21st century if effective adaptation methods are applied.

P-1107-17

Earth's changing oceans: Effects and implications for iceberg calving from Antarctica's ice shelves

C. Walker (1)
(1) Georgia Institute of Technology, School of Earth and Atmospheric Sciences, Atlanta, GA, France

Ice shelves are freely floating seaward extensions of the Antarctic ice sheet. They can extend hundreds of kilometers into the ocean and drain the vast majority of ice from Antarctic ice sheet to the ocean. Iceberg calving from these ice shelves is the primary means of discharging ice from the Antarctic Ice Sheet into the Southern Ocean and, although calving events occur sporadically, when they do occur they remove large amounts of mass in a nearly instantaneously. This cycle forms part of the natural cycle of ice shelf advance and retreat with typical recurrence times between major calving events of the order of several decades. However, changes in calving rates have also been implicated in some of the most rapidly changing regions of Antarctica. Scambos et al. (2003) showed that the abrupt disintegration of both Larsen A and Larsen B ice shelves occurred following a series of abnormally warm summers. Not only were these disintegrations surprising in terms of size, but also in the speed at which they occurred; approximately 13,500 km^2 of ice was lost by the collective Antarctic ice shelves due to collapse in the last three decades of the 20th century, deemed to be possibly related to the approximately 3 degrees C increase in temperature at the Antarctic Peninsula over the last half of the century (Steffen et al., 2010). Despite the fact that calving accounts for at least half of the mass loss from the ice sheet (Rignot et al., 2013), but its relation to the changing climate remains poorly understood.

Many major and minor ice shelves of Antarctica exist in a colder climate further South than the peninsular ice shelves and have not experienced comparable surface warming nor are they currently showing any signs of peninsular-style disintegration. They have, however, experienced increased basal melting over the past decade with some speculation that these ice shelves may especially be susceptible to ocean forcing. To realistically assess the evolution of ice shelves it is necessary to investigate the precursor to calving: the initiation and propagation of rifts through the ice. As ice flows toward the open water rifts eventually become the boundaries at which icebergs separate from their parent ice shelf. An example of such a rift was detected in October 2011, at Pine Island Glacier (PIG) in West Antarctica. The PIG flows outward into the Amundsen Sea, creating a 30-km floating ice tongue. As the floating shelf elongates from the grounding line, cracks eventually form and icebergs calve off later. Rifts can initiate far upstream of the calving front and propagate for decades before an iceberg detaches. While many studies have examined the dynamics of vertical crevasse penetration, fewer studies have examined lateral propagation and little is currently known about the forces and underlying mechanisms that drive rift propagation. For example, it has been proposed that rifting is the cumulative result of many environmental factors, such as ocean swell induced flexure caused by pulses of ocean swell or that rifting is primarily the result of internal mechanical stresses acting to fracture the ice.

In this study we continue the monitoring work that was published in 2013, conducting observations of 15 ice shelves around Antarctica over a 15 year period between 2000 and 2015. While previously we only compared tidal swell data with rift propagation data sets, we now use a variety of oceanic data and model results to better characterize the effect of ocean changes on ice sheet and specifically the evolving effect that Earth's changing oceans might have on solid ice discharge rates from Antarctica's ice shelves.

The Irreversibility of Sea Level Rise

K. Zickfeld (1) ; K. Tokarska (2)
(1) Simon Fraser University, Vancouver, BC, Canada; (2) University of Victoria, Victoria, Canada

Recent research has shown that sea level continues to rise even if carbon dioxide emission will be halted completely. Here we explore whether artificial atmospheric carbon dioxide (CO2) removal (also referred to as "negative emissions") has the potential to reverse thermosteric sea level rise on timescales relevant to human civilization. Specifically, we investigate how much CO2 needs to be removed from the atmosphere for sea level rise to be reversed and stabilized permanently, and the degree to which the reversibility of sea level rise depends on the amount and duration of CO2 emissions prior to the time of artificial CO2 removal. To investigate these questions, an Earth System model of intermediate complexity is forced with a range of emission scenarios entailing different amounts of net negative CO2 emissions. We find that in order to reverse and stabilize sea level rise, atmospheric CO2 concentrations need to be returned to pre-industrial levels. Thermosteric sea level rise is linked to the integrated net radiation flux at the top of the atmosphere, and will stop rising only when this flux becomes negative (i.e. when there is a net radiation loss to space). Our results suggest that while sea level rise can be reversed temporarily with negative emission technologies deployed at a scale that is currently deemed to be technologically feasible, reversal and permanent stabilization of sea level rise requires the removal of all anthropogenic CO2 from the atmosphere.

Future stratospheric ozone in a changing climate

U. Langematz (1)
(1) Freie Universität Berlin, Institut für Meteorologie, Berlin, Germany

As a result of the Montreal Protocol on Substances that Deplete the Ozone Layer and its subsequent amendments and adjustments that constrained the production and consumption of halocarbons, the decline of stratospheric global ozone seems to have ceased. Model projections suggest a future recovery of the global mean ozone column to levels around the year 1980, when only low levels of ozone depleting substances (ODSs) existed in the stratosphere. However, the timing of the return of ozone to historical levels depends not only on the concentrations of ODSs but is also affected by thermal and dynamical changes associated with increasing greenhouse gas concentrations. For example, while the amounts of ODSs steadily decrease in the stratosphere, with appropriate meteorological conditions and given the long lifetimes of ODSs, individual years with strong ozone decrease still may occur in the near future.

Here, an overview of future projections of the ozone layer based on chemistry-climate model simulations will be presented. The impact of climate change on stratospheric ozone recovery will be discussed.

Stratosphere–Troposphere Coupling in a Changing Climate

M. Baldwin (1)
(1) University of Exeter, Exeter, United Kingdom

Stratospheric variability and change has substantial effects on surface weather and climate, especially on the Annular Modes, with shifts in the jet streams, storm tracks, precipitation, and likelihood of blocking events. Despite unambiguous observations of this phenomenon, as well as numerical simulations, a clear physical explanation of this downward coupling has been elusive. In this talk I will discuss recent advances in our understanding—how pressure changes (movement of mass) in the stratosphere affects surface climate. However, movement of mass in the stratosphere is not sufficient to fully explain the observed surface changes—surface effects are than would be expected theoretically, and are larger than at the tropopause. This "tropospheric amplification" is easily quantified, and suggests a role for eddy feedbacks in response to the movement of mass. I will discuss the future implications for surface climate, jets, storm tracks, etc.—assuming that we know how the stratosphere will change during the remainder of this century.

O-1108-01

Sub-seasonal climate predictability associated with an anomalously strong stratospheric polar vortex

A. Charlton-Perez (1) ; O. Tripathi, (1) ; M. Sigmond, (2) ; F. Vitart, (3)
(1) University of Reading, Meteorology, Reading, Berkshire, United Kingdom; (2) Environment Canada, Canadian centre for climate modelling and analysis, Victoria, Canada; (3) ECMWF, Reading, Berkshire, United Kingdom

There has been a great deal of recent interest in producing weather forecasts on the 2-6 week sub-seasonal timescale which bridges the gap between medium-range (0-10 day) and seasonal (3-6 month) forecasts. While much of this interest is focused on the potential applications of skilful forecasts on the sub-seasonal range, understanding the potential sources of sub-seasonal forecast skill is a challenging and interesting problem particularly because of the likely state-dependence of this skill (Hudson et al., 2011). One such potential source of state-dependent skill for the Northern Hemisphere in winter is the occurrence of stratospheric sudden warming (SSW) events (Sigmond et al., 2013). Here we show, by analysing a set of sub-seasonal hindcasts, that there is enhanced predictability of surface temperature and circulation not only when the stratospheric vortex is anomalously weak following SSWs but also when the vortex is extremely strong. During the third and fourth weeks following anomalously strong polar vortex conditions northern Europe and northern Russia are on average three degrees Celsius warmer than their climate norm, with similarly sized cold anomalies over northwestern North America. Sub-seasonal forecasts initialised during strong vortex events are able to successfully capture their associated surface temperature and circulation anomalies. This results, for some regions, in a significant enhancement of forecast skill compared to forecasts initialised during cases when the stratospheric state is close to climatology. We demonstrate that the enhancement of skill for forecasts initialised during periods of strong vortex conditions is comparable to that achieved for forecasts initialised during SSW events. this result indicates that additional confidence can be placed in sub-seasonal forecasts when the stratospheric polar vortex is significantly disturbed from its normal state. This presentation will discuss this result and its implications for understanding the impact of stratospheric climate change and its tropospheric impact.

O-1108-02

Characteristics of stratospheric warming events during Northern Winter

P. Maury, (1) ; C. Claud (1) ; E. Manzini (2) ; A. Hauchecorne (3) ; P. Keckhut (4) ; K. Kodera (5)
(1) CNRS, Ipsl/lmd, Palaiseau, France; (2) Max Planck Institut, Hamburg, Germany; (3) CNRS, Latmos, Guyancourt, France; (4) LATMOS-IPSL, Guyancourt, France; (5) Solar-Terrestrial Environment Laboratory, Nagoya university, Nagoya, Japan

The polar mid-stratosphere is characterized by the setting up of westerly winds around the pole during the wintertime; the so-called polar vortex. The polar vortex is one of the most variable features of the zonal-mean circulation of the earth atmosphere, due to a highly non linear interaction between planetary-scale Rossby waves and the zonal flow. Indeed, the interaction between the upward tropospheric propagating waves and the polar vortex leads to a zonal flow weakening, implying a large day-to-day vortex variability. In the most dramatic cases, the polar vortex breaks down, the stratospheric polar flow can reverse its direction and the temperatures can rise locally by more than 50K in a span of a few days. Such phenomena are known as major Sudden Stratospheric Warmings (SSWs) and constitute, since their discovery in 1952 (Scherhag,1952) the most impressive dynamical events in the physical climate system. On the contrary, situations where the temperature increase is not associated to a polar vortex breakdown are known as minor SSWs.

There is actually a renewed interest about SSWs since Baldwin and Dunkerton (2001) have shown that the major SSWs can influence weather in the troposphere. This stratospheric-tropospheric linkage has been statistically highlighted but no physical explanation has been proposed. Also, other studies, that incorporate both major and minor SSWs, show that events in the stratospheric zonal flow associated with SSWs present downward-propagating anomalies that can reach the troposphere (Limpasuvan et al 2004), implying that minor SSWs have to be also considered in the study of the stratospheric-tropospheric dynamical coupling.

In this study, we propose a global characterization of stratospheric warmings situations based on a temperature threshold in the 50-10hPa layer between 70N-90N, in order to better assess the properties of daily stratospheric temperature variability during the northern winter. The originality of this approach consists in evaluating the wintertime positive temperature anomalies in terms of intensity and duration without distinction between minor and major SSWs. We will show that there is a wide

spectrum of warming types, where major SSWs are the most extreme, but other events – the minor SSWs – share some common properties with them. They can even have a surface signature if one look the stratospheric wave reflection on the polar vortex.

O-1108-03

Update of stratospheric temperature interannual variability and trends from space sounders and ground-based lidars observations

A. Hauchecorne (1) ; P. Keckhut (1) ; C. Claud (2) ; B. Funatsu, (3) ; S. Khaykin, (1) ; G. Angot, (1) ; P. Maury, (2)
(1) LATMOS-IPSL, Guyancourt, France; (2) CNRS, Ipsl/lmd, Palaiseau, France; (3) CNRS, Letg-rennes costel, université rennes2, Rennes, France

The stratosphere is expected to cool, in conjunction with the global warming at the surface and in the troposphere, due to the increase of greenhouse gas concentration in the atmosphere, and also to stratospheric ozone loss. This is already observed but the rate of cooling is not constant and there is still a debate on its amplitude. Several other factors may influence the evolution of the stratospheric temperature. External forcings, like the solar variability that modulate the UV solar flux and strong volcanic eruptions injecting aerosols in the stratosphere, participate to its decadal variability. The variability of the stratospheric dynamics is also adding some complexity to the system. For instance global climate models predicts an increase of the occurrence frequency of sudden stratospheric warming (SSW) events not yet confirmed by the observations. A monitoring of the stratospheric temperature evolution is crucially needed to better understand the complexity of the processes playing a role in the coupling between the stratosphere, the troposphere and the climate.

The stratospheric temperature is measured at a global scale by satellite instruments; mainly microwave sounders AMSU (Advanced Microwave Sounding Unit) on board meteorological satellites. These sounders are very useful to provide the global overview but may suffer from biases and orbital drifts and have a poor vertical resolution in the upper stratosphere. Since 2000 radio-occultation sensors, among them the US-Taiwan COSMIC constellation, provide well-resolved and accurate temperature profiles but limited to the upper troposphere-lower stratosphere. Rayleigh lidars implemented within the NDACC (Network for the Detection of Atmospheric Composition Change) international network measure accurately the temperature profile from the middle stratosphere to the upper mesosphere but in a very few locations. They are used climate change monitoring, dynamics studies and satellite validation.

In this presentation we will present an update of the interannual variability and trends in the stratospheric temperature from AMSU, Rayleigh lidar and radio-occultation measurements. Similarities and differences in the temperature evolution captured by these various sensors will be evaluated. The contribution of anthropogenic and natural forcings to the observed changes will be discussed. A particular focus will be given to the role of SSW events to the stratospheric temperature evolution as a function of latitude and season.

O-1108-04

Role of the middle atmosphere for low-frequency climate variability

T. Reichler (1) ; Z. Bowen (1)
(1) University of Utah, Atmospheric Sciences, Salt Lake City, Utah, United States of America

It is commonly believed that the ocean represents the dominant source for climate variability on longer, interdecadal time scales and that this drives the low-frequency variability of the atmosphere. Here, we provide evidence for the existence of opposite pathways. Investigating long control simulations with coupled and uncoupled climate models we find considerable multi-decadal variability in the atmosphere that is independent of the ocean and that influences climate. The middle atmosphere represents one source for such low-frequency variability. The variability is related to relatively long-lived fluctuations in the strength of the stratospheric polar vortex, which in turn project on the state of the North Atlantic Oscillation. This creates signals in ocean temperatures over the deep convective region to the south of Greenland, which, over the course of several years, propagate into the deep ocean. These events modulate and drive intrinsic low-frequency variability in the Atlantic Multidecadal Overturning Circulation (AMOC) and explain about 20% of the natural AMOC variability. Our findings support the view that trends and low-frequency variations in the middle atmosphere extend their influence beyond the troposphere into the ocean and that this constitutes an important source of climate variability. We discuss natural and anthropogenic sources for such low-frequency stratospheric variability.

O-1108-05

The millennium water vapour drop in the stratosphere in chemistry-climate model simulations

S. Brinkop (1) ; M. Dameris (1) ; P. Joeckel, (1) ; H. Garny, (1) ; S. Lossow, (2) ; G. Stiller (2)
(1) DLR-Deutsches Zentrum fuer Luft- und Raumfahrt, Institut fuer physik der atmosphäre, Oberpfaffenhofen, Germany; (2) KIT – Karlsruher Institut für Technologie, Imk-asf, Karlsruhe, Germany

This study investigates the millennium water vapour drop, the abrupt and severe water vapour decline in thestratosphere beginning in year 2000, by means of various simulations using the Chemistry-Climate Model (CCM)EMAC. Since the beginning 1980s, balloon borne stratospheric water vapour measurements and correspondingsatellite measurements starting in the early 1990s indicated a long-term steady increase of water vapour concentrations.However, the multi-year data sets also show significant fluctuations on different time scales. In theyear 2000, an extraordinary sudden drop of stratospheric water vapour concentration has been observed followedby persistent low values for several years. Solomon et al. (2010) showed that this drop slowed down the rate ofincrease in global surface temperature over the following decade by about 25%. So far, the stratospheric watervapour variations observed by satellite from 1992 to 2012 are not reproduced by CCM simulations forced byobserved changes in sea surface temperatures, greenhouse gases and ozone-depleting substances (Gettelman et al.,2010, Randel and Jensen, 2013).However, the CCM EMAC is able to reproduce the signature and pattern of the water vapour disturbances inagreement with those derived from observations. In this paper we present results of a hierarchy of simulationswith the CCM EMAC, demonstrating that it is possible to retrace the observed water vapour fluctuations in thestratosphere (incl. the millennium drop), if suitable inner and outer boundary conditions are applied.

The ARISE project: dynamics of the atmosphere and climat

E. Blanc (1) ; A. Charlton-Perez (2) ; P. Keckhut (3) ; L. Evers (4) ; P. Heinrich (1) ; A. Le Pichon (1) ; A. Hauchecorne (5)
(1) CEA, Arpajon, France; (2) University of Reading, Department of meteorology, Reading, United Kingdom; (3) LATMOS-IPSL, Guyancourt, France; (4) Royal Netherlands Meteorological Institute (KNMI) , De Bilt, Netherlands; (5) CNRS, Latmos, Guyancourt, France

It has been robustly demonstrated that variations in the circulation of the middle atmosphere influence weather and climate throughout the troposphere all the way to the Earth's surface. A key part of the coupling between the troposphere and stratosphere occurs through the propagation and breaking of planetary waves and gravity waves. Limited observations of the middle atmosphere and these waves in particular hamper our ability to faithfully reproduce the dynamics of the middle atmosphere in numerical weather prediction and climate models.

An exciting scientific development in recent years has been the potential for a number of novel ground-

based measurement techniques to give new and complementary measurements of the middle atmosphere. The main challenge of the ARISE (Atmospheric dynamics InfraStructure in Europe) project[1] is to combine for the first time existing national and international observation networks which observe the middle atmosphere including: the International infrasound monitoring system developed for the CTBT (Comprehensive nuclear-Test-Ban Treaty) verification, the NDACC (Network for the Detection of Atmospheric Composition Changes) lidar network, localized European observation infrastructures at mid latitudes (OHP observatory), tropics (Maïdo observatory), high latitudes (ALOMAR and EISCAT), infrasound stations developed at national level in European countries and satellite measurements. This joint network provided advanced data products, with the scope to assemble the derived upper atmospheric wind and temperatures into NWP models.

The ARISE infrastructure is unique because of its coverage (from polar to equatorial and tropical regions in the European longitude sector and adjacent regions), its ability to sense a wide range of altitudes (including stratosphere, mesosphere, lower thermosphere, ionosphere) and the involved scales both in time (from seconds to tens of years) and space (from tens of meters to thousands of kilometers). We are about to embark upon a new phase of development to allow the network be improved by i) including innovative instrumentation for measurements in the middle atmosphere between 40 and 80 km where temperature and wind measurements are especially rare, ii) adding measurements in low latitude African stations where only infrasound observations are currently available, iii) and by automating lidar and radar measurements for routine observations.

The major ARISE objective is to provide a full description of gravity and planetary waves in the stratosphere and mesosphere for wave parameterization and assimilation in the models. This could lead to a better prediction of extreme events such as Sudden Stratospheric Warming and improvement of the tropospheric weather forecasts on weekly time scales. The societal impact is potentially very large, including for sectors such as agriculture, industry, energy consumption, transport, insurance and risk quantification.

ARISE objectives are also i) to better characterize the coupling between atmospheric layers and effects on the global atmospheric circulation and climate, ii) to quantify the trends in extreme events relate to climate, iii) to determine the impact of the Earth's geo-space.

The project is multidisciplinary and includes European groups with complementary expertise in weather forecasting, climate, extreme events monitoring. It has partners in a number of international organizations including the ECMWF (European Centre for Medium-Range Weather Forecasts), WMO (World Meteorological Organization), SPARC (Stratospheric Processes And their Role in Climate), ROSMIC (Role Of the Sun and the Middle atmosphere-thermosphere-ionosphere In Climate), IRGGEA (International Research Group in Geophysics Europe Africa).

This presentation will review recent advances in this topic especially obtained in the framework of the ARISE project. It will also discuss perspectives and future project challenges related to climate.

[1] ARISE is an infrastructure Design Study project funded by the European Commission under the H2020 program.

Stratospheric chemistry-climate interactions and their importance for the surface climate in Antarctica

P. Braesicke (1) ; J. Keeble (2) ; L. Abraham (3) ; S. Kellmann (1) ; J. Pyle (2) ; G. Stiller (1) ; X. Yang (4)

(1) KIT, IMK-ASF, Eggenstein-Leopoldshafen, Germany; (2) University of Cambridge, Cas, Cambridge, United Kingdom; (3) University of Cambridge, Ncas, Cambridge, United Kingdom; (4) BAS, British antarctic survey, Cambridge, United Kingdom

One prominent example of anthropogenic environmental change is the annually recurring ozone hole in the Southern Hemisphere (SH). This systematic change in stratospheric composition affects circulation and tropospheric climate. To improve our understanding of how a stratospheric change induces shifts in tropospheric climate, we investigate model integrations run with the fully coupled chemistry climate model UM-UKCA. Results are confronted, where appropriate, with satellite observed changes from the MIPAS instrument on ENVISAT.

Comparing two climate-equilibrium runs with and without an ozone hole we find statistically significant changes in the models thermal structure and circulation. Polar lower stratospheric cooling, in conjunction with the elevation of the high latitude tropopause and followed by an increase in the vertical component of the EP flux from November to December are consistent with a surface warming of the Antarctic Peninsula in December. The seasonal change of circulation is accompanied by an apparently descending anomaly of the EP flux divergence in the stratosphere, thus suggesting an active role of stratospheric dynamics in the surface response.

The robustness of such a circulation response to ozone changes can be studied diagnosing differences of long-lived trace gas distributions as an indicator for large-scale circulation changes. Here, we contrast the MIPAS observed year-to-year variability in N2O to changes in the seasonal evolution of N2O in different modelled climate equilibrium states with different ozone amounts. We conclude that the climate system can respond sensitively (but coherently) in its seasonal evolution to small chemical perturbations and the circulation adjustments modelled are consistent with observed interannual variability. This finding supports the applicability of the UM-UKCA climate equilibrium runs to the interpretation of the Antarctic Peninsula warming.

Stochastic parameterizations of the gravity waves emitted from convection and fronts: theory, validation, and impacts of the middle atmospheric circulation

A. De La Camara (1) ; F. Lott, (1) ; L. Guez, (1) ; A. Hertzog, (1)

(1) Laboratoire de Meteorologie Dynamique, Paris, France

Internal gravity waves (GWs) propagating vertically from their tropospheric sources impact the circulation of the middle atmosphere, and are crucial for the reversal of the mesospheric jet and the maintenance of the quasi-biennial oscillation. Their spatial scales being too small to be represented in current Earth System models, they need to be parameterized. Nevertheless, mechanisms for GW emission by fronts and jets remain elusive nowadays. As a result, non-orographic GW parameterizations have traditionally assumed an arbitrarily uniform source of waves, which makes them insensitive to the annual cycle of the GW sources or to a changing climate. For these reasons, much effort has been made over the last decade to develop schemes that relate the GWs to their sources.

A recently developed stochastic parameterization of gravity waves is used and adapted to represent the gravity waves produced by convection and mid-latitude fronts. For the fronts, the parameterization uses a theory of the spontaneous adjustment that relates directly the gravity waves field to potential vorticity anomalies. With relatively little modification to the theory, we show that the spontaneous adjustments occurring in the troposphere are sufficient to produce the right amount of waves in the mesosphere. We also predict the gravity wave field present during the Concordiasi long-duration balloon campaign in the lower stratosphere, and show that the gravity waves predicted by the parameterization are quite realistic. The impacts on the climate are also addressed with the General Circulation Model LMDz, with a particular emphasis on the annual cycle in the stratosphere. We also address the significance of including the GWs sources on the middle atmosphere response to a changing climate. Preliminary results show that when GW sources are included, the middle atmosphere response to climate change is stronger than without the sources, the impacts even reaching the surface at least in the Southern Hemisphere.

On the coupling between polar and tropical regions during springtime: variability of tropical intrusion and Frozen In Anticyclones

N. Huret (1) ; R. Thiéblemont (2) ; A. Hauchecorne (3) ; YJ. Orsolini (4) ; K. Matthes (2)
(1) LPC2E/CNRS and Orléans University, Orléans, France; (2) GEOMAR, Kiel, Germany; (3) CNRS, Latmos, Guyancourt, France; (4) NILU, Kjeller, Norway

Recent observational and modeling transport studies of Arctic stratospheric final warming have shown that tropical/subtropical air masses can be transported to high latitudes and remain confined within a long-lived "frozen-in" anticyclone (FrIAC), embedded in the summer easterlies for several months.

We first present a climatology of these sporadic events over the period 1960–2011 using ERA-40 and ERA Interim reanalyses. This study highlights stratospheric favorable preconditioning for FrIACs occurrence, that is: i) early and abrupt final warming, ii) no stratospheric major warming during the previous winter, and iii) East phase of the Quasi-Biennial Oscillation. We will present in detail the FrIAC in spring 2011, which was the largest ever recorded. Our climatology further suggests that the frequency of occurrence of FrIACs has increased over the last decade (among the nine cases detected over the period 1960–2011, five occurred between 2002 and 2011).

A chemistry climate model is then used for the first time to investigate FrIACs characteristics and variability. Simulations were performed with the NCAR's Community Earth System Model (CESM, version 1.0.2), a coupled model system including the Whole Atmosphere Community Climate Model (WACCM). FrIACs characteristics (i.e. spatial extent and duration), are overall consistent by comparing with FrIACs detected ERA-40 meteorological reanalyses. Dynamical analysis reveals that FrIACs are associated with an abrupt and early winter-to-summer stratospheric circulation transition, characterized by an amplification of planetary wave activity. Furthermore, our model results confirm that FrIACs occur preferentially under the easterly phase of the QBO and in absence of MSW during the preceding winter. Finally, we notice that extreme climate change conditions (RCP8.5 scenario) do not influence FrIACs frequency.

P-1108-05

Stratospheric ozone causes a negative feedback in CO2-driven climate change simulations

M. Ponater (1) ; S. Dietmüller, (1) ; M. Dameris (2) ; R. Sausen, (1)
(1) DLR-Institut für Physik der Atmosphäre, Earth System Modelling, Oberpfaffenhofen, Germany; (2) DLR, Institut für physik der atmosphäre, Oberpfaffenhofen, Germany

Ozone has been considered mainly as a contributor to climate change in terms of radiative forcing. However, it is also providing a radiative feedback when climate change is induced by, for example, a radiative forcing from CO2 increase. Interactively coupled chemistry-climate models can be used to identify and quantify this feedback. In a set of simulations forced by CO2 increase of different strength we find a negative ozone radiative feedback, which reduces the climate sensitivity compared to a model system where the ozone distribution is prescribed. Stratospheric ozone is more important than tropospheric ozone for this chemical feedback. The feedback mechanisms mainly works through intensification of the Brewer-Dobson circulation as sea surface temperature increases. The stratospheric water vapour feedback is modified by interaction with the ozone feedback, becoming less positive than in simulations with fixed ozone. Hence, a negative ozone feedback and a reduced water vapour feedback overlap constructively in CO2-driven simulations with interactive ozone, giving a global sea surface temperature response that is 4 to 10% smaller than in a corresponding simulation without interactive chemistry.

P-1108-06

Evidence by remote sensing and combined-model approaches for the role of gravity waves in sudden stratospheric warmings

P. Preusse (1) ; M. Ern, (1) ; BG. Song, (2) ; T. Trinh, (1) ; F. Friedl-Vallon, (3) ; P. Bechtold, (4) ; HY. Chun, (2) ; J. Orphal, (3) ; M. Riese, (1)

(1) Forschungszentrum Juelich GmbH, IEK-7, Juelich, Germany; (2) Yonsei University, Seoul, Republic of Korea; (3) Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany; (4) ECMWF, Reading, United Kingdom

Observations of absolute values of gravity wave momentum flux (GWMF) from the satellite instruments SABER ad HIRDLS in conjuncture with global stratospheric and mesospheric winds are used to investigate the role of GWs in the different phases of the sudden stratospheric warmings (SSWs) during the recent decade. Both GWMF and its vertical gradient as a proxy for drag are enhanced before the central date of major SSWs. After the central date of the SSW, GWMF and gravity wave drag in the stratosphere are strongly reduced. However, GWs contribute to the downward propagation of newly formed polar jets and of elevated stratopauses to their «climatological» altitude. This is likely at least in part due to poleward propagation of GWs. In order to shed light on the sources, propagation direction and phase speed spectra of the waves we complement the observations by high-resolution global model fields of ECMWF. We use these fields to infer the characteristics of GWs in the lower stratosphere and couple the results to global ray-tracing. This allows us to a) infer sources of GWMF by backward ray-tracing and b) to study the interaction of GWs in the stratosphere and mesosphere by forward ray-tracing in the background of geostrophic winds inferred from MLS and SABER. The current satellite observations can not reveal the propagation direction of the waves and model data need still to be proven to be fully realistic: the advantages of both approaches would be combined in limb-imaging measurements of a future mission. A concept for such an instrument is presented.

P-1108-07

The impact of biogenic bromine emissions from the oceans on the middle atmosphere in a changing climate

BM. Sinnhuber (1) ; G. Krysztofiak (2) ; S. Meul (3)
(1) Karlsruhe Institute of Technology, Institute for Meteorology and Climate Research, Eggenstein-Leopoldshafen, Germany; (2) University of Orléans, LPC2E, CNRS, Orléans, France; (3) Freie Universität Berlin, Berlin, Germany

Bromine from very short-lived substances, primarily from natural oceanic sources, contribute substantially to the halogen loading of the free troposphere and stratosphere with an important impact on atmospheric chemistry. This source of atmospheric bromine has so far been ignored in most chemistry-climate model simulations of tropospheric and stratospheric ozone trends. Here we will present chemistry climate model simulations over the past decades including the biogenic emissions of bromine from the oceans and their impact on atmospheric chemistry and ozone trends. We will discuss possible interactions between oceanic emissions, atmospheric chemistry and climate change.

Norway; (3) Australian Antarctic Division, Climate processes and change, Kingston, Australia; (4) National University of Ireland, Experimental physics, Kildare, Ireland; (5) Istituto de Astronomia y Fisica del Espacio, Buenos Aires, Argentina; (6) Utah State University, Center for atmospheric and space sciences, Logan , United States of America

The international Network for the Detection of Mesopause Change (NDMC, http://wdc.dlr.de/ndmc) is a global program with the mission to promote international cooperation among research groups investigating the mesopause region (80–100 km) with the goal of early identification of changing climate signals.

NDMC is contributing to the World Climate Research Program, WCRP.

Measurements of the airglow at the mesopause altitude region (80–100km) from most of the European NDMC stations including spectro-photometers and imagers allow monitoring atmospheric variability at time scales comprising long-term trends, annual and seasonal variability, planetary and gravity waves and infrasonic signals. The measurements also allow validating satellite-based measurements such as from the TIMED-SABER instrument.

Examples will be presented for airglow measurements and for related atmospheric dynamics analysis on the abovementioned spatio-temporal scales and comparisons with satellite-based instruments as well as with LIDAR soundings. Focus will be on climate signals in the mesopause region.

Connections between water and energy: Clouds, water vapour, radiation and precipitation

G. Stephens (1)

(1) JPL, California Institute of Technology, Pasadena, United States of America

Water and energy are intimately coupled together in the Earth's climate system. Each controls the other. This talk will concentrate on atmospheric feedbacks that develop between water and energy that influence the global hydrological cycle response in a warming and moistening climate. As the planet warms, the amount the global precipitation increases is determined by the increased emission from the atmosphere that is mostly controlled by the increases to water vapor. The increases to water vapor, especially that transported to the upper atmosphere by convection, fundamentally affects the radiation balance both directly through the influence the clear-sky emission and by enhancing the absorption of radiation by the upper tropospheric clouds that develop as a consequence of the moistened upper troposphere. Thus feedbacks develop between radiation, clouds and precipitation develop that influence how the global hydrological cycle responds to a warmed climate. These feedbacks, and others will be discussed in the context of both global and regional changes to the hydrological cycle.

Land processes and the global water cycle: Past results and upcoming CMIP6 plans

S. Seneviratne (1) ; B. Van Den Hurk (2) ; G. Krinner (3) ; H. Kim (4) ; C. Derksen (5) ; T. Oki (4)

(1) ETH, Zurich, Institute for atmospheric and climate science, Zurich, Switzerland; (2) KNMI, Model Development, De Bilt, Netherlands; (3) LGGE, Grenoble, France; (4) University of Tokyo, Global hydrology and water resources engineering, Tokyo, Japan; (5) Environment Canada, Climate research division, Toronto, Canada

Terrestrial processes play an essential role in the global water cycle, through a range of mechanisms. Soil moisture-climate interactions affect both extreme temperatures and precipitation on land (e.g. Seneviratne et al. 2010, Hurk et al. 2011, Seneviratne et al. 2013, Guillod et al. 2015) and also explain discrepancies between global-scale patterns in wetting and drying and respective trends over land (Greve et al. 2014). But recent analyses suggest that models may share common biases in their representation. Snow-climate feedbacks are also of strong relevance, but associated with substantial uncertainties (Derksen and Brown 2012, Brutel-Vuilmet et al. 2013). This presentation will provide an overview on the role of land surface exchanges in the global water cycle and on current perspectives for future research in this field. In particular, it will highlight plans for the Land Surface, Snow, and Soil moisture Multimodel Intercomparison Project (LS3MIP) under the 6th phase of the Coupled Model Intercomparison Project (CMIP6), which will allow a better validation, assessment, and quantification of the underlying processes and feedbacks in current climate models.

Changes in continental water cycle and extreme events

O. Zolina (1)

(1) Joseph Fourier University, Le laboratoire de glaciologie et géophysique de l'environnement, Grenoble, France

Ongoing and projected changes in continental water cycle are closely connected with extreme events which provide specific mechanisms of water cycle changes. We are going to address observed variability and change in continental water cycle in the context of climate extremes. Although hydroclimate extremes result from many factors that sometimes act together, water is a central component of these extremes via either its excess or scarcity. The major factor underlying hydroclimate extremes is precipitation, closely associated with flooding and droughts resulting from long dry periods and substantial water deficits over large regions. Among the major problems of changes in water cycle associated with extremes we will consider changes in temporal structure of precipitation

or precipitation timing. Over last several decades both wet and dry periods have become longer in several large European regions, specifically in Central and Eastern Europe. This effect is not associated with changes in the number of wet days but, rather, with the grouping of wet days into prolonged wet and dry periods, increasing the likelihood of floods and droughts, respectively. Another critical problem for accurate quantification of the impact of extremes on water cycle is scaling of precipitation. Representation of the impact of precipitation extremes on the water cycle strongly depends on spatial and temporal scales resolved by observational networks and models. With given resolutions we only partly capture the effect of extreme events in changes of hydrological cycle. We will demonstrate potential of very dense observational networks for accurate estimation of the role of hydroclimate extremes in continental scale water cycle. We will also consider the role of atmospheric moisture transport in forming extreme precipitation in different midlatitudinal regions, analyzing mechanisms associated with cyclone activity and transports by the mean flow. Finally, we will discuss the requirements for data characteristics and model resolution for accurate estimation of the strongly localized nature of hydroclimate extremes and their impact on continental water cycle.

Congo Basin precipitation : understanding sources and variability

E. Dyer (1) ; D. Jones, (1) ; D. Noone, (2) ; J. Nusbaumer, (3)
(1) University of Toronto, Department of physics, Toronto, Canada; (2) Oregon State University, College of earth, ocean, and atmospheric sciences, Corvallis, United States of America; (3) University of Colorado, Department of atmospheric and oceanic sciences, Boulder, United States of America

The Congo Basin is an extremely interesting and dynamic hydrological region, spanning six countries and a range of ecosystems. It is home to over 75 million people who rely on forest and freshwater resources along with agriculture for subsistence. It has the second largest continuous rainforest in the world, the second largest river by discharge and is one of the main regions of deep convection in the tropics. In many ways the Congo Basin is similar to the Amazon but in comparison is greatly understudied. According to the IPCC 5th Assessment Report agreement between models in CMIP3 and CMIP5 ensembles is low in this region. CMIP5 shows better agreement in boreal winter and worse agreement in boreal summer. Unlike other African regions, there have not been dedicated measurement campaigns, such as the African Monsoon Multidisciplinary Analysis, and the availability of rain gauge and other in situ observations is sparse. An understanding of the current seasonality and variability in Congo Basin precipitation is a step towards good predictions of changes in the future.

We examine the relative importance of vapor from neighbouring regions to precipitation variability in the Congo Basin, using a new water tracer capability in the Community Earth System Model (CESM1.2), in which water is tagged as it is evaporated in geographically defined regions. In this approach, regional vapor tracers are tracked through phase changes until the vapor is precipitated. We employ a small ensemble using CESM1.2 in an AMIP configuration, and results are compared with the ECMWF Interim reanalysis, the Global Precipitation Climatology Project data set and the Climate Research Unit rainfall data set. The tagged water results are compared to results from a stable isotope ensemble using the same model setup, where water isotopes are tagged as they enter the atmosphere. The results from the stable isotope enabled model are evaluated using the International Atomic Energy Agency's Global Network of Isotopes in Precipitation dataset.

A recycling ratio is calculated for the basin during dry and rainy seasons, showing a consistently high ratio with very high recycling during the dry seasons. Although local moisture evaporation does play a large role in the bulk of Congo Basin precipitation, the variability of local moisture sources cannot necessarily account for the total variability or seasonality. We find that the southern and western Indian Ocean are significant sources, providing important contributions to variability in Congo Basin precipitation. We find that the vertical structure of moisture flux convergence is important in determining the rainy seasons and is potentially an explanation for the signature of the vapor source of Congo Basin precipitation. Using tagged vapor and also tagged water isotopes to examine atmospheric vapor, important processes which characterise Congo Basin precipitation can be explored. This will contribute to a better understanding of how precipitation in the region may change in the future.

P-1109-02

Typhoon Bopha: Impact of an extreme tropical cyclone on the atmospheric water and energy cycle

T. Garot (1) ; H. Brogniez, (1) ; N. Viltard, (1)
(1) Laboratoire Atmosphère Millieux Observations Spatiales, Guyancourt, France

In a context of global warming, theory and modeling predict that hurricane intensity should increase with increasing global mean temperatures. It is therefore important to better study the extreme cyclones, which could become the average case. Typhoon Bopha formed on November 25 and dissipated on December 9, 2012. It was the strongest tropical cyclone to ever hit the southern Philippine island of Mindanao, making landfall as a Category 5 super typhoon with winds of 280 km/h. Bopha caused substantial damage to Mindanao, leaving behind hundreds of thousands of homeless and more than 500 fatal casualties. During the life cycle of the typhoon, the Megha-Tropiques satellite provided 2 to 5 sampling of the tropical atmosphere per day, thanks to its low inclination orbit (20°). At that time, the two microwave radiometers SAPHIR and MADRAS were both performing measurements thus giving the opportunity to investigate (i) how the typhoon impacted the atmospheric humidity of its environment and (ii) the temporal evolution of its rain field. For this purpose, three different levels of upper tropospheric humidity retrieved from SAPHIR, rain rates and releases of total latent heat estimated from MADRAS were monitored along the storm track. We will discuss the mean behavior of the typhoon that shows strong lagged oscillations of humidity and convection during its life cycle and deepens its spatial asymmetries and their relationship with the nearby environment. This analysis was completed with the use of the traking algorithm TOOCAN that allows to study how each individual convective clusters contributed to the life cycle of the typhoon.

P-1109-03

Cold/Shoulder Season Precipitation Near 0˚C

P. Groisman (1) ; S. Gulev (2) ; O. Zolina (3) ; R. Vose (4) ; I. Hanssen-Bauer (5) ; O. Bulygina (6)
(1) UCAR at NOAA National Climatic Data Center, Asheville, North Carolina, United States of America; (2) RAS P.P. Shirshov Institute for Oceanology, Moscow, Russia; (3) Joseph Fourier University, Le laboratoire de glaciologie et géophysique de l'environnement, Grenoble, France; (4) NOAA National Climatic Data Center, Asheville, United States of America; (5) Norwegian Meteorological Institute, Oslo, Norway; (6) Russian Inst. For Hydrometeorological Information, Obninsk, Russia

Small changes in atmospheric conditions lead to major changes in the types or amount of near-0°C precipitation. For example, if near-surface temperatures are slightly above (below) 0°C, rain or wet snow (snow) occurs; if a slightly above-freezing inversion occurs (or not) aloft, freezing rain (snow) can reach the surface. It also needs to be recognized that solid precipitation amounts near 0°C (such as wet snow) can be the highest in a winter storm.

With global climate change in the extratropics, the 0°C isotherm will not disappear and associated precipitation events will continue to occur. Rain should fall farther upslope in mountainous regions, thereby increasing the risk of flooding. Alterations in temperatures, storm intensity and track will alter the likelihood and occurrence of near-0°C precipitation including freezing rain. Weakening of the atmospheric circulation in the extratropical regions may lead to more polar jet stream meandering that can lead to more persistent near 0°C events. The overall warming, together with a larger influx

of the water vapour in the winter atmosphere from the oceans (including ice-free portions of the Arctic Ocean) will allow more water vapour in the winter atmosphere that can increase the amount of near-0°C precipitation. And, near-0°C temperatures should generally move poleward and arrive at many locations earlier in spring or later in autumn. This could potentially affect the seasonal cycle of near-0°C precipitation.

Despite significant progress in addressing near-0°C precipitation, it remains a challenging issue. Kunkel et al. (2013; Bull. Amer. Meteorol. Soc.) indicated that freezing precipitation was associated with the lowest level of understanding for both detection and attribution amongst several types of hazardous weather conditions affecting the U.S.

The overall issue of near 0°C precipitation is linked with several phenomena. These include blizzards (just snow), rain-on-snow (both phases with a particularly importance of the precipitation interaction with pre-existed snowpack), and freezing rain and drizzle (just liquid). The specific hazards associated with these events include: Heavy snowfall/rainfall transition around °C; Blizzards, Rain-on-snow events, Freezing rain and freezing drizzle, and Ice load on infrastructure.

Our presenttion will overview what we know and what we do not know about changes in these phenomena and formulate major tasks to advance in understanting of near-0°C precipitation, its changes, and impact.

P-1109-04

Current and future changes in precipitation and its extremes across wet and dry regions

CL. Liu (1) ; R. Allan (1)
(1) Department of Meteorology, University of reading, Reading, United Kingdom

Global warming is expected to enhance fluxes of fresh water between the surface and atmosphere, causing wet years to become wetter and dry years drier, with serious implications for water resource management. Defining wet and dry regions as the upper 30% and lower 70% of the precipitation totals across the tropics (30oS-30oN) each month we combine observations and climate model simulations to understand changes in the wet and dry extremes over the period 1850-2100.

Observed decreases in precipitation over the driest tropical land (1950-2010) are also simulated by coupled atmosphere-ocean climate models (-0.3%/decade) with trends projected to continue into the 21st century. Discrepancies between observations and simulations over the wettest land regions since 1950 are explained by decadal fluctuations in El Niño southern oscillation, the timing of which is not represented by the coupled simulations. When atmosphere-only simulations are instead driven by observed sea surface temperature they are able to adequately represent this variability over land.

By considering changes in the intensity distribution of precipitation, we find that global distributions of precipitation trends are dominated by spatial changes in atmospheric circulation. Unforced variability appears to dominate trends for the present day but land-surface feedbacks and secular changes in atmospheric circulation patterns become increasingly important into the future. Projected increases in extreme precipitation with warming over land are not diagnosed for the present day due to these dynamical influences which indicate that natural variability over land is not a good proxy for future climate change.

Nevertheless, the tendency for the wettest part of the tropical circulation to become wetter (precipitation increases with warming by 3%/K over wettest tropical ocean grid points) and the driest part of the atmospheric circulation to become drier (precipitation decreases of -2%/K over the driest tropical land grid points) is a robust result that emerges over the 21st century in response to the substantial surface warming. This indicates that enhancement in seasonality and wet and dry extremes (flooding and drought) may be anticipated over the coming century.

P-1109-05

Assessment of climate transformation in Belarus according to the COSMO-CLM model simulations

I. Partasenok (1) ; B. Geyer (2) ; V. Melnik (1)
(1) Hydromet, Minsk, Belarus; (2) Institute of Coastal Research, System analysis and modelling, Geesthaht, Germany

According to climatic investigations deviations of annual temperature have increased during last decades in Belarus. The period of significant transformation of the temperature regime has been observed since 1970s, and rapidly since 1989.

We used simulations of the COSMO model in CLimate Mode (COSMO-CLM or CCLM) for detailed assessment of climate transformation in Belarus. This is a nonhydrostatic regional climate model developed from the Local Model (LM) of the German Meteorological Service by the CLM-community.

The coastDatII dataset was produced with the COSMO-CLM at the Institute of Coastal Research of HZG to give a consistent and homogeneous database mainly for assessing weather statistics and climate changes since 1948, e.g., in frequencies of extremes for Europe. The simulation was done for 1948 to 2012 and a horizontal grid size of 0.22 degree in rotated coordinates. Global reanalysis data of NCEP1 were used as forcing.

The observed gridded data (E-Obs) was applied in the study for estimation of adequacy of the model simulations. We used the E-Obs v.10.0 gridded dataset (European Climate Assessment & Dataset) for the period of 1950-2012 as an European daily high-resolution gridded dataset the surface temperature and precipitation data.

We calculated means of seasonal temperature and precipitation over Belarus for 1955-2012 period. The calculations of temperature showed differences in the coastDatII and E-Obs varied within 0.6-2 oC depending on season. The largest deviations were obtained in winter and consist of 1.7-2.0 oC, in spring differences were as 0.8-1 oC; in summer were obtained the smallest deviations within 0.6-0.8 oC and in autumn they were about 1.0-1.3 oC. Yearly means differ for both period on 0.9 oC. During the year the E-Obs values were higher than coastDatII except summer when values derived from CCLM exceed the observed ones. Analysis of min/max values of seasonal temperature proved smoothed course of the temperature with less amplitude in CCLM.

Calculated differences of annual sums of precipitation were not significant and lied within 7%. But differences of seasonal sums varied from 10 to 20 %, especially in summer season when difference was about 50 %. It could be explained as an incorrect calculation of precipitation forced by convective process.

Analysis of annual temperature trends according to coastDatII showed statistically significant increasing of temperature over entire territory of Belarus: from 0.22 oC per decade on the West to 0.3 oC per decade of the East of the country. Trends of annual precipitation showed remarkable increasing (up to 12 mm per decade) in the North and North-East part of the Belarus but in the central and southern parts of the country sums of annual precipitation varied within norm.

Physical properties and evolution of mesoscale high cloud systems

S. Protopapadaki (1) ; C. Stubenrauch (1) ; A. Feofilov (1)
(1) Laboratoire de Météorologie Dynamique, Université de paris 6, Paris, France

Representing about 40% of the Earth's total cloud cover, clouds in the upper troposphere play a crucial role in the climate system by modulating the Earth's energy budget and heat transport. These clouds often form mesoscale cloud systems extending over several hundred kilometres. Ubiquitous cirrus (semi-transparent ice clouds in the upper troposphere) evolve as the outflow of convective and frontal systems or form in cold air supersaturated

with water. Both their evolution with climate change and their feedback can only be reliably estimated if these cloud systems are adequately represented in climate models. Only satellite instruments are able to give a picture as a whole of these systems. IR sounders are observing our planet since 1979, with improvements in spectral resolution: from the TIROS-N Operational Vertical Sounders (TOVS) onboard the NOAA polar satellites through the Atmospheric InfraRed Sounder (AIRS) onboard Aqua since 2002, and to the InfraRed Atmospheric Sounding Interferometer (IASI) on board the MetOp platforms since 2006. The good spectral resolution of these instruments allows reliable cirrus identification, both from day and night-time observations. For this study we have developed a novel method to describe mesoscale high cloud systems, taking into account their horizontal extent. The occurrence of convection within these systems will be estimated by using cloud emissivity and a clustering method. This allows a distinction between in situ cirrus and cirrus linked to convective or frontal systems. The vertical extent of these cloud systems, essential for determining the energy balance at the Earth surface, can only be determined from active instruments (CALIPSO lidar and CloudSat radar synchronous with AIRS). This data set will be explored and distributed within the framework of the GEWEX Process Evaluation Study on Upper Tropospheric Clouds and Convection (UTCC PROES).

We will relate the horizontal extent of the anvil to the convective strength of the system and we will present first results on the variability of high cloud systems with their surrounding atmosphere. Analyzing the evolution and properties of mesoscale cloud systems as a whole and their role in generating cirrus clouds will be a major advancement in climate studies, also giving a new impulse in climate model evaluation.

Long-term changes in snowfall over Japan and its regionality

H. Takahashi (1) ; S. Sugimoto (1)
(1) Tokyo Metropolitan University, Tokyo, Japan

We examined the long-term changes in snowfall over Japan for recent 50 years, using observational data and a regional climate model.

Climate change can significantly influence the snowfall on the Japan Sea side of Japan because the seasonal surface air temperature is higher than 0 deg C in northern winter. This side of Japan is one of the heaviest snowfall regions on Earth. These heavy snowfalls are a consequence of the northwesterly flow of the Asian winter monsoon from Eurasia and the region's windward (northwestern side) position along Japan's northeast-southwest trending central mountain range. Two main factors influence precipitation over the Japan Sea side. One is the activity of cold and dry northwesterly winds of the Asian winter monsoon, and the other is sensible and latent heat fluxes on the Japan Sea,which are strongly associated with the sea surface temperature (SST).

The snowfall amount can be influenced by total precipitation amount and ratio of snowfall amount to the total precipitation. Total precipitation is modulated by many factors. On the other hand, the ratio of snowfall amount to the total precipitation is basucally due to surface air temperature. Thus, we investigated the both factors, focusing on regional difference of the long-term changes.

Results showed that snowfall has drastically changed over the Sea of Japan side of Japan around late 1980's. Concurrent with the drastic change in snowfall, surface air temperature has dramatically increased. However, the drastic changes in snowfall was unclear over the some regions, which was modulated by the total precipitation changes. The regionality of long-term changes in snowfall will be discussed.

P-1109-08

Analysis of freezing rain occurrence over Eastern Canada using regional climate model simulations

J. Thériault (1) ; É. Bresson (2) ; M. Cholette (1) ; D. Paquin (2) ; R. Laprise (1) ; R. De ÉLia (2)
(1) Université du Québec, Earth and Atmospheric sciences, Montréal, Canada; (2) Ouranos, Montreal, Canada

Winter storms can lead to many types of precipitation at the surface when the temperature is around 0°C. Freezing rain is the most damaging precipitation type produced during these storms. Its occurrence is associated with favourable synoptic conditions leading to a temperature inversion associated with temperatures >0°C aloft and subfreezing temperature near the surface. The overall goal of this study is to investigate the changes in the occurrence of freezing rain with our changing climate using regional climate model outputs. In particular, a study of the occurrence of freezing rain is conducted with climate simulations produced by the Canadian Regional Climate Model 5 (CRCM5) over Eastern Canada. This is achieved using existing empirical techniques commonly used to solve for the various winter precipitation types produced during storms. These techniques are based on the vertical temperature structure that affects strongly the type of precipitation reaching the surface. The results show that the model resolution impacts the vertical temperature structure. This suggests that the model resolution will impact the production of freezing rain by the model. Hence, the differences in the freezing rain occurrence diagnosed at different model resolutions are summarized. Overall, this study started addressing how well regional climate models can account of winter precipitation types to assess how their occurrences will evolve in our changing climate.

Climate and Ocean: past, current and future changes and variability - a challenge for observations, models and assessment

M. Visbeck (1)
(1) GEOMAR & Kiel University, Kiel, Germany

The ocean covers more than 70 % of the surface of our planet and plays a key role in supporting life on earth. It hosts the most diverse and important ecosystems, and contributes to global and regional elemental cycling. The ocean regulates our climate, and through climate, habitats are shaped that allowed humans to thrive and develop our societies. The marine system provides us with natural resources such as food, materials, substances, and energy. Furthermore, the oceans and the regional seas are essential for international trade, recreational and cultural activities.

A growing world population with increasing levels of affluence has had a noticeable impact on the environment causing 'global change'. In the area of climate in particular increasing levels of greenhouse gas emissions have altered the planetary heat balanced and caused changes in both global and regional climate.

The Intergovernmental Panel for Climate Change (IPCC) most recent assessment reminds us that: "The ocean's heat capacity is about 1,000 times larger than that of the atmosphere, and the oceans net heat uptake since 1960 is around 20 times greater than that of the atmosphere." About 90% of this extra heat has been stored in the ocean. The ocean plays a crucial role in climate change, in particular in variations on seasonal to decadal time scales. One example is sea level: the addition of heat and freshwater flux from the melting glaciers and ice sheets have cause the sea level to rise. The latest IPCC gives a best estimate rate for 1961 to 2003 as 1.8 ± 0.5 mm yr-1. However, the regional differences are large and the interplay between natural climate and ocean variability and change remains a challenge for assessments.

Finally the IPCC addresses the adequacy of ocean observing systems: "Many ocean observations are poorly sampled in space and time, and regional distributions often are quite heterogeneous. Furthermore, the observational records only cover a relatively short period of time (e.g., the 1950s to the present). Many of the observed changes have significant decadal variability associated with them, and in some cases decadal variability and/or poor sampling may prevent detection of long-term trends. When time series of oceanic parameters are considered, linear trends are often computed in order to quantify the observed long-term changes; however, this does not imply that the original signal is best represented by a linear increase in time." Thus this provides an opportunity for the global ocean observing community to rise to the challenge and deliver a fit-for-purpose more integrated, more cost effective and more sustained ocean observing system.

K-1110-02

How do we observe and model the changing ocean physics, biogeochemistry, and ecosystems?

N. Pinardi (1)
(1) University of Bologna, Department of Physics and Astronomy, Bologna, Italy

The oceans play a crucial role as a climate regulator, and changing ocean physics, biogeochemistry, and biology have direct impact on human well-being through hazards and ecosystem services changes.

Long-term, globally-coordinated, and high-quality sustained ocean observations are required to understand and model the role of the ocean in the earth's climate, to monitor ocean change, and to provide initial conditions to predict the evolution of climate on scales including seasonal, decadal, and centennial. Building on national efforts, these observations are internationally coordinated through the Global Ocean Observing System and the Joint WMO-IOC Technical Commission for Oceanography and Marine Meteorology, building on the processes of a common Framework for Ocean Observing devised and adopted by the ocean observing community.

Observations and models combine to provide the best possible estimates of the present and future state of the ocean. These observations and forecasts inform decision-making about coastal protection, the marine economy, long-term changes in patterns of drought and flood, and the human consequences linked to climate change. Our confidence in the observations and models has increased over time, even as some key critical knowledge gaps remain.

Pacific Ocean western boundary currents and the interlinked equatorial Pacific circulation system were among the first to be explored by pioneering oceanographers. The widely accepted but poorly quantified importance of these currents – in processes such as the El Niño-Southern Oscillation, Pacific Decadal Oscillation and Indonesian Throughflow – has triggered renewed interest, with ongoing efforts seeking to understand the heat and mass balances of the equatorial Pacific, and possible changes associated with greenhouse-induced climate change. Only a concerted international effort through WCRP/CLIVAR will close the observational, theoretical and technical gaps currently limiting a robust answer to these elusive questions. This work will present a review of the boundary current characteristics, variations and their effects on local and remote climate, as well as their future projections.

O-1110-02

Preliminary results from the international South Atlantic Meridional Overturning Circulation (SAMOC) Initiative

S. Speich (1) ; S. Garzoli (2) ; A. Piola (3) ; E. Campos (4)
(1) Ecolne normale superieure, Departement de geosciences, paris, France; (2) NOAA, Aoml - phod, Miami, United States of America; (3) Servicio de Hidrografia Naval, Buenos Aires, Argentina; (4) Universidade de Sao Paolo, Instituto oceanográfico, Sao Paolo, Brazil

Within the MOC, the South Atlantic Ocean plays a key role as a nexus for water masses formed elsewhere and en-route to remote regions of the global ocean. Because of this important interbasin exchanges, the South Atlantic Ocean is the only major ocean basin that transports heat from the pole towards the equator. However, the South Atlantic is not merely a passive conduit for remotely formed water masses. Indeed, within this basin water masses are significantly altered by local air-sea interactions and diapycnal/isopycnal fluxes, particularly in regions of intense mesoscale activity and steep topography. These contributions have been shown to have a crucial role in the strength of the MOC in paleoceanographic and modelling studies.

The monitoring of the North Atlantic portion of the MOC has been ongoing for a decade now through the RAPID/MOCHA/WBTS program as well as other national and international initiatives. They all provide a scope for understanding the MOC variability in that region. Given the complex, multibasin nature of the MOC, achieving a more complete understanding of its behaviour and changes requires a more comprehensive observing system, one that extends across neighbouring ocean basins as the one we are developing for the South Atlantic within the CLIVAR SAMOC initiative.

In this presentation, we will discuss the preliminary results on estimates of the daily MOC strength at 35°S during a ~20 month long pilot array of mooring as well as model outputs and Argo data. The MOC variability show to be as large as that at 26N, with both eastern and western boundary flows contributing equally to the variance.

The full array was re-established in the fall of 2013 in collaboration with France, Brazil, Argentina and South Africa.

Exceptional 20th-Century slowdown in Atlantic Ocean overturning circulation

S. Rahmstorf (1) ; J. Box, (2) ; G. Feulner, (1) ; M. Mann, (3) ; A. Robinson, (4) ; S. Rutherford, (5) ; E. Schaffernicht, (1)
(1) Potsdam Institute for Climate Impact Research, Potsdam, Germany; (2) Geological Survey of Denmark and Greenland (GEUS), Copenhagen, Denmark; (3) Pennsylvania State University, University Park, United States of America; (4) Universidad Complutense de Madrid, Madrid, Spain; (5) Roger Williams University, Bristol, United States of America

Possible changes in Atlantic meridional overturning circulation (AMOC) provide a key source of uncertainty regarding future climate change. Maps of temperature trends over the twentieth century show a conspicuous region of cooling in the northern Atlantic. Here we present multiple lines of evidence suggesting that this cooling may be due to a reduction in the AMOC over the twentieth century and particularly after 1970. Since 1990 the AMOC seems to have partly recovered. This time evolution is

consistently suggested by an AMOC index based on sea surface temperatures, by the hemispheric temperature difference, by coral-based proxies and by oceanic measurements. We discuss a possible contribution of the melting of the Greenland Ice Sheet to the slowdown. Using a multi-proxy temperature reconstruction for the AMOC index suggests that the AMOC weakness after 1975 is an unprecedented event in the past millennium ($p>0.99$). Further melting of Greenland in the coming decades could contribute to further weakening of the AMOC.

The meridional overturning circulation (MOC) transports heat from the subtropics to high latitudes and hence plays an important role in the Earth's climate. A region crucial for the MOC is the northern North Atlantic and the adjacent Nordic Seas, where waters transported northwards in the MOC upper limb progressively cool, gain density and eventually sink into the southward flowing lower limb. Here we will discuss the variability of the subpolar gyre circulation, the MOC and heat transport as quantified from a joint analysis of hydrographic and velocity data from eight repeats of the Greenland to Portugal OVIDE section (1997-2014), satellite altimetry and ARGO float measurements. For each repeat of the OVIDE section, the full-depth absolute circulation and transports were assessed using an inverse model constrained by ship-mounted Acoustic Doppler Current Profiler data and by an overall mass balance. The obtained circulation patterns revealed remarkable transport changes in the whole water column and evidenced large variations (up to 50% of the lowest value) in the magnitude of the MOC computed in density coordinates ($MOC\sigma$). The extent and timescales of the $MOC\sigma$ variability in 1993-2014 were then evaluated using a monthly $MOC\sigma$ index built upon altimetry and ARGO data at the OVIDE section location. The $MOC\sigma$ index, validated by the good agreement with the estimates from repeat hydrographic surveys, shows a large variability on monthly to decadal time scales, with an inter-annual variability from less than 15 Sv to about 25 Sv (1 Sv = 1,000,000 m3s-1). The heat transport estimated from the repeated hydrographic OVIDE sections varies between 0.29 and 0.70 ± 0.05 PW and is linearly related to the $MOC\sigma$ intensity.

The uptake of atmospheric carbon dioxide in the subpolar North Atlantic Ocean declined rapidly between 1990 and 2006. This reduction in CO2 uptake was related to warming at the sea surface, which—according to model simulations—coincided with a reduction in the Atlantic MOC. Here, we use the observed oceanic transport of volume, heat and carbon dioxide to track the CO2 uptake in the subtropical and subpolar regions of the North Atlantic Ocean over the past two decades. We separate anthropogenic carbon—derived from human activities—from natural carbon by assuming that the latter corresponds to a pre-industrial atmosphere, whereas the remaining is anthropogenic. We find that the uptake of anthropogenic carbon dioxide occurred almost exclusively in the subtropical gyre. In contrast, natural carbon dioxide uptake—which results from natural Earth system processes—dominated in the subpolar gyre. We attribute the weakening of contemporary carbon dioxide uptake between 1997 and 2006 in the subpolar North Atlantic to a reduction in the natural component. We show that the slowdown of the MOC was largely responsible for the reduction in carbon uptake, through a reduction of oceanic heat loss to the atmosphere, and for the concomitant decline in anthropogenic carbon dioxide storage in subpolar waters. To understand the mechanisms controlling the variability of the transport of anthropogenic carbon (Tcant) across the subpolar gyre, we decomposed it according to the net, the diapycnal and the isopycnal circulation. The diapycnal component is found to be the main driver of the Tcant variability. From this analysis, we propose a simplified estimator for the variability of Tcant based on the intensity of the $MOC\sigma$ and on the difference of anthropogenic carbon dioxide concentration between the upper and lower limb of the $MOC\sigma$ (ΔCant). This estimator shows a good consistency with the diapycnal component of Tcant, and helps to disentangle the effect of the variability of both the circulation and the Cant increase on the Tcant variability. We find that ΔCant keeps increasing over the past decade, and it is very likely that the continuous Cant increase in the water masses will cause an increase in Tcant across the subpolar North Atlantic Ocean at long timescale. Nevertheless, at the timescale analyzed here (1997-2010), the $MOC\sigma$ controls the Tcant variability, blurring any Tcant trend.

Oxygen Minimum Zones (OMZs), defined as suboxic ($O2<20$ µmol/L) subsurface layer and mainly associated with Eastern Boundary Upwelling Systems (EBUS), would contract and expand during cold and warming periods, respectively. In the current context of the ocean deoxygenation, OMZs are known to play a key-role on the evolution of climate (greenhouse gases) and on the ecosystems and fisheries (nitrogen loss, respiratory barrier, sulfidic events) at both local and global scales. The objective of the AMOP project ("Activities of research dedicated to the Minimum of Oxygen in the eastern Pacific") is to provide an estimate of physical and biological processes contributing to the O2 budget off Peru. The central hypothesis is that the physical and biogeochemical O2 contribution to the OMZ maintaining and variability depends on the characteristics of the different OMZ layers, where the oxycline behaves as an engine of an intense but intermittent biogeochemical and ecosystem activity. The project is focused in one of the most intense and shallow OMZs associated with the most productive upwelling system (10 % of the world fisheries), the Peruvian OMZ. The trans-disciplinary approach is based on a cruise that took place in January-February 2014 off Peru and that consisted in 8 fixed stations (~54 h) on 3 transects at 7°S, 12°S and 14°S with the RV Atalante. The cruise also benefited from experimental development (instrumentation, sensors: argo-floats experiments; drifting lines; a trimaran dedicated to ocean-atmosphere exchanges; nanomolar O2 measurements). AMOP has also led to the deployment of the first long term (2013-2014) subsurface mooring off Peru providing unprecedented information of the OMZ variability at diurnal to intraseasonal timescales, and invaluable data for the validation of a high resolution regional ocean-atmosphere-biogeochemistry coupled modeling platform under development within the project. This French-Peruvian-German project involving 5 other countries (~90

participants) is viewed as one of the main pilot projects of the SOLAS Mid Term Strategy Initiative on OMZ-EBUS. In this presentation, preliminary results of the project will be presented both on observations and modeling, illustrating current challenges for the investigation of OMZ dynamics in Eastern Boundary current systems.

P-1110-01

Recent changes and trends of the upwelling intensity in the Canary Current Upwelling System

A. Benazzouz (1) ; K. Hilmi (2)
(1) Institut National de Recherche Halieutique, Département océangraphie, Casablanca, Morocco; (2) Institut National de Recherche Halieutique, Département océanographie, Casablanca, Morocco

A summary of current knowledge for the quantification of the upwelling intensity from wind and SST is provided on the Canary Current Upwelling System (8°N-43°N) from 1982 to 2011. Statistical analysis of trends and seasonal changes of the upwelling activity are carried out in this work. Linear trends in upwelling intensity are estimated from both atmospheric forcing (wind stress) and thermal oceanic response (SST), both derived from satellite data, with a particular focus on the Cap Ghir of the moroccan area (30.5 °N).The results indicate different spatial trends in the upwelling favorable winds and an apparent increasing coastal warming associated with intensification of winds at the regional scale off Northwest Africa is found.

P-1110-02

Long term marine time-series expose underlying climate-driven changes in South America during the last 40 years

A. Arias (1) ; E. Alberdi, (2) ; R. Freije, (3) ; J. Marcovecchio, (1)
(1) Argentine Institute of Oceanography (IADO), CONICET, Bahía Blanca, Argentina; (2) Argentine Institute of Oceanography (IADO), CONICET, Bahia Blanca, Argentina; (3) Universidad Nacional del Sur, Chemistry, Bahia Blanca, Argentina

Climate Change is creating a dynamic of continuous changes in ecosystems. Generally, the expected consequences of these changes are global; however, the occurrence of extreme events and specific environmental problems are usually local or regional phenomenon. One of the keys to uncover climate-driven changes are the long term time-series of observations. While there are a number of long-term biological time-series on land, there are relatively few in marine environments. This is highlighted by the fact that the Intergovernmental Panel on Climate Change (IPCC) noted 28586 significant biological changes in terrestrial systems, but only 85 from marine and freshwater systems. The present research deals with this gap in the state of the art, focusing in an area which holds scarce to null long-term research on ocean observation and climate driven changes: the South Atlantic Ocean. From the results of the analysis of up to 40 years of oceanographic physicochemical variables measured at the Bahia Blanca Estuary (Dissolved Oxygen, pH, Chlorophyll, Phaeopigments, Temperature, Salinity, NH4, Particulate Organic Matter, NO2, NO3, Phosphorous, etc.) unknown underlying trends were uncovered. In order to test the variables trend throughout several time-scales, the continuous wavelet transform (CWT) was used to divide the continuous-time function into wavelets. Moreover, the use of Cross Wavelet Correlation (CWC) allowed to light the relationship between the variables throughout different time-scales. After that, a correlation analysis which linked the ocean observations to biological documented changes was assessed. As result, novel hypotheses were raised in the field of phytoplankton and zooplankton assemblages climate-driven control, crustaceans catches and fisheries recruitment. For instance:

- "climate-driven variations in ocean Temperature, pH, DO and Salinity can restrict the growth of the phytoplankton assemblages, leading to other factors (i.e., grazing) the size control of the cells"
- "low interannual variability of water temperature and water salinity favours higher fishing yields and vice versa»

Undoubtedly, these findings will strengthen the theory which propose climate-driven changes at marine coastal ecosystems as a consequence of global climate change and will be of high relevance for the international dialogue on "anthropogenic vs. climate-induced changes" over the oceanic ecosystems.

P-1110-03

Past and future seasonal changes in Sea Surface Temperature in the Western English Channel as derived from satellite data and CMIP5 multimodel ensemble

B. L'hévéder (1) ; S. Speich (2) ; F. Gohin (3)
(1) CNRS, LMD, Paris, France; (2) Ecolne normale superieure, Departement de geosciences, paris, France; (3) Ifremer, Dyneco/pelagos, Brest, France

Seasonal changes in Sea Surface Temperature (SST) in the Western English Channel are estimated for the last decades from high-resolution satellite data, obtained by concatenating Ifremer AVHRRSST, OSTIA and ODYSSEA data over 1986-2013. Coastal seas, well separated from offshore waters by intense frontal structures, present colder SST by about 1°C in the English Channel to 2°C in the Iroise Sea in summer. A significant warming trend, concentrated in the autumn season, is highlighted. It is stronger offshore, with a SST annual mean increase of 0.32°C/decade, while it amounts to 0.23°C/decade in coastal waters, where a strong vertical mixing induced by tides and wind acts to reduce surface warming.

The performance of an ensemble of global climate models, participating in the Coupled Model Intercomparison Project Phase 5 (CMIP5), in simulating recent seasonal changes of SST in the region is estimated. The median of CMIP5 models reproduces very well the observed SST mean seasonal cycle in offshore seas, but it less proficient in coastal waters due to model coarse resolution and absence of tidal forcing and related processes. In the Iroise Sea, the trend of the annual mean SST is relatively well simulated, albeit somewhat underestimated (0.20°/decade) and evenly distributed throughout the year.

The regional values of the annual mean SST as generated by the CMIP5 future scenarios simulations, range from 0.5°C (RCP2.6) to 2.5°C (RCP8.5) by year 2100, with a seasonal modulation leading to a more intense warming in summer than in winter. This increase in SST may strongly affect marine biomes, in particular phytoplancton and algae population density and phenology in the Western English Channel.

Comparing coastal and open ocean sea level variability and trend from altimetric data

A. Melet (1) ; F. Birol, (2) ; B. Meyssignac (2)
(1) CNES/LEGOS, Toulouse, France; (2) LEGOS, Toulouse, France

Since 1993, altimetry has provided an unprecedented opportunity to study sea level variability with a quasi-global coverage. Satellite altimetry indicates that sea level has been rising fast in response to global warming, but with large regional variations. However, standard altimetric data do not allow to study sea level variability and rise close to the coast, where the socio-economic impacts of sea level rise are the greatest. Recently, along-track altimetric data have been reprocessed at LEGOS/CTOH using algorithms adapted to coastal regions to recover information in coastal zones (this reprocessed coastal product is referred to as the XTRACK dataset here).

In this study, we first intercalibrate the along-track Topex-Poséidon, Jason-1 and Jason-2 XTRACK dataset to that distributed by AVISO to have consistent sea level data in the open ocean. Then, sea level trends are computed with the XTRACK dataset to analyse how sea level rise varies as a function of the distance to the coast. Spectral analyses are performed to assess the frequency bands for which

coastal sea level variability and open ocean variability differ.

Analyses are performed over two regions (West coast of Africa and southwest Pacific). They will be extended to the global ocean to provide a map of sea level trends over the 1993-2012 period for the coastal zones of the global ocean.

During the last deglaciation, centennial to millennial scale large climate changes occurred with a climate decoupling between the North and South poles called the bipolar seesaw. These events, expression of the complex interaction between the ocean, the atmosphere and the cryosphere, are not well understood yet. Associated with these events, CO2 outgassing from the ocean to the atmosphere occurred. These increases in atmospheric CO2, preceding the Earth's global temperature increase, have been an important factor of the deglaciation. The Southern Ocean plays a key role in the global climate. Intermediate and bottom waters formation occurs within the Southern Ocean and it is the region where the deeper ocean and the atmosphere are connected due to low density gradient and wind driven upwelling. We present the climatic behavior of the different Southern Ocean sectors during these climatic events, with a precise time scale. Thanks to the complementary archives and skills of Lund University and IPSL researchers, we combine the terrestrial records from the few islands present, in this mainly oceanic hemisphere, with oceanic high resolution records, using volcanic tephra to obtain a robust chronology for the marine records chronology and inconsequence a common 14C age scale. This multi-proxies approach allows reconstructing robust quantitative records of temperature and wind intensity evolution. Sediment core records from the South-East Pacific sector of the Southern Ocean indicate that both temperature increase and intensification of the Southern Ocean upwelling in this area are coeval in this area as well as, within dating uncertainty of the records, with the temperature increase over the Antarctic and atmospheric CO2 increase. In the Indian sector, a terrestrial record indicates a possible delay between the break in the increase of Antarctic temperature (Antarctic cold reversal within the deglaciation) and westerly wind belt shift. In the meanwhile, ocean records indicate that the sea surface temperature increase and the intensification of the Southern Ocean upwelling preceded the decrease or shift of the Antarctic circumpolar current. Such well-dated high resolution records will allow studying leads and lags between the climatic records of different North and South latitudes and thus establish the link between Southern Ocean and North Atlantic circulation changes. The space and time mapping of climatic changes will be compared to climate model experiments to disentangle the role of the different atmospheric and oceanic climate mechanisms of the bipolar seesaw. It is a necessary step to improve climate models that indicate a different response to fresh water discharge experiments designed to reproduce these rapid climatic events with a bipolar seesaw signature. Indeed the different models, used for future climate simulations, indicate different responses in the different sectors (Atlantic, Indian and Pacific) of the Southern Ocean for these experiments.

Interannual variability of upper ocean stratification in Bay of Bengal: observational and modeling aspects

F. T S (1) ; P. Anant (2) ; C. Gnanaseelan, (2)

(1) INDIAN INSTITUE OF TROPICAL METEOROLOGY, T D DIVISION, PUNE MAHARASHTRA, India; (2) Indian Institute of Tropical Meteorology, T. s division, pune, India

The annual cycle and interannual variability of stratification in Bay of Bengal (BoB) are studied using both observations and Global Ocean Data Assimilation System (GODAS) analysis during 2003-2012. Annual cycle of stratification and SST evolves coherently (correlation coefficient is 0.85) highlighting its role on modulating air-sea interaction over this climatologically important region. Spatial distribution of stratification shows strong seasonality in ARGO observations, whereas it is highly underestimated in GODAS with highest discrepancies during fall and spring. The annual cycle of SSS in GODAS is out of phase with observations implying possible potential feedbacks. During La Niña years, SSS drop in fall and winter and are lesser than those reported during El Niño years. All these features are misrepresented in GODAS. As stratification modulates air-sea interaction over BoB especially during El Niño and La Niña years, such misrepresentation of ocean stratification may lead to improper thermocline-SST coupling in the models. The mean stratification and its interannual variability in GODAS are weaker than observed even though interannual variability in fresh water flux (P-E) is higher in GODAS. Detailed analysis of GODAS with in-situ observations reveals that upper ocean current shear (vertical) is overestimated in GODAS leading to unrealistically strong mixing which is primarily responsible for the deeper penetration of surface warm and freshwater resulting weaker stratification. As GODAS is used to initialize the ocean model of the Coupled Forecasting System for seasonal prediction of Asian monsoon, proper representation of stratification is essential. This study advocates the need of accurate representation of mixing in GODAS for improved summer monsoon forecast.

Methane distributions and sea-to-air fluxes in the South China Sea and the West Philippines Sea

HC. Tseng (1) ; CTA. Chen, (2) ; AV. Borges, (3) ; TA. Delvalls, (1)

(1) University of Cadiz, Physical Chemistry Department, Cadiz, Spain; (2) National Sun Yat-sen University, Department of oceanography, Kaohsiung, Taiwan; (3) University of Liege, Unité d'océanographie chimique, Liege, Belgium

We collected 700 water samples in the South China Sea (SCS) and 300 water samples in the West Philippines Sea (WPS), during 8 cruises from August 2003 to July 2007 in order to determine methane (CH4) distributions from surface to depths of 4250 m. The surface CH4 concentrations were above atmospheric equilibrium, both in the SCS and the WPS, with an average concentration of 4.5±3.6 and 3.0±1.2 nM, respectively. The sea-to-air fluxes were computed, showing that the SCS emits CH4 at a rate of 8.6 µmol m-2 d-1 and the WPS at a rate of 4.9 µmol m-2 d-1. In the SCS, the CH4 emissions were higher over the continental shelf (11.0 µmol m-2 d-1) than over the deep ocean (6.1 µmol m-2 d-1), owing to higher productivity and closer coupling with the sediments in the continental shelf. The SCS emited 30.1*10^6 mol d-1 CH4 to the atmosphere and exported 1.88*10^6 mol d-1 CH4 to the WPS during the wet season.

Both the concentrations of CH4 and chlorophyll a were higher in the 200m surface layer of the WPS, however, not correlated unlike recent reports suggesting the occurrence of CH4 production in surface oxic waters directly related to phytoplankton activity. CH4 concentrations generally decrease with depth below the euphotic zone but remain constant below 1,000 m, both in the SCS and the WPS. Some high CH4 values were observed at mid-depths in the SCS, and were most likely attributed to the anoxic generation of CH4 or the release of CH4 from sediments, gas hydrates or gas seepage.

Why should coral reefs care about ocean acidification: general consensus, misconceptions and future research priorities

R. Rodolfo-Metalpa (1) ; F. Houlbrèque (1) ; C. Payri (1)
(1) Institut de Recherche pour le Développement, Umr entropie-laboratoire d'excellence corail, Nouméa cedex, New Caledonia

Ocean acidification (OA) is one of the main threats for marine habitats, likely causing changes in biodiversity and ecosystem functions within this century. Ocean acidification might affect various physiological parameters at different stages of the animal life history, from their reproduction to larval phases and adult growth. Coral reefs, harboring a large part of the world's ocean biodiversity, will be the most affected by OA, as reef calcification and dissolution rates are related to seawater carbonate chemistry. Studies show a decline in net calcification rates as a result of decreasing pH and carbonate ion concentrations, and increasing dissolution rates of carbonate skeletons. This alarming general consensus has convinced the scientific community to deeply investigate marine ecosystems face to climate change, becoming among the top global ocean research priorities. After more than a decade studying OA responses of single species, mostly acclimated for short-time periods in laboratory conditions to projected acidified levels, it is time to progress our knowledge by better projecting ecological impacts of future climate change scenarios.

Recent findings show that some calcifiers do not seem to be affected by OA. Not only were their responses highly species-specific but varied among experiments. These divergent results have clearly shown that our actual knowledge on biological responses to OA and the physiological mechanisms involved are extremely limited and that some assumptions we have used so far might be inaccurate. In addition to these gaps of knowledge, all the data collected so far are single species responses to artificial conditions. Only few studies have scaled-up single species responses to the ecosystem scale. In our study, we aim at deciphering past misconceptions on the effects of OA, and promoting challenging research priorities in the field. This includes: i) to simultaneously test OA with other global environmental alterations, such as warming and eutrophication, which will likely exacerbate the organism's sensitivity to OA; ii) to perform experiments in natural conditions, over longer periods, to guarantee at least a complete acclimation of organisms to natural variations. This requires a rapid implementation of in situ experimental systems able to change and to maintain suitable altered conditions; iii) to investigate keystone species/habitats potential abilities to adapt fast enough to environmental changes in order to guarantee vital ecosystem functions in the future. The best way to do that is through the use of sites naturally enriched in CO2 which have successfully been used as natural laboratories to study natural response of ecosystems to OA.

In Bangladesh, the Ganges, Brahmaputra, and Meghna Rivers come together to form the largest river delta in the world. This low-lying region of the Bay of Bengal is one of the most densely populated countries in the world and is prone to monsoonal flooding, potentially aggravated by an intense annual cyclonic activity. In this context, sea-level rise, along with tectonic, sediment load and groundwater extraction induced land uplift/subsidence, significantly exacerbate the Bangladesh's coastal vulnerability. Here we present the goals and first results of a Belmont Forum/IGFA-funded project, BanD-AID (http://Belmont-SeaLevel.org) that addresses the causes and consequences of coastal vulnerability of Bangladesh, The project's outcome will establish an advanced observation system based on contemporary space geodetic sensors to quantify (1) causes of sea-level rise and land motion and establish their robust vertical datum link, and (2) human interactions that governs coastal vulnerability and resilience in Bangladesh. We present the first results such as the apparent sea level rise at the Bangladesh coast gained by combining space geodetic observations, including satellite altimetry, GRACE and GPS/InSAR, together with in-situ tidal and river gauges, and different reconstructed sea-level approaches. This unique combination of different satellite techniques and in-situ information offers the possibility to better quantify the major contributions to the relative sea-level rise at the Bangladesh delta, towards addressing its coastal vulnerability and future sustainability.

Sea-level rise has been recognized as a major source of coastal vulnerability. Several areas, including low-lying Pacific islands and low lying countries such as Kiribati, Tuvalu, Marshall Islands and Bangladesh have been identified as being highly vulnerable to the effects of sea-level rise. While the major global source of sea-level rise is climate change, several other local factors can have as strong or stronger an effect than climate-based sea-level rise on coastal vulnerability.

We will present several case studies illustrating situations where increased coastal vulnerability is not solely attributed to climate change. We describe several other factors that can enhance the relative sea-level rise, such as natural factors like tectonic motions, erosion, sediment loading and local sea-level variability, and human factors like poorly designed development. Illustrating these factors using examples from Kiribati, Vanuatu, New Caledonia and Bangladesh, we emphasize that although climate related sea-level rise is a global issue, it can be locally combined with several other factors, modulating its value and impact. Studies of each individual case at the local scale are mandatory for adequate prediction and mitigation in the future.

Influence of climate changes on mangrove ability to fix and store CO2

C. Marchand (1) ; T. Meziane, (2) ; M. Allenbach (3) ; A. Leopold, (3) ; TT. Nhutrang (4) ; A. Alfaro (5)
(1) Institut de Recherche pour le développement (IRD), Paris, France; (2) MNHN, Paris, France; (3) University of new caledonia, Noumea, New Caledonia; (4) University of Sciences, VNU, Ho Chi Minh City, Vietnam; (5) University of Technology of Auckland, Auckland, New Zealand

Mangroves are forested ecosystems developing in the intertidal zone of tropical and subtropical coastlines. They cover up to 140,000 km² worldwide, and extend from 30°N to 38°S (1). They are amongst the most productive ecosystems in the world (2). Furthermore, they have been suggested to be enhancers of heterotrophic secondary production and offshore fisheries. In addition, it is well recognized that tropical mangrove ecosystems provide a high abundance of food, shelter, and breeding and nursery habitats for a diverse community of terrestrial, aquatic and aerial organisms, including many endangered species (3). At a larger scale, the high net primary productivity of mangroves and low decomposition rates results in global atmospheric CO2 sinks (4). In addition, mangroves are crucially important ecologically and economically, supporting a wide variety of ecosystem services (5). For example, mangroves stabilize the shoreline and serve as barriers against erosion. One of the most dramatic examples of the efficiency of this biological system as protection from catastrophic climatic events was demonstrated in 2004, when a large-scale tsunami devastate most coastal areas, but mangrove forested shorelines were significantly less affected (6). The annual economic value of mangroves, including products and services has been estimated to be US$ 200,000-900,000 ha-1 (7). Mangrove ecosystems have been decreasing dramatically worldwide, mainly due to habitat destruction. Once mangroves covered more than 200,000 km2 worldwide (8). However, human population growth and urbanization of coastal areas, expansion of industrial activities, and exploration and exploitation of natural resources have resulted in a current decrease in mangrove area of 1 to 2% per year. This declining rate is equivalent or even higher than that of other threatened ecosystems, such as coral reefs or primary rainforests (9). Mangrove ecosystems also are also threatened by climate change. However, the responses of mangrove ecosystems to climate changes are not well understood (10). Relative sea-level rise may be the greatest threat to mangroves because most mangrove sediment surface elevations are not keeping pace with sea-level rise (11). Additionally, the increases of temperature and atmospheric CO2 concentrations may also modify their functioning and distribution. Reduced mangrove area and health will increase the threat to human safety and shoreline development from coastal hazards, such as erosion, cyclonic events, and tsunamis (12). Mangrove habitat loss also may reduce coastal water quality, biodiversity, and fish and crustacean breeding and nursery habitats. Such ecological deterioration may have direct and indirect adverse effect on adjacent coastal habitats, and may eliminate a major resource for human communities that rely on mangroves for numerous products and services. Mangrove destruction also has the potential to release large quantities of stored carbon, which can have dramatic global implications (13). A synthesis of the current knowledge will be proposed, and our project of mangrove monitoring in the Indo-pacific area will be presented.

Dengue fever is the most important mosquito-borne viral disease, with 390 million people being infected each year and 2.5 billion people living in areas at risk of dengue worldwide. The rapid global spatial spread over the past 40 years is likely to be due to recent socio-economic changes such as global population growth and uncontrolled urbanisation but these factors need to be associated with suitable climatic conditions before dengue fever can establish itself in a given country, for it is transmitted by a number of mosquito species, mainly Aedes aegypti, whose life cycle is influenced by temperature, rainfall and humidity. In the following contribution, we focus on the South Pacific region, a vast, oceanic region where dengue epidemics are recurrent, aiming at disentangling socio-economic factors from climate factors.

We first analyse an original dengue database covering the 1971-2009 period across the South Pacific. In the Pacific region, dengue epidemics occurred every 3 to 6 years, with each epidemic wave caused by the regional circulation of 1 of the 4 dengue virus serotypes, with very limited serotype co-circulation. There are no apparent spatial propagation patterns in the region, and countries such as French Polynesia and New Caledonia are the most regularly affected. There is a weak anti-correlation between the major El Niño climate variability and the annual number of countries experiencing an epidemic, suggesting a link between climate and dengue epidemics. However, while the South Pacific has experienced a weak + 0.5°C trend in temperature, there is no detectable overall/regional long-term trend in the evolution of the number of affected countries for the past 40 years. However, local trends exist: New Caledonia is experiencing a positive trend whereas dengue epidemic frequency is decreasing in some smaller islands. We then analyse dengue epidemic profiles per country (endemic, regular epidemics, or sporadic epidemics). We identify variables linked to the different profiles by fitting a statistical model based on variables characterizing the socio-economic situation (e.g. GDP) or climate (e.g. temperature) in each country. These statistical models are able to reproduce the major epidemic profiles. Assuming the socio-economic variables to remain constant over time, we project these models for the next 100 years using models of the IPCC-AR5 under RCP8.5.

Finally, we focus on the case of New Caledonia where very high quality data allows a more quantitative analysis. At present, dengue epidemics there occur approximately every 6 years. Using spatial statistical modelling, we show that the primary variables explaining the spatial distribution of incidence rates are the mean temperature and a variable highly correlated with people's way of life. Using this model, we show that by the end the 21st century, with temperature increasing by approximately 3°C as projected by 6 IPCC-AR5 models in New Caledonia, mean incidence rates will be multiplied by two, with areas currently at low risk of dengue fever being highly exposed in the future. In terms of dengue epidemics recurrences, we also build a temporally dynamic model at weekly time

scales allowing the detection of the beginning and length of dengue epidemics. One key variable is the number of days where temperature exceeds 32 °C. As this number will increase substantially over the next 100 years in the IPCC-AR5 models, we show that the proportion of dengue epidemic years will rise from 17 % at present to 100 % in the RCP8.5 scenario and 66 % in the RCP4.5 scenario, with the duration of dengue epidemics substantially increasing compared to the present day. Implications for the future of dengue virus circulation in the South Pacific are discussed on the basis of our results

Mass mortality events in atoll lagoons: present environmental control and increased future vulnerability with climate change

S. Andrefouet (1) ; C. Dutheil, (1) ; C. Menkes (2) ; M. Bador (3) ; M. Lengaigne (4)

(1) IRD, Noumea, New Caledonia; (2) IRD, LOCEAN, Noumea, New Caledonia; (3) CERFACS, Climate Modelling and Global Change team, Toulouse, France, France; (4) UPMC, Paris, France

Several geomorphologically closed atolls of the Pacific Ocean have experienced in recent decades mass benthic and pelagic lagoonal life mortalities, that are due to unusual calm weather conditions lasting for several weeks. These events, although poorlyknown and characterized, pose a major threat for resource sustainability for islanders, and need to be taken into account for long-term resource management. A sample of eleven mortality events on eight atolls from the central South Pacific occurring between 1993 and 2012 were revisited to estimate the environmental thresholds required to trigger such events. We investigated thresholds and spatial patterns of sea surface temperature, significant wave height and wind stress satellite data. Then, using these thresholds, spatial maps of present-day potential risk are produced for the central South Pacific region. The highest risk zone lies north of the Tuamotu Archipelago in French Polynesia. To assess future risks in a climate change era, a regional climate model is used to downscale the projected future climate and to estimate the potential change in risk by the end of the 21st century. This process highlights a relative risk increase of up to 60% for the eastern Tuamotu atolls/ However, caution is required given the limited number of case-studies available to train the analysis and identify thresholds. This study suggests that long-term monitoring of the biophysical conditions of the lagoons at risk is needed to precisely identify the physical thresholds and better understand the biological processes involved in these rare, but consequential, mass mortality events.

Mesopelagic heterotrophic N2 fixation related to organic matter composition in the Solomon and Bismarck Seas (Southwest Pacific)

M. Benavides (1) ; PH. Moisander, (2) ; H. Berthelot (3) ; T. Dittmar, (4) ; O. Grosso (5) ; S. Bonnet (6)

(1) Mediterranean Insitute of Oceanography, Marseille, France; (2) University of Massachusetts Dartmouth, Biology, Dartmouth, United States of America; (3) Aix Marseille University, Mediterranean institute of oceanography, Marseille, France; (4) Institute for Chemistry and Biology of the Marine Environment , Research group for marine geochemistry, Oldenburg, Germany; (5) CNRS, Mediterranean institute of oceanography, Marseille, France; (6) IRD, Mediterranean Institute of Oceanography, Noumea, France

The oceans play a key role in absorbing carbon dioxide (CO2) emitted by human activities. This absorbing power depends largely on the activity of microalgae, which take up CO2 using nutrients and sunlight. The availability of nutrients is thus essential for maintaining life in the oceans and balancing global CO2 levels. In open ocean areas nitrogen is mainly provided through nitrogen fixation, a process performed by specific microorganisms called diazotrophs. Primary production in the oceans is strongly limited by the availability of fixed nitrogen. In open ocean nutrient-impoverished areas, which make up ~50% of the global ocean surface, nitrogen is mainly provided through the process of biological atmospheric nitrogen (N2) fixation. N2 fixation is carried out by the so termed diazotrophs, marine microorganisms that may belong to the cyanobacteria, bacteria or archaea. For many years, autotrophic diazotrophs were thought to be the most abundant diazotrophs in the ocean. Autotrophic diazotrophs need light to fix carbon dioxide via photosynthesis, and therefore are constrained to the sunlit layer of the ocean, which is generally less than 100 m deep. Recent investigations have revealed that heterotrophic diazotrophs, which cannot photosynthesize, are present in greater abundance than autotrophic diazotrophs in the world's oceans. Heterotrophic diazotrophs are not constrained by the availability of light and therefore are able to live in the dark ocean, the largest and less studied habitat on Earth. This discovery significantly expands the boundaries where N2 fixation was though to be possible and theoretically increases the inputs of fixed nitrogen to the ocean, which remain unaccounted for. The diazotrophs inhabiting mesopelagic dark waters are heterotrophic and depend on organic matter for their nutrition. In this habitat, these microorganisms can live in association with oxygen minimum zones or local oxygen deficit microzones like organic particles. However, the relationship of heterotrophic diazotrophic activity and diversity with organic matter is unknown. We investigated N2 fixation along two transects in the Bismarck and Solomon Seas (Southwest Pacific, Transects 1 and 2 respectively). In Transect 1, transparent exopolymer particles (TEP) where higher and oxygen concentrations lower than in Transect 2. The presence of N- and P-containing dissolved organic matter (DOM) compounds was also higher in Transect 1 than in Transect 2, as revealed by Fourier transform ion cyclotron mass spectrometry. N2 fixation rates (0.09-1 nmol N L-1 d-1) were higher in Transect 1 than in Transect 2, and correlated positively with TEP and negatively with oxygen, reflecting the dependence of mesopelagic heterotrophic diazotroph activity on organic matter. The scores of the multivariate ordination of DOM samples (principal coordinate analysis) were negatively correlated with bacterial abundances and positively correlated with N2 fixation rates. We interpret these results as an active bacterial exploitation of the DOM pool and its use to sustain diazotrophic activity. Phylogenetic analyses of the nifH gene detected γ-, δ-, α- and β-proteobacteria (Cluster I), Cluster III and Cluster IV. The relative importance of anaerobic Cluster III phylotypes in our clone library (26% of sequences), suggests that N2 fixation was partially supported by diazotrophs with a particle-attached lifestyle. Custom-designed quantitative PCR primer-probe sets were designed for three selected phylotypes. The abundances of a phylotype close to Cluster III ranged from undetectable to 1000 nifH gene copies L-1. Altogether, our results provide new insights into the mysterious ecology of heterotrophic diazotrophs and suggest that in situ organic matter sustains their N2 fixation activity. The input of fixed N2 by these organisms is significant and potentially contributes significantly to nutrient replenishment and primary production in the SW Pacific.

Autonomous observations with Bio-Argo floats in the Southern Ocean

S. Blain (1) ; H. Claustre (2) ; S. Speich (3) ; J. Uitz (2) ; A. Poteau (2) ; G. Obolensky (1) ; M. Rembauville (1)

(1) Université Pierre et Marie Curie, CNRS, laboratoire Océanographie microbienne, banyuls/mer, France; (2) CNRS, Université pierre et Marie Curie, Laboratoire océanographique villefranche, Villefranche sur mer, France; (3) Ecole normale superieure, Departement de geosciences, paris, France

The Southern Ocean (SO) is the most remote and the least understood of the world's oceans, although it plays a crucial role in past and present climate state and changes. It is unique in being the only zonally unbounded ocean. For this reason, it is the major link by which water properties are exchanged among the other oceans. Moreover, the SO is a major source of natural CO2 due to the upwelling of CO2-rich deep waters and a major sink of anthropogenic CO2 due to the formation of intermediate and bottom waters. The SO also largely contributes to supply nutrients from the deep ocean to the upper water layer everywhere in the world ocean. For all these reasons, the SO plays a critical role in the control of the Earth's climate. In turn it is very sensitive to climate variability. Given its critical

role, changes in the SO have global ramifications. In fact, such changes are already under way. But at present, the SO remains particularly under-explored. The SO extends over a vast area of the Earth's surface and it is located far away from the other continents and most of the research facilities. Extreme weather conditions and significant sea-ice coverage prevail over most of the year. This results in a scarcity of oceanographic data that limits our ability to understand key climatic-relevant processes and document ongoing changes.

The SOCLIM (Southern Ocean and Climate) project intends to implement a cutting-edge approach that will qualitatively and quantitatively improve the observation of the SO via pioneering in situ data acquisition with deployment of instrumented profilers and moorings.

Ten new-generation Bio-Argo floats were launched in water off South of Africa in the Antarctic Circumpolar Current from December 2014 to January 2015 and they are now entering the Indian sector of the SO. These floats are equipped with sensors that measure salinity, temperature, chlorophyll-a, color dissolved organic matter, backscattering at 700nm, transmission at 650nm, oxygen, nitrate and light attenuation at different wavelengths. They are collecting data in the Sub-Antarctic and Antarctic zones south east of Africa and around the Kerguelen Plateau. We will present the first data gathered during the austral summer and fall 2015. They will provide first insights in the dynamics of the termination of phytoplankton blooms in different environments and contribute to quantify the biological pump of CO2 in the SO. We will also present the plan for the deployment of an instrumented mooring in the region of Kerguelen to be deployed in 2016.

P-1111-04

Carbon production and export are fuelled by dinitrogen fixation and dissolved organic nitrogen in the South-western Pacific Ocean: results from the VAHINE mesocosms experiment

S. Bonnet (1) ; H. Berthelot (2) ; T. Moutin (2) ; S. L'helguen (3) ; K. Leblanc (4) ; S. Hélias (4) ; O. Grosso (4) ; N. Leblond (5) ; B. Charrière (6)

(1) IRD, Mediterranean Institute of Oceanography, Noumea, France; (2) Aix Marseille University, Mediterranean institute of oceanography, Marseille, France; (3) University of Bretagne Occidentale, Lemar, Brest, France; (4) CNRS, Mediterranean institute of oceanography, Marseille, France; (5) CNRS, Lov, Villefranche sur mer, France; (6) CNRS, Centre de formation et de recherche sur les environnements méditerranéens, Perpigan, France

The oligotrophic ocean represents 80 % of the global surface ocean. Its role on CO2 sequestration has long been considered to be low, but this view is currently challenged by new studies highlighting alternative pathways for carbon export to the deep ocean. In these systems, carbon production is limited due to nitrogen (N) scarcity but dinitrogen (N2) fixation and dissolved organic nitrogen (DON) would represent significant nitrogen (N) sources for the ecosystem. Here we deployed in New Caledonia large in situ mesocosms in order to investigate (1) the contribution of N2 fixation and DON use to primary production (PP) and particle export and (2) the fate of the freshly produced particulate organic N (PON) i.e. whether it is preferentially accumulated and recycled in the water column or exported out of the system. The mesocosms were fertilized with phosphate (P) in order to prevent P-limitation and promote N2 fixation. The diazotrophic community was dominated by diatoms-diazotrophs associations (DDAs) during the first part of the experiment for 10 days (P1) followed by the unicellular N2-fixing cyanobacteria UCYN-C the 9 last days (P2) of the experiment. N2 fixation rates averaged 9.8±4.0 nM d-1 and 27.7±8.6 nM d-1 during P1 and P2, respectively. NO3- concentrations (<40 nM) in the mesocosms were a negligible source of N indicating that N2 fixation was the main driver of new production all along the experiment. The contribution of N2 fixation to PP was not significantly different during P1 (9.0±3.3 %) and P2 (12.6±6.1 %). However, the e-ratio that quantifies the efficiency of a system to export particulate organic carbon (POCexport) compared to PP (e-ratio = POCexport/PP) was significantly higher ($p<0.05$) during P2 (39.7±24.9 %) than during P1 (23.9±20.2 %) indicating that the production sustained by UCYN-C was more efficient at promoting C export than the production sustained by DDAs. During P1, PON was stable and the total amount of N provided by N2 fixation (0.10±0.02 µM) was not significantly different from the total amount of PON exported (0.10±0.04 µM), suggesting a rapid and probably direct export of the recently fixed N2 by the DDAs. During P2, both PON concentrations and PON export increased in the mesocosms by a factor 1.5-2. Unlike in P1, this PON production was not totally explained by the new N provided by N2 fixation. The use of DON, which concentrations decreased significantly from 5.3±0.5 µM to 4.4±0.5 µM, appeared to be the missing N source. The DON consumption of about 0.9 µM during P2 is even higher than the total amount of new N brought by N2 fixation (about 0.25 µM) during the same period. These results suggest that while DDAs mainly rely on N2 fixation for their N requirements, both N2 fixation and DON can be significant N-sources for carbon production and export following UCYN-C blooms in New Caledonia and by extension in the N-limited Ocean where similar events are likely to occur. This study confirms that in the South West Pacific, N2 fixation is a biogeochemically relevant process able to provide sufficient new N to drive new carbon production and export. These results are particularly important in the context of increasing temperatures that will probably increase the diazotrophic activity in the future ocean.

P-1111-05

The role of dinitrogen fixation on carbon export in the South Pacific: results from the OUTPACE project (Oligotrophy to UlTra-oligotrophy south PACific Experiment)

S. Bonnet (1) ; T. Moutin (2)

(1) IRD, Mediterranean Institute of Oceanography, Noumea, France; (2) Aix Marseille University, Mediterranean institute of oceanography, Marseille, France

The additional CO2 in the atmosphere, mainly resulting from fossil fuel emissions linked with human activities (anthropogenic CO2), is the main cause of global warming. The ocean has acted as a major sink of anthropogenic CO2 preventing a greater accumulation in the atmosphere and therefore a greater increase in the earth temperature. Although the biological pump provides the main explanation for the vertical gradient of carbon in the ocean, it was thought to be in an equilibrium state with an associated near-zero net exchange of CO2 with the atmosphere. Climate alterations are beginning to disrupt this equilibrium and the expected modification of the biological pump will probably considerably influence oceanic carbon sequestration (and therefore global warming) over a decadal time scale.

The overall goal of the OUTPACE (Oligotrophy to UlTra-oligotrophy PACific Experiment) project is to obtain a better representation of the influence of nitrogen fixation on the biological carbon pump in the South Western Pacific Ocean. The international OUTPACE cruise took place between February 18 and April 2, 2015, involved 30 scientists onboard, and covered around 5 000 km in the South Western Pacific Ocean from the North of New Caledonia to Tahiti.

The very first results are discussed in the context of global climate change and, more particularly, considering the role of the ocean in carbon sequestration through biological processes.

P-1111-06

The 3-dimensional potential vorticity structure and meridional overturning circulation of the Southern Ocean revealed using ARGO floats and data from instrumented elephant seals

C. Chapman (1) ; JB. Sallée (2)

(1) CNRS.LOCEAN-IPSL, Paris, France; (2) Sorbonne Universités, LOCEAN-IPSL, Paris, France

The meridional overturning circulation (MOC) of the Southern Ocean is a fundamental component of the climate system. The MOC exhibits first order control over the heat and CO2 budgets of the globe, forming the Earth's

large CO2 sink and mediating the exchange of heat, salt and chemical constituents southward and between ocean basins. Understanding the MOC is vital for understanding the climate system and predicting its future states.

To date, the vast majority of studies interpret the Southern Ocean MOC through a quasi 2-dimensional framework known as the Transformed Eulerian Mean (TEM). The TEM framework, developed for the study of the large scale atmospheric circulation, generally relies on zonal or streamwise averages. However, the Southern Ocean circulation is not 2-dimensional. Phenomena such as meso-scale turbulence, forced topographic meanders and mixing processes are highly localised due to the interaction between the Southern Ocean currents and large scale bathymetry. These local dynamics effect not only the regional, but the global potential vorticity structure of the Southern Ocean. It has been hypothesised that these local dynamics might have a strong influence on the MOC. We will present the results of a systemic program to study the MOC as a 3-dimensional system. Employing hydrographic profiles obtained from ARGO floats, cruises and instrumented elephant seals we develope maps of the 3-diemensional potential vorticity, geostrophic velocity and the associated fluxes due to stationary meanders. Using approximate force balances, we will use these maps to investigate the local overturning in the upper 2000m. Finally, we will discuss the implications for the large scale overturning.

P-1111-07

The O2C3 Project :Observing Pacific island societies facing climate change. Methodological, epistemological, ethical, and political implications

V. David (1) ; PY. Lemeur (1) ; C. Sabinot, (2) ; G. David (3) ; M. Mangeas (4) ; E. Rodary (5) ; V. Naidu (6)
(1) IRD, Département sociétés umr gred, Nouméa, New Caledonia; (2) IRD, Umr 228 " espace pour le développement", Nouméa, New Caledonia; (3) Institut pour le Développement (IRD), UMR 228 ESPACE DEV, Montpellier, France; (4) Institut de recherche pour le développement, Mathematics, espace-dev, Montpellier, France; (5) IRD, Département sociétés umr gred, Montpellier, France; (6) University of the South Pacific, School of governance, development and international affairs, Suva, Fiji

Pacific island societies bear the historical hallmark of vulnerability, mobility and resilience. They have displayed adaptive capacities on the long run as far as livelihood, social institutions and political organization are concerned. The current intensification of global and climate changes could jeopardize these polities as well as pushing them to elaborate innovative solutions to face these dramatic trends. Current research programs carried out by IRD social scientists with colleagues from other institutions on changing livelihoods, health, coastal and marine governance and the value of place and land give clues about the individual and collective agency developed by Pacific islanders to deal with the risks and uncertainties inherent in this unstable situation. Against these emerging and serious challenges, there is a growing consensus about the need to think more broadly and Oceania-wide by sharing information, establishing data bases, and participating in collaborative research on the human and societal dimensions of climate change. The joint Francophone Pacific and Anglophone Pacific project Oceania Observatory of Climate Change and Its Consequences (02C3) is an effort to replicate GOPS, the South Pacific Integrated Observatory for the Environment, Terrestrial and Marine Biodiversity in the Social Sciences and Humanities, to enhance cooperation and collaboration initially among scholars based in New Caledonia and Fiji (USP) but with the intention to promote immediate Oceania wide collaboration.

The focus of the O2C3 observatory would be on peoples' knowledge, norms and practices in an encompassing framework, including various registers of knowledge: local/traditional, administrative, scientific, statistical, legal, professional... This self-evident idea raises serious challenges as far as methods, epistemology, data management and ethics are concerned. Collecting legal texts and scientific articles dealing with the issue does not raise specific difficulty, aside from localizing and accessing sources and making relevant information available to all. Identifying mobility forms linked to climate change (climate and environmental refugees, let alone mining refugees) is also feasible. When it comes to local knowledge, practices and representations of environmental and climate changes, things become trickier. There is a need for developing an in-depth reflection (1) on pertinent disciplinary and trans-disciplinary concepts that could be mobilized in social sciences for collecting and analyzing these data and (2) on the methodological and ethical implications of this type of data production and maintenance.

The O2C3 project seeks to contribute to this effort by bringing together social scientists to cooperate on the human dimensions of climate change. The first step would be to develop a collective framework on the issue of producing, collecting, managing social data on climate change and how to make them available quickly to stakeholders and decision makers. The second step would be to establish an expanding network of social scientists and humanity scholars that will focus on Pacific Island Countries and Territories (PICTs) people's awareness of climate change causes and consequences, stake holder standpoints, and governments' policies and policy implementation on climate change. Third step, it will build and host a shared digital database of information relating to climate change that will be a useful resource for above-mentioned decision makers, academics and other stakeholders.

P-1111-08

Variability in subtropical-tropical cells drives oxygen levels in the tropical Pacific Ocean

O. Duteil (1) ; C. Boening (1) ; A. Oschlies (1)
(1) GEOMAR, Kiel, Germany

Previous studies found a negative trend in oxygen concentrations in tropical regions during the last decades. Employing a biogeochemical circulation model, we highlight the importance of wind driven ocean transport associated with the Subtropical-Tropical Cells (STCs) in setting the oxygen levels in the tropical ocean. The observed and simulated slowdown of the STCs by 30 percent from the 1960s to the 1990s caused a decrease in oxygen transport to the tropics. Transport of phosphate was similarly reduced, decreasing export production and respiration. The effects of physical transport and biological consumption partly compensate, damping oxygen interannual and decadal variability. Our results suggest that the observed residual oxygen trend in the tropical Pacific is mainly driven by changes in oxygen transport. Accordingly, the observed recent strengthening of the STCs leads us to expect a pause in the oxygen decrease or even an increase of tropical Pacific oxygen values in the near future.

P-1111-09

Impact of the initialization with different ocean reanalyses on forecast bias in seasonal hindcasts

E. Exarchou (1) ; C. Prodhomme (1) ; V. Guemas, (1) ; F. Doblas-Reyes (1)
(1) IC3, Barcelona, Spain

We analyze seasonal hindcasts performed with EC-Earth3 that are initialized from two different ocean reanalysis estimates (ECMWF-ORAS4 and MERCATOR-GLORYS2V1), with the goal to investigate the impact of the different ocean reanalysis on the model bias and the model forecast skill. The seasonal hindcasts are four months long, consist of 10 ensemble members and they are initialized every May and November between 1993 and 2009. We find that the forecast initialized with ORAS4 is globally more skillful than the one initialized with GLORYS, particularly in the tropics. To study how the SST bias development relates with skill, we focus on the Tropical Atlantic, and in particular in two specific regions: the Atlantic3 region (ATL3), and the Angola-Benguela Area (ABA), where most climate models exhibit strong systematic biases. In both sets of hindcasts, a strong warm surface temperature bias develops in less than one month in winter or summer in ABA, and a strong cold surface temperature bias develops in one month in winter in ATL3. The biases in ATL3 in the hindcasts initialized with GLORYS2V1 are particularly strong in 1997, 2001 and 2003, and are caused by subsurface temperature errors in GLORYS. Despite the warm surface temperature

biases in ABA, monthly mean netsurface fluxes errors are negative, indicating that errors in SST most likely have an oceanic origin; this is also corroborated by the presence of strong subsurface temperature biases. Errors in the upwelling of the water masses could be in turn related to wind stress errors. We further investigate this possibility by performing additional sensitivity experiments using fixed windstress over the upwelling regions.

P-1111-10

Ant invasions in the light of climate change: forecasting a major threat for island biodiversity and economy

H. Jourdan (1) ; C. Gomez (2)
(1) IRD-Institut de Recherche pour le Développement, UMR 237 IMBE, Nouméa, New Caledonia; (2) IRD- Institut de Recherche pour le Développement, Umr 237 imbe, Nouméa, New Caledonia

In the last four centuries, spread of exotic species have been steeply rising through human mediated transportation, and have been responsive for major changes to natural ecosystems as well as major consequences and damages to human activities with tremendous associated economic costs. This situation is especially exacerbated in island context, where biological invasions are considered as the main driver of change and threat for both biodiversity and human societies. In the same time, the whole biosphere is experiencing consequences of climate change. There is, now, a wide consensus that climate change will also contribute to exacerbate threats posed by invasive species to ecosystems and human societies. Scientists estimate that this will be especially true for ectotherm organisms, whose current distributions are limited by thermal barriers. But to date, these assumptions have not been widely tested or validated. Among ectotherm organisms, ants are recognised as major invasive organisms, according to their high contribution and dominance in ecosystems, high aggressiveness in context of invasion as well as economic losses related to their spread (decreased of agricultural production, damage to infrastructure, management expenses..). Then this insect group represents an ideal biological model to test current assumptions, especially in the context of fragile insular ecosystems which are considered as major biodiversity hotspots.

Here we present first results of a study, which aims at providing a better understanding of the patterns and processes behind ant invasions as well as the impacts they have on invaded communities and the projections that one can infer from these for the future as a consequence of global environmental change (under climate change driver).

To better understand the main determinants of the distribution of exotic ant species, we developped species distribution models (SDM) to predict suitable ranges for 20 major invasive ants across Pacific islands. We also explored the evolution of these patterns in the future. We modeled current distributions, based on bioclimatic parameters, soil characteristics and land cover. Future climatic data were sourced from the 5th IPCC assessment report, and it had been calibrated and statistically downscaled using the WorldClim data for 'current' conditions, in order to compare projections. Also, we used ordination analysis to define invasiveness potential and develop spatial projection of life history traits on dynamic invasive fronts, localized on distribution maps. Then, to better fit our predictions, we made a downscale to New Caledonia biodiversity hotspot, which is already affected by 16 ant species and at risk from the last 4 species. It provides us an unvaluable opportunity to validate in the field current occurrences, then field data have been use to recalibrate our prediction of the distribution. More answers are needed regarding future ant species assemblages, ecological determinants of the distribution dynamics of introduced ants: How climate is impacting life history traits that will facilitate invasiveness? How ant species assemblages get structured under the influence of life history traits or biotic interactions?

NB: Our project is involved in a current European Eranet Biodiversa funded project 2013-2016 "(FFII) Forecasting Future Invasions and their Impacts."-

P-1111-11

Climate change impacts on marine fisheries: assessing the catchment in Peninsular Malaysia

AHM. Kamal (1) ; J. Ismail (2) ; H. Idris (3)
(1) Universiti Putra Malaysia Bintulu Sarawak Campus, Animal Science and Fishery, Bintulu, Sarawak, Malaysia; (2) Universiti Putra Malaaysia Bintulu Sarawak campus, Animal science and fishery, Bintulu, Malaysia; (3) Universiti Putra Malaysia Bintulu Sarawak Campus, Animal science and fishery, Bintulu, Malaysia

Global climate change variations over the past 30 years have produced numerous impacts in the abundance and production performance of marine fish and fisheries worldwide. The consequences in terms of flooding of low-lying estuarine habitats due to over rainfall, fluctuation of temperature, dilution of water parameters, devastation of feeding and breeding habitats, salinity fluctuations and acidification of waters, high siltation in coastal area, changes in the sea water table and breeding triggers have raised serious concerns for the well-being of marine fisheries and their production. This study shows that the overall total catchment of marine fisheries was decreased 38% in 2009 compared to 1998 while considers the fishing gears and vessels number used in Peninsular Malaysia. Registered vessels number was increased up to 92% in 2009 compared to 1998 which eventually increased the total catchment volume of marine fisheries. In 2009, the catching efforts and performance was far low as per vessels compared to 1998. Analysis of climate change variables shows that temperature was decreased as rainfall was increased within the year from 1998 to 2009. However, it is still early to conclude that whether climate change variables could have unpleasant impacts on fish production in the tropical seas like Malaysia. In spite of that it is predicted that the prolong exists of monsoon and increases of rainfall in this area resulting the stresses and sometimes interfering on the habitat, reproductive cycle and their related ecosystems in this coastal marine environment in tropics.

P-1111-12

Inter-annual Variability of the Upper Ocean Temperature in the Tropical Western Indian Ocean

M. Manyilizu (1) ; D. Francois (2) ; P. Penven (3) ; C. Reason, (4)
(1) University of Dodoma, College of Informatics and Virtual Education, Dodoma, Tanzania, United Republic of; (2) Commonwealth Scientific and Industrial Research Organisation (CSIRO), Marine and atmospheric research, Wembley, Australia; (3) Institut de Recherche pour le Developpement (IRD), Centre ird de bretagne, Bretagne, France; (4) University of Cape Town, Department of oceanography, Cape Town, South Africa

Interannual variability of the upper ocean temperature in the tropical western Indian Ocean has been studied using a regional ocean model. The strongest SST variability occurs in the offshore region lying over high subsurface temperature variations located between 30 and 130 m. Such a region corresponds with strong variations in the thermocline depth. The lowest SST variations occur in the Tanzanian shelf waters and lie over the subsurface waters with the smallest temperature variations in the upper 200 m. Such smallest temperature variations match with weak variations in the thermocline depth. However, the region with the highest variability of the subsurface temperature is more explained by interannual variability related to strong thermocline variations. The thermocline variations can be associated with local Ekman pumping and/or remote influence from the large-scale climate modes. Anomalous local downwelling (upwelling) and downwelling (upwelling) Rossby waves generated during ENSO and IOD events lead to anomalies in the thermocline depth and hence in subsurface temperature. The strong variability in the offshore region is related to strong interannual variability in the thermocline associated with ENSO and the IOD.

P-1111-13

THOT (TaHitian Ocean Time series): a new kind of long-lasting deep-sea oceanographic station in the central South Pacific

E. Martinez (1) ; H. Claustre (2) ; M. Rodier, (1) ; A. Poteau (2) ; A. Mignot (3) ; M. Taquet (1) ; C. Ponsonnet (4) ; K. Maamaatuaiahutapu (5) ; C. Maes (6)

(1) IRD-Ifremer-UPF-ILM, Ecosystèmes insulaires océaniens, Tahiti, French Polynesia; (2) CNRS-Université pierre et Marie Curie, Laboratoire océanographique villefranche, Villefranche sur mer, France; (3) Massachusetts Institute of Technology, Cambridge, Massachusetts , United States of America; (4) Direction des Ressources Marines et Minières, Tahiti, French Polynesia; (5) University of French Polynésia, Tahiti, French Polynesia; (6) IRD-CNRS-Ifremer-UBO, Laboratoire de physique des océans, Plouzane, France

Through various physical, chemical and biological processes as well as their synergetic interactions, oceans play a key-role in the modulation of climate system, carbon cycle and marine ecosystems. In the central South Pacific, including the 47 % of the French maritime domain of French Polynesia, ocean dynamic plays a key-role in the El Niño Southern Oscillation (ENSO). ENSO is the dominant mode of interannual variability in the Pacific with strong effects at global scales. It also modulates the decadal oscillations of the Pacific Ocean and longer-term trends. Furthermore, being part of the South Pacific subtropical gyre, variability of the French Polynesia waters is representative of those in the subtropical gyres of the global ocean. To observe and characterize climate changes in this region, the deployment of long-lasting oceanographic survey stations is necessary to follow the evolution of oceanographic key parameters (e.g., temperature, salinity, oxygen, phytoplankton biomass). However, presently there is no deep-sea monitoring observatory in the central South Pacific.

The objective of the TaHitian Ocean Time-series (THOT) project is to set up a deep-sea oceanographic station to observe and improve the understanding of climate changes in the French Polynesia waters as representative of subtropical gyre and Pacific scales. This project will be part of existing international programs on climate and ocean observations (Bio-ARGO, CLIVAR). It will provide a synergy and complementarity to long-term observations for global ocean

Implementation of a mooring station, such as those already existing, is complex in French Polynesia due to its geographical, scientific, logistical and technological remote context. Thus the originality of THOT is to set up a long-lasting station to observe climate changes based on 1) a regular deployment of physical-biogeochemical profiling floats in the area of interest over the next two/three years; 2) then to deploy the next generation of biogeochemical profiling floats capable of horizontal displacement to replace in their initial position.

P-1111-14

Diazotrophic impacts on the biogeochemistry of the South Western Tropical Pacific and the implications of rising temperature and CO2

C. Menkes (1) ; C. Dupouy (2) ; I. Berman-Franck (3) ; S. Bonnet (2) ; F. Deboissieu (1) ; J. Lefèvre (4) ; M. Rodier, (5) ; I. Biegela (6)

(1) IRD, LOCEAN, Noumea, New Caledonia; (2) IRD, Mio, Noumea, New Caledonia; (3) Bar Ilan University , Mina & everard goodman faculty of life sciences, Ramat Gan, Israel; (4) IRD, Legos, Noumea, New Caledonia; (5) Institut de Recherche pour le Développement, Umr-241 eio, Papeete, France; (6) IRD, Mio, Marseille, France

The physical, chemical, biological, and biogeochemical characteristics of the south western tropical Pacific Ocean have been studied since the 1980's. The initial studies focused on the equatorial upwelling which crosses the Pacific and annually enriches surface seawaters. Primary productivity in this high-nutrient, low-chlorophyll (HNLC) region is limited by the availability of Fe and regulated by intense zooplankton grazing which provide forage for tuna fisheries. In contrast, in the Melanesian Archipelagoes, the upper layer of the tropical ocean (between 15 and 25°S) is characterized by stable thermal stratification and nutrient-depleted (DIN, DIP), oligotrophic water especially in austral summer. Expansive surface blooms in the region experience strong seasonal and El Nino/La Nina cycles. Thus, primary producers include a high abundance of organisms fixing atmospheric dinitrogen (diazotrophs) that inject new-nitrogen into the system, the diazotrophs (including the cyanobacterium Trichodesmium spp, diatom-diazotroph associations, and unicellular cyanobacteria, and heterotrophic bacteria). The new production sustained by diazotrophy and the transfer of this " new N" to the planktonic food web critically impacts regional and global carbon and nitrogen cycling. In coastal lagoons, cyanobacteria are a major component of the food web, and run-off from land drainage and pollutions from land may affect the coastal carbon cycle and lagoon equilibrium. Here we will present a comprehensive review of the biogeochemical investigations over the last 30 years and examine the predicted impacts of increasing sea surface temperatures and elevated atmospheric pCO2 (leading to ocean acidification) on the growth, abundance, and contributions of diazotrophs to carbon and nitrogen cycling in this region.

P-1111-15

Indian Ocean warming trends simulated by an OGCM

R. Sivankutty (1) ; C. Gnanaseelan, (1)

(1) Indian Institute of Tropical Meteorology, Theoretical Studies Division, Pune, Maharashtra, India

Tropical Indian Ocean (TIO) SST shows a steady increasing trend over the last 50 years. Many recent studies suggests that this surface warming has significant influence on large scale summer monsoon circulation features. In this study we investigate he reasons behind the TIO warming using OGCM simulations. The surface heat flux changes alone cannot explain the surface warming pattern in TIO. Significant changes large scale surface circulation in TIO is simulated by the model. The surface circulation change in TIO closely corresponds to surface wind changes and associated geostrophic response in the ocean. We propose an air-sea coupled feedback mechanism to explain the increased warming rate of central and eastern TIO. Results of model sensitivity experiments controlling the surface forcing parameters confirms that, TIO warming pattern is highly modulated by oceanic processes.

1112 - The Arctic Climate system

ORAL PRESENTATIONS

K-1112-01

The Physical Basis of Arctic Change

C. Lee (1)

(1) University of Washington, Seattle , United States of America

Research suggests that the Arctic responds to climate change earlier, and with greater intensity, than other components of the earth system, making it a useful barometer for the health of the global environment. Observed changes in the Arctic marine and cryosphere, including increased seasonality, rapid sea ice loss and accelerated melting of the Greenland ice sheet, are consistent with these ideas of 'Arctic amplification'. Such changes can produce substantial environmental and societal stress, with regional implications and potentially profound global impacts. The resulting challenges include accelerated coastal erosion, changing weather patterns and rising sea level. Arctic environmental change can also produce new opportunities, such as expanded resource extraction and shortened shipping routes. Accurate predictions of Arctic environmental change and its global impact are needed to inform the response to these challenges and support planning of future activity.

However, current predictions sometimes differ from observed Arctic change, motivating efforts to advance our understanding of the physical processes.

This presentation will provide an overview of our current understanding of some prominent changes in the Arctic ocean and cryosphere. A complex interplay between the physics of the atmosphere, cryosphere and ocean, with the potential for positive feedbacks (such as that between reduced ice cover, reduced albedo and increased absorption of solar radiation, known as the ice-albedo feedback) govern the observed response to climate change. This motivates efforts to establish integrated, interdisciplinary, international programs to advance understanding and, ultimately, improve predictive ability. Sustained, climate-scale Arctic observing represents a critical component of such efforts, and the state of such observing systems and their underlying technologies will thus be briefly reviewed here.

K-1112-02

Assessment of Arctic Feedbacks

B. Soden (1)

(1) University of Miami, Miami, FL, United States of America

Radiative feedbacks in the Arctic play a key role in determining the energy and moisture budgets both at the surface and top of atmosphere which, in turn, influences the atmospheric and oceanic circulation. The Arctic has experienced dramatic declines in summer sea ice over the past decade which has triggered a series of interconnected responses in the surface energy budget and the atmospheric feedbacks. The Arctic has become warmer, wetter, and cloudier. All of these changes further modulate the radiative fluxes at the surface. Observations indicate that the most pronounced warming occurs during boreal winter, with an increase in Arctic mean temperature of roughly 1K. This warming is associated with a pronounced sea ice loss in boreal summer which increases the evaporation rates (i.e. moisture flux). The resulting increase in water vapor and cloud cover enhances the downward long wave flux at the surface, contributing to earlier melt onset and the delayed autumn freeze up. This study will summarize the importance of these relationships using multiple observational data sets and compare the observed feedback strengths to those simulated in coupled ocean-atmosphere models.

K-1112-03

Biological impacts of recent climate change in the Arctic

D. Hik (1)

(1) University of Alberta, Department of Biological Sciences, Edmonton, Alberta, Canada

The ecology of the Arctic is changing in response to shifts in the climate system. Although Arctic species are well adapted to seasonal and diurnal variability in physical conditions, many of the observed climate-driven changes are leading to fundamental shifts in the structure and diversity of biological processes. What happens in both the marine and terrestrial environments has both local and global implications. For example, the tundra is a huge biome extending across 30 degrees latitutde. Vegetation changes show a complex pattern at larger scales, but overall there has been a rapid increase in woody vegetation (shrubs, trees), changes in phenology and albedo as a consequence of earlier snowmelt, and changes in foodweb structure and trophic interactions. Freshwater ecosystems are facing similarly large changes, and the ability of rivers, lakes and wetlands to maintain adequate streamflows, water levels and water quality for ecosystem sustainability is poorly understood. In the marine environment, there is already compelling evidence of a shift towards an increasingly pelagic system in the absence of summer sea ice. In both terrestrial and marine ecosystems, extreme events (e.g. winter rain, fire, storm surges) can overturn long-term trends, but there are still insufficient observations to adequately predict the future. I will provide a brief overview of current understanding of how Arctic ecosystems are responding to climate change and variability, and the most important research needs identified during the 3rd International Conference on Arctic Research Planning (ICARP III).

O-1112-01

The Regional Arctic System Model (RASM) - A Tool to Advance Science and Reduce Prediction Uncertainties of Arctic Climate Change

W. Maslowski (1)

(1) Naval Postgraduate School, Oceanography, Monterey, California, United States of America

Some of the largest changes due to climate warming are expected in the Arctic. However, 21st century projections of the magnitude of these changes vary widely in the latest suite of global climate predictions. In addition, several studies point to strong sensitivity of climate projections to multi-parameter space, varying within physically acceptable bounds. Such variations and sensitivities are the source of large uncertainties and limited skill in reconstructions of the past and present Arctic System, and in projections of the future state of this region.

We introduce a new tool for regional climate modelling, the Regional Arctic System Model (RASM), and demonstrate its advanced capability in simulating some critical physical processes and feedbacks, which significantly improve model representation of observed seasonal to decadal variability and trends in the sea ice cover.

RASM is a limited-area, fully coupled ice-ocean-atmosphere-land model that uses the Community Earth System Model (CESM) framework. It includes the Weather Research and Forecasting (WRF) model, the LANL Parallel Ocean Program (POP) and Community Ice Model (CICE) and the Variable Infiltration Capacity (VIC) land hydrology model. The ocean and sea ice models used in RASM are regionally configured versions of those used in CESM, while WRF replaces the Community Atmospheric Model (CAM). RASM has recently been upgraded to CICE Version 5.0 (CICE5.0) with (i) the new prognostic salinity thermodynamic model to represent sea ice growth and melt, (ii) a new anisotropic rheology to capture anisotropic sea ice dynamics at the multi-floe scale (of order 2-10km) and (iii) a form drag scheme to more accurately approximate ice-ocean and ice-atmosphere stresses. In addition, a streamflow routing (RVIC) model was recently implemented in RASM to transport the freshwater flux from the land surface to the Arctic Ocean. The model domain is configured at an eddy-permitting resolution of 1/12° (or ~9km) for the ice-ocean and 50 km for the atmosphere-land model components. It covers the entire Northern Hemisphere marine cryosphere, terrestrial drainage to the Arctic Ocean and its major inflow and outflow pathways, with optimal extension into the North Pacific / Atlantic to model the passage of cyclones into the Arctic. All RASM components are coupled at high frequency (i.e. 20-minute intervals) to allow realistic representation of inertial interactions among the model components.

Model results are presented from both fully coupled and a subset of RASM, where the atmospheric and land components are replaced with prescribed realistic atmospheric reanalysis data for 1948-2009. Seleceted physical processes and resulting feedbacks will be discussed to emphasize the need for high model resultion and fine-tuning of many present parameterizations of sub-grid physical processes when changing model spatial resolution. We also investigate sensitivity of simulated sea ice states to scale dependence of model parameters controlling ice dynamics, thermodynamics and coupling with the atmosphere and ocean. Finally, we show that sea ice extent commonly used to evaluate the model skill is not a sufficient model constraint as the modeled sea ice thickness distribution and volume can vary significantly while ice extent remains unchanged.

IPCC AR5: Projections of Arctic Change

K. Riemann-Campe (1) ; R. Gerdes (1) ; M. Karcher (1) ; F. Kauker (1)

(1) Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Sea ice physics, Bremerhaven, Germany

The climate is changing, which is particularly visible in the Arctic sea ice state. To plan the access to shipping routes, resource extraction, etc. several groups with different

interests would like to know the future development of Arctic sea ice coverage.

Climate scenario simulations with global coupled climate models, contributing to the coupled model intercomparison project phase 5 (CMIP5), are used to exploit possible scenarios for the sea ice distribution under climate change during the coming decades. Their results are also discussed in the IPCC assessment report no. 5 (AR5). More than 30 models take part in the CMIP5 experiments and together they estimate a very large uncertainty range for Arctic sea ice. CMIP5 models simulate the global climate change and their individual strengths differ regionally. Several studies show that if a limited number of CMIP5 models are chosen with respect to their regional strengths, the range of uncertainty decreases considerably for selected variables.

Within the projects ACCESS (Arctic Climate Change, Economics and Society) and ICE-ARC (Ice, Climate, Economics – Arctic Research on Change) we compare satellite sea ice concentration observations with simulated sea ice concentration of 34 CMIP5 models. The skill of the models varies within the region in the Arctic, the time period of the satellite observation used and the satellite data processing. Thus, we analyse two different satellite derived products over individual regions, which have been discussed as potential sites for resource extractions, as well as the whole Arctic for two different time periods. From this, we select the best four CMIP5 models with regard to the misfit between model and observations. Although the models agree on the general future reduction on sea ice area, they differ in the magnitude of the sea ice decrease and thus the timing of when the Arctic becomes 'ice-free'.

The sea ice coverage correlates well with the near surface air temperature in summer and with the position of warm Atlantic water during winter. These correlations exist in the chosen models but with strong differences. For example, the position of the warm Atlantic water entering the Arctic via the Fram Strait and the Barents Sea Opening varies considerably in the four chosen models. Therefore, one reason for the differences in future sea ice estimates from different models is the simulated change of the atmospheric and oceanic northward heat transport into the Arctic.

Different sea ice projections between climate models can be understood not only being due to differences of the sea ice model component, but the model realisation of oceanic and atmospheric northward heat transport.

Reconstruction of the Greenland ice sheet surface mass balance over 1900-2014 with the help of the regional climate MAR model

X. Fettweis (1) ; H. Gallée (2)
(1) University of Liège, Department of geography, Liège, Belgium; (2) Laboratoire de Glaciologie et Géophysique de l'Environnement, Grenoble, France

With the aim of studying the recent Greenland ice sheet Surface Mass Balance (SMB) rates with respect to the last century, we have forced the regional climate MAR model with ERA-Interim (1979-2014), ERA-40 (1958-2001), NCEP1 (1948-2014), NCEP2 (1979-2014), 20CR (1880-2012) and ERA-20C (1900-2010) reanalysis. While all of these forcing products are reanalyses, MAR simulates significant differences in SMB over the common period. A temperature correction of +1°C (resp. -1°C) had notably to be applied to the MAR boundary conditions given that ERA-20C (resp. 20CR) is ~1° colder (resp. warmer) over Greenland than ERA-Interim data over 1980-2010.

Discrepancies in simulated SMB is particularly high in regions where SMB measurements are missing suggesting that uncertainties in the current SMB reconstruction are high and observations are still needed before performing future projections. Comparisons with SMB measurements (along K-Transect), ice cores and satellite derived melt extent allows to select the best reanalysis forced data set.

All of these simulations show that i) the period 1961-1990 usually chosen as reference for SMB and ice dynamics (stable ice sheet) over Greenland is a period when the SMB was abnormally high in respect to the last 120 years; ii) SMB has been significantly decreasing after this reference period. Both ERA-20C and 20CR forced simulations suggest a precipitation increase over the last century but only the ERA-20C forced simulation suggests that SMB during the 1920-1930 warm period over Greenland is comparable with the SMB of the 2000's.

Many extreme events can be attributed to anthropogenic climate change whilst others can not. This has motivated us to study the time of an anthropogenic emergence (TAE) of six indices representing temperature and precipitation extremes. We used multiple historical runs and RCP8.5 projections from six CMIP5 models. We define a quasi-natural variability for each of these indices at gridbox level and for sub-continental regions and the globe as a whole. We determine when an anthropogenic emergence occurs by comparing index distributions across moving windows with the quasi-natural variability. We also investigated how TAE compared for mean temperature and precipitation with extremes. We found earlier emergence of extreme temperatures in equatorial regions compared to other parts of the world and some seasonal variability in TAE. Spatial aggregation reduces variability in mean and extreme temperature and precipitation leading to earlier TAE values. Using limited observational datasets, the same TAE methodology was applied and signs of emergence found. Finally, using the CMIP5 models, we show the regions of the world where anthropogenic signals can already be detected in our temperature and precipitation indices to aid in the study of attribution of extreme events to climate change.

Extreme heat waves with the Heat Wave Magnitude Index and their occurrence in the future

A. Dosio (1) ; J. Sillmann () ; S. Russo, (1)
(1) European Commission Joint Research Centre, Institute for Environment and Sustainability, Ispra, Italy

Heat waves are defined as prolonged periods of extremely hot weather and their intensity, duration, and frequencies are expected to increase in the future under climate change.

Recently, a new Heat Wave Magnitude Index (HWMI) was developed that, by taking into account both heat wave duration and intensity, enables the quantification of the magnitude of heat waves across different time periods and

regions of the world.

Here we first apply the HWMI to grade the observed heat waves occurred in Europe since 1950: in fact, although the worst event in the last decades occurred in Russia in 2010 (the strongest recorded globally in recent decades exceeding in amplitude and spatial extent the previous hottest European summer in 2003), many other heat waves, documented in literature and in newspapers, occurred in different European regions in the past decades.

Subsequently, we apply the HWMI to the predictions from several regional climate models (RCM) from the COordinated Regional climate Downscaling Experiment (CORDEX). RCMs have been used to downscale CMIP5 Global Circulation Models under different Representative Concentration Pathway (RCP), namely RCP4.5 and RCP8.5. We focus on two regions, Africa and Europe, for which a large ensemble of models' results is available.

Results show that, by the end of this century, under the most severe emission scenario, events with magnitude even greater than the one in Russia in the summer of 2010 will become more frequent and are projected to occur as often as every 10 years for regions such as southern Europe and central Africa.

The Role of Teleconnection Patterns in Wave Climate and Storms Distribution: The SW Spanish and Wales Coasts Examples

R. Nelson Guillermo (1) ; A. Giorgio (2) ; P. Michael (3) ; T. Thomas, (3)

(1) Universidad del Atlantico, Basic Sciences, Barranquilla, Colombia; (2) Cadiz University, Faculty of marine sciences, Cadiz, Spain; (3) University of Wales Trinity Saint David (Swansea), Swansea, United Kingdom

Tele-connection patterns such as the North Atlantic Oscillation (NAO) and Arctic Oscillation (AO) are influenced by climate change, as models predict a weakening of the overturning circulation that may affect both regional and global climate, sea level and extreme waves. Occurrence and distribution of storms are important variables in the incidence of coastal erosion, deterioration and/or complete destruction of ecosystems. This work presents the characterization of wave climate and energy, coastal storms and their recurrence intervals, related to several regional cycles in Cadiz (SW Spanish Atlantic coast), Tenby and Swansea (S Wales, UK). At the former site, wave records include 22 years of data covering the period between 1987 and 2012. Storm characterization was carried out using the Storm Power Index and five classes were obtained, from class I (weak events) to V (extreme events). Storm occurrence probability was 96% for class I (i.e. almost one event per year) to 3% for class V. The return period for class V was 25 years and ranged from 6 to 8 years for classes III and IV storms, e.g. significant and severe events. Classes I and II showed a period of recurrence ranging from 1 to 3 years. Approximately 40% of the change in monthly wave data and storminess indices was related to several teleconnection patterns, being the Arctic Oscillation (AO), with 21.45%, and the North Atlantic Oscillation (NAO), with 19.65%, the most important drivers of change.

Timescales of Change: Unraveling East Africa's Climate Paradox

B. Lyon (1) ; A. Giannini (1) ; N. Vigaud (1)

(1) IRI, Columbia University, Palisades, NY, United States of America

East Africa is currently facing something of a climate paradox. Over roughly the past 15 years, the region has been experiencing an increased frequency of drought, particularly during the «long rains» season from March-May. In a seeming contradiction, there is a general consensus among climate change projections that the region of East Africa will become wetter as a result of anthropogenic climate change by the end of the current century. One possible explanation of this discrepency is that the climate models are not properly responding to increasing greenhouse gases and their influence on East African climate: The future climate of East Africa may in fact become drier, not wetter. Another possibility is that the recent rainfall decline is associated with processes in the climate system operating on shorter time scales than long-term climate change. In this case, the recent rainfall decline may be masking longer-term climate change. A third possibility is that there is an interaction of processes operating on these different time scales.

This paper will review recent and ongoing research that is helping to explain the recent variations in East African climate. A combination of observational and climate model experiments indicate that the recent rainfall decline in East Africa has been associated with decadal-scale variations of the climate system, specifically in the Pacific Ocean. Evidence is presented that the rainfall decline in East Africa was manifest as an abrupt shift towards drier conditions that occurred in 1998-99 when the Pacific Decadal Oscillation (PDO) shifted from its warm to cold phase. This shift in the PDO was associated with a colling of eastern equatorial Pacific while the western Pacific has remained anomalously warm. Observational evidence indicates that the recent rainfall decline in East Africa was part of a near-global scale shift in seasonal rainfall patterns, with similar shifts observed previously over the past century. Results from climate model experiments, using only observed sea surface temperatures in the tropical Pacific as forcing, indicate the models are able to reproduce the recent drying in East Africa and the associated shift in global precipitation patterns. However, observations also indicate that the western Pacific warm pool region has continued to warm over the past several decades, an increase which almost certainly contains an anthropogenic component. Current work is investigating whether this combination of «natural» decadal variations and anthropogenic change, particularly in sea surface temperatures in the Pacific warm pool region, led to an exacerbation of recent East African droughts (we note that the devastating drought in 2010-11 was likely the most severe of the past 50 years). Understanding the physical processes associated with climate model projected increases in East African rainfall and how realistic they are in light of what is known about the behavior of the current climate system remains a critical next step in fully unraveling the East African climate paradox.

Physical insights on future European summer heat waves and record-breaking temperatures

M. Bador (1) ; L. Terray (1) ; J. Boé (1)

(1) CERFACS/CNRS, Sciences de l'univers au cerfacs, ura1875, Toulouse, France

Recent summer heat waves had strong socio-economic impacts in different parts of Europe. This highlights the need for improved understanding of key processes and feedbacks. We focus on the detection of an anthropogenic signal on record-breaking summer temperature using historical and 21st century simulations from a set of CMIP5 climate models. Results show that simulated and observed record evolutions follow the stationary climate theoretical record rate until the 1980s. They then diverge from the expected value, with an increase of the number of warm records and a decrease of the cold ones. These changes are shown to accentuate over the 21st century. The influence of internal variability based on control simulations is used to estimate an anthropogenic signal emergence time around 2030.

We then focus on a set of case studies of future heat waves. We analyze a high spatial resolution simulation (from 1950 up to 2100) of the ALADIN regional atmospheric model driven by the CNRM-CM5 model. Based on warm spell duration indices, we select a few intense events that occur in the second part of the 21st century. Heat waves are generally associated with quasi-stationary anticyclonic circulation anomalies that produce clear skies and warm air advection. They are often associated to anomalously dry land surface conditions. For each case study, we perform ALADIN sensitivity experiments by perturbing either the prescribed large-scale circulation and/or the initial soil moisture content. We then infer the dominant mechanisms and the feedbacks operating to amplify or mitigate the heat waves. We also perform a worst-case scenario where we try to generate an extreme heat wave in order to assess the associated temperature rise and its possible saturation due to negative feedback.

Global future changes of precipitation extremes

A. Toreti (1) ; P. Naveau, (2) ; M. Zampieri, (3) ; A. Schindler, (4) ; E. Scoccimarro, (5) ; E. Xoplaki (6) ; HA. Dijkstra, (7) ; S. Gualdi, (3) ; J. Luterbacher (6)

(1) European Commission, Joint Research Centre, Ispra, Italy; (2) Laboratoire des Sciences du Climat et de l'Environnement, IPSL- CNRS, Gif-sur-Yvette, France; (3) Centro Euro-Mediterraneo sui Cambiamenti Climatici, Lecce , Italy; (4) Federal Office of Meteorology and Climatology, MeteoSwiss, Zurich, Switzerland; (5) Centro Euro-Mediterraneo sui Cambiamenti Climatici, Lecce, Italy; (6) Justus-Liebig-University Giessen, Geography: Climatology, Climate Dynamics and Climate Change, Giessen, Germany; (7) Utrecht University, Department of physics and astronomy, Utrecht, Netherlands

Precipitation extremes have a strong impact on ecosystems and societies especially in exposed and vulnerable areas. In a climate change context, where exposure and vulnerability are also expected to change, it is essential to achieve a better understanding and an improved characterisation of these events. By analysing the latest global climate model simulations from the Coupled Model Intercomparison Project Phase 5 and by using an innovative statistical approach, seasonal changes in daily precipitation extremes under the high emission (RCP8.5) and the mid-range mitigation emission (RCP4.5) scenarios are investigated. Two future time periods (2020-2059, 2060-2099) are compared with the historical time period 1966-2005 and the results presented in terms of very high risk events. Furthermore, global models are evaluated w.r.t. precipitation extremes by using the available (high-resolution) gridded observations during the selected time period of the historical run. At the European scale, complex changes in the tail behaviour are also assessed. Results show that in the historical period a reliable characterisation of daily extreme precipitation cannot be achieved for large areas of the world, where an estimation of the return levels cannot be obtained. This is the case, for instance, during boreal winter for a belt elongated over the subtropics and tropics of the Northern Hemisphere and the oceanic areas west of the three continents of the Southern Hemisphere. In the Euro-Mediterranean area, northern Eurasia, and North America, the simulations show lower intermodel variability and higher correlation with the observations in boreal winter. Conversely, for Australia, southern Asia, and the Middle East, all seasons are characterised by larger intermodel variability and lower correlation with the observations. Concerning the future projections, the main findings point to an intensification (more pronounced at the end of the century under the high-emission scenario RCP8.5) of precipitation extremes almost everywhere in the world and in all seasons. However, a lack of reliability and consistency affects the subtropics/tropics. The zonal means of the identified changes clearly show more pronounced increases over the high latitudes of both hemispheres in all seasons, with the exception of the Northern Hemisphere in the mid-century boreal summer, associated with larger intermodel variability. Over the Southern Hemisphere, a sharp decrease in the estimated positive changes from the high to the middle latitudes is evident in all seasons followed by (with the exception of the austral winter) a strong increase towards the low latitudes. Stronger hemispheric differences are also estimated over the high latitudes for RCP8.5 at the second half of the century that are most prominent in summer and autumn. At the regional level, models show a better agreement on the projected increase of return levels over land, although large variability affects the estimated seasonal changes over specific areas (e.g., eastern Asia in summer).

O-1113-07

Weakened Flow, Persistent Circulation and Prolonged Heat Waves in Boreal Summer

D. Coumou (1) ; J. Lehmann, (1) ; K. Kornhuber, (1) ; V. Petoukhov, (1)

(1) Potsdam Institute for Climate Impact Research, Potsdam, Germany

Changes in atmospheric circulation can strongly alter the frequency and/or magnitude of high-impact extreme weather events. The Northern Hemisphere mid-latitudes have seen significant changes in the large-scale summer circulation over the last decades and this might have contributed to more prolonged heat waves (1-3). The zonal mean zonal wind (or "jet") has weakened by about 5% over 1979-2014, likely driven by the much more rapid warming in the Arctic as compared to the rest of the Hemisphere. In conjunction with the summer jet, the kinetic energy associated with transient synoptic-scale weather systems (the Eddy Kinetic Energy, or EKE) has seen a significant weakening as well. The observed decline in EKE is more pronounced in relative terms than that of the jet (by about 10% over 1979-2014), which is consistent with theoretical arguments and climate model simulations. Transient eddies are both forced by the jet via vertical shear but can also accelerate it via the eddy-driven jet (4, 5). The observed summertime weakening of both jet and EKE is also a robust signal in future projections of CMIP5 climate models (5, 6). At the same time, for some wave numbers, we have seen an increased occurrence-frequency of high-amplitude quasi-stationary waves during recent boreal summers. We argue that this increase in frequency is associated with a recent cluster of resonance events which can create such high-amplitude waves.

The reduction in amplitude of fast-moving transient waves (as captured by EKE) and the more-frequent occurrence of high-amplitude quasi-stationary waves both favor more persistent weather conditions. It has been demonstrated that high-amplitude quasi-stationary waves in the atmosphere are statistically associated with extreme weather at the surface (7, 8). Especially regions at the western boundary of the continents show the strongest association between surface extremes and high-amplitude upper-level waves. In contrast, strong transient wave activity, i.e. large EKE, is linked to moderate surface temperatures and vice versa (3). Over most continental regions affected by storm tracks, there is a significant negative correlation between monthly EKE and surface temperature. Thus, the hottest summers are associated with extremely low EKE, while mild summers are associated with more pronounced EKE. Again the western boundaries of the continents are especially sensitive since these regions are most directly influenced by the storm tracks.

In conclusion, boreal summer circulation has seen pronounced changes over the last decades, trends which seem to have amplified since the onset of rapid Arctic Amplification around 2000. Especially the reduction in EKE, but also in zonal mean flow, have created conditions favorable for the buildup of heat and drought over the continents. Moreover, a cluster of resonance events is observed since 2000, which has increased the occurrence-frequency of high-amplitude quasi-stationary waves with wavenumbers close to 7. Thus, this generally implies a weakening of transient synoptic eddy activity and more-frequent states of quasi-stationary flow. These observed changes in large-scale flow point towards more persistent flow patterns and therefore more extreme surface weather. This is also consistent with the pronounced increase in heat extremes in Europe and other mid-latitude regions (9, 10).

Climate Model Simulation of Present and Future Extreme Events in Latin America and the Caribbean: What Spatial Resolution is Required?

R. Oglesby (1) ; C. Rowe, (2) ; R. Mawalagedara, (3)

(1) University of Nebraska, Lincoln, Earth and atmospheric

sciences and daugherty water for food institute, Lincoln NE, United States of America; (2) University of Nebraska, Lincoln, Earth and atmospheric sciences, Lincoln NE, United States of America; (3) University of Nebraska, Lincoln, Earth and atmospheric sciences and daugherty water for food institute, Lincoln, United States of America

Latin America and the Caribbean are regions presently at grave risk to a variety of extreme climate events. These include flooding rains, damaging winds, drought, heat waves, and in high elevation mountainous regions, excessive snowfalls. The causes of these events are numerous. For example, flooding rains and damaging winds are often associated with tropical cyclones, but also can occur, either separately or in tandem, due to smaller, more localized storms. Similarly, heat waves and droughts can be large scale or localized, and frequently occur together (as excessive drying can lead to enhanced heating, while enhanced heating in turn promotes additional drying). Even in the tropics, extreme snow and ice events can have severe consequences due to avalanches, and also on water resources. Understanding and modeling the climate controls behind these extreme events requires consideration of a range of time and space scales. A common strategy is to use a global climate model (GCM) to simulate the large-scale (~100 km) daily atmospheric controls on extreme events. A limited area, high resolution regional climate model (RCM) is then employed to dynamically downscale the results, so as to better incorporate the influence of topography and, secondarily, the nature of the land cover. But what resolution is required to provide the necessary results, i.e., minimize biases due to improper resolution? In conjunction with our partners from participating Latin American and Caribbean nations, we have made an extensive series of simulations, both region-wide and for individual countries, using the WRF regional climate model to downscale output from a variety of GCMs, as well as Reanalyses (as a proxy for observations). The simulations driven by the Reanalyses are used for robust model verification against actual weather station observations. The simulations driven by GCMs are designed to provide projections of future climate, including importantly how the nature and number of extreme events may change through coming decades. Our results suggest that for proper simulation of both mean climate, and importantly extreme events, a spatial resolution of 4 km is required in regions of complex mountainous topography. A somewhat coarser resolution of 12 km is adequate in regions without much topographic relief, and where differing land covers account for most of the spatial heterogeneity.

O-1113-09

Should we expect more extreme rainfall from Atlantic tropical cyclones as a response to global warming?

F. Chauvin (1) ; H. Douville (1)
(1) Météo-France, CNRM-GAME, Toulouse, France

Daily precipitation extremes increase in intensity over many regions of the globe in simulations of a warming climate, including the tropics where observational constraints suggest that this sensitivity could be higher than expectations for the extratropics and from the Clausius-Clapeyron (CC) relationship (e.g. O'Gorman 2012). Here, the focus is on heavy precipitation related to Atlantic tropical cyclones (TCs). The objective is to investigate whether the sensitivity to global warming of TC rainfall is mainly controlled by the atmospheric water holding capacity, following the CC relationship, or could be even higher due to a dynamical cyclone amplification associated with an increased release of latent heat in the atmosphere. This amplification may lead to rates of change reaching twice the CC rate (Trenberth 2007). Our investigation is based on TRMM satellite precipitation observations and atmospheric ERA-Interim reanalysis in association with the IBTracs observed TC dataset on the one hand, and on coupled ocean-atmosphere simulations performed with a stretched version of the CNRM-CM5 global climate model on the other hand. For the CNRM-CM5 simulation an objective TC-tracking has been performed.A water budget analysis has been conducted along the cyclone tracks for both observation and model. It was found that moisture convergence is the dominant contribution to TC rainfall, as expected from previous case studies. Results also show that our climate model captures quite well the water budget derived from ERA-Interim, although the latter shows a systematic underestimation of TC rainfall, as compared with TRMM, possibly due to an underestimation of TC winds. Moreover, the analysis of our climate scenario suggests that the increase of spatially aggregated TC mean rainfall follows the CC relationship, while super CC rates are only reached in the very inner core of the TCs.

Temperature and precipitation extreme compound events in Southeastern South America and the associated atmospheric circulation

M. Rusticucci () ; B. Tencer (1) ; ML. Bettolli, (2)
(1) School of Earth and Ocean Sciences, University of Victoria, Victoria, Canada; (2) University of Buenos Aires, Atmosphere and ocean sciences, Buenos Aires, Argentina

Compound events consist of the simultaneous or successive occurrence of two or more extreme events, the combination of extreme events with conditions that amplify the impact of the events, or the combination of events that are not individually extreme but can lead to extreme impacts when occurring together (IPCC, 2012). In this paper we analyse the joint occurrence of extreme temperature and heavy precipitation events (simultaneous or lagged by one day) in southern South America during 1961-2000.

The study is based on a comprehensive dataset of daily precipitation and daily minimum and maximum temperature observed at meteorological stations of the region and compiled during the CLARIS LPB project. Four different extreme temperature events were defined: warm nights (days) correspond to days with minimum (maximum) temperature exceeding the 90th percentile of the daily distribution; cold nights (days) are days with minimum (maximum) temperature below the 10th percentile. Heavy precipitation events are events with daily rainfall above the 75th percentile of the empirical distribution of rainy days. A compound event is defined when one of the above temperature extremes occurs simultaneously with, preceded or followed by a heavy precipitation event.

The existence of a significant statistical relation between these extremes could help to better characterize the uncertainties associated with projections of extreme precipitation events for a future warmer climate. Results show that the probability of occurrence of an intense precipitation increases during or after a warm night, but decreases during a cold night, compared to the expected likelihood of occurrence of this type of events in the absence of a relation between temperature and precipitation extremes. Warm days are usually associated to the occurrence of heavy precipitation events on the same day or the day before, but they rarely occur afterwards. On the contrary, cold days happen more often after an intense rain.

In order to characterize the atmospheric circulation during the occurrence of a compound event, we use a synoptic classification developed by Barrucand et al (2014) and based on daily mean fields of geopotential height at 500hPa from the NCEP2 reanalysis. The associated circulation during a compound event of warm nights or warm days and heavy precipitation shows a trough over the Pacific Ocean and a cold front over the continent that lead to warm and wet air advected to the east of the region of study. Cold days and heavy precipitation events in the southwestern part of the domain of study are usually characterised by a positive anomaly of geopotential height at the southern part of the continent associated with an eastern anomaly over the region.

Capability of CORDEX RCMs in simulating extreme rainfall events over South Africa

S. Abba Omar (1) ; A. Babatunde (2)
(1) University of Cape Town, Environmental and Geographical Science, Cape Town, South Africa; (2) Climate Research Analysis Group (CSAG), Department of environmental and geographical science, university of cape town, Cape Town,

South Africa

In South Africa, extreme rainfall events often lead to widespread destruction, damage infrastructure, displace communities, strain water management and even destroy lives. Past studies have shown that reliable predictions of extreme rainfall events from regional climate models (RCMs) could help reduce the impact of these events. The present study evaluates the ability of nine RCMs in simulating extreme rainfall events over South Africa, focusing on the Western Cape (WC) and east coast region (EC). This study defines an extreme rainfall over a location as rainfall that is equal or above the 95th percentile of the rainfall distribution at that location, and defines widespread extreme rainfall events (WEREs) over an area as events during which more than 50% of the grid-points in the area experience extreme rainfall. The 95th percentile threshold values were calculated over 11 years (1989-2008) of South Africa's daily rainfall data from nine RCMS which participated in the Coordinated Regional Climate Downscaling Experiment (CORDEX). The simulations were compared to two observation datasets (TRMM and GPCP), and to ERAINT rainfall data to understand whether these RCMs improve on the results from ERAINT. A self organizing map (SOM) was used to characterize WEREs identified in all the datasets into archetypal groups, and ERAINT data is used to describe the underlying circulations for each archetypal rainfall pattern. The number of WEREs mapped to each rainfall pattern for each dataset allows us to get an idea of whether certain RCMs are more likely to simulate certain rainfall patterns.

The results show that RCA35, REMO and WRF seem to be the best at simulating the 95th percentile threshold values over the whole of South Africa. However, it was found that CCLM seems to do the best over the WC and PRECIS does the best over the EC. Downscaling ERAINT with CCLM produces fewer WEREs, whereas downscaling ERAINT with PRECIS produces a higher number of WEREs simulated over both areas (WC an EC). The SOMs identifies five major patterns of WERE over areas. The first pattern (TRW) links WERE in WC or EC with tropical activities, producing a tropical temperate through that is truncated at the coast. The second pattern links WERE in WC or EC with mid-latitude rainfall activities(MLW). The third pattern produces an isolated WERE over each area (ISW). The forth pattern, which is unique to WC, links WERE in WC with rainfall activities over the Agulhas current. The fifth pattern, which is unique to EC, links WEREs in EC with both tropical and mid-latitude rainfall activities, hence producing TTTs. PRECIS has the tendency to overestimate the frequency of TRW WEREs over both the EC and WC whereas, WRF only shows this tendency over the EC. ARPEGE simulates more WEREs associated with ISW over the EC region and over the WC WRF and CRCM5 underestimate the frequencies of these events. Over the EC the frequency of WEREs associated with mid-latitude rainfall activity seems to be simulated reasonably well by the RCMs whereas over the WC most of the RCMs overestimate the frequency of these types of WEREs.

The potential risk of climate change and extreme climatic events on coastal cities of Nigeria

S. Ayanlade (1)
(1) Obafemi Awolowo University, Ile-Ife, Nigeria, Dept. of Geography,, Ile-Ife, Osun, France

This study examines the potential risk of climate change and extreme climatic events on coastal cities of Nigeria. The study applied satellites data, Remote sensing and Geographical Information System (GIS) methodologies to assess the environmental and societal implications and the risk of climatic events such as flooding, coastal erosion and seas surface rise on coastal cities of Nigeria. The risk of climate variability and extreme weather events cannot be overemphasized on urban settlements that occupy millions of people in Nigeria. It is obvious from the report of Nigerian National Population Commission (NPC, 2006) that a large percentage of Nigeria's urban population lives in coastal cities. Previous studies have reported that Climate change has been affecting and will continue to affect almost, if not all, the sectors of the urban economy including the most sensitive ones such as water and health sectors. Such impacts and the risk of climatic event are now obvious in many coastal cities of Nigeria. The impacts of climate change and urban risk may be felt also by a wide spectrum of socio-economic variables like human health, transport, energy, industry and other service sectors in the coastal cities. Increases in population growth rates in the coastal cities of Nigeria, combined with a likelihood of a 1m sea-level rise, could create high risk on tourism-oriented economies, ecology, and other societal implications. Though, the report of IPCC, (2007) has shown that there are some uncertainties about the nature and magnitude of risk and vulnerability to climatic changes, it is necessary to make some assumptions about risk of changes in climate in order to assess potential such risk on coastal urban settlements of Nigeria. Thus, the general objectives of this study has been to assess the spatiotemporal risk of climatic event; map out a composite of scenarios for climate change impacts; to examine the risk of climatic extreme events on coastal cities of Nigeria; and their implications on physical, economic and social environments. This study holds the benefit for better understanding of a need to have a coastal zone management plan to address the possible coastal cities risk indicated in this study.

P-1113-03

The Climate Expectancy : a resolute parametrical approach to redefine the climate

V. Cailliez (1)
(1) Chambre d'Agriculture de la Creuse, GUERET, France

1) The 30-year average, a largely outdated concept :

Since the climatic break (or powerful acceleration) that happened throughout the world in the late 70s, temperatures are following a steep slope. Considering the whole set of GCM simulations (see IPCC AR5), this trend is not going to slow down, to speak gently. So, we can no longer ignore that the mathematical operation of averaging applies not only on values but also on time, when used on a chronological series.

If we don't renew the definition of climate normality, we will be using the 30-year average of 1981-2010 (i.e. the 1996 expectancy) until 2021, when the 30-year average of 1991-2020 is to be calculated and released. What was tolerable in times of slow and weak fluctuations is becomming unacceptable in a situation where a strong trend is at work (from +0.3°C to +0.5°C per decade in France since the climatic break, for instance).

The link with climate extremes is obvious. An extreme is qualified by its distance to normality. If we define the normality better, we define better what is away from it.

2) Redefining the climate :

The World Meteorological Organization (WMO) classical definition of the climate can be written : observation time series = 30-year average + anomaly time series

The proposition is to refine the 3 terms of the equation by an homogenization of the observed meteorological datas, followed by a separation between the random part of the series (replacing the anomaly) and the organized part which is, in fact, the climate expectancy. The underlying idea is to consider that a 'real' anomaly in a time series should be what is totally unexpected, and so, what is part of a random series.

3) Organizationnal analysis :

The purpose is the separation of the long-term organizations (trend, cycles...) from the short-term ones (persistance...). Considering the long-term organizations, we can write :

Par(t) = (a*t+b)+Amp1*sin(2Πt/P1+Phas1)+Amp2*sin(...)+...+ParWLTO(t)

where Par(t) is the homogenized series and WLTO means Without LongTerm Organization.

The short-term organization is treated in an auto-regressive process :

ParWLTO(t) = A1.ParWLTO(t-1)+...+Akmax.ParWLTO(t-kmax)+ParWSTO(t)

where Ai are the auto-regression coefficients and kmax is the (maximum) horizon of significant persistance. WSTO means Without long term and ShortTerm Organization.

We can now easily deduce the expression of the climate expectancy ClimPar(t) :

ClimPar(t) = Par(t)-ParWSTO(t)

On this expression, it is easy to figure out that we can have a different value of the climate expectancy on each observed data till the last one. The compatibility with the classical WMO definition is achieved simply by centering ParWSTO(t).

The randomness of the ParWSTO(t) series can be verified with multiple statistical tests like the runs tests. It happens that the separation between organized and random parts is excellent. We experienced this with 30-year to 60-year long daily datas of maximum and minimum temperatures, located in the central region of France called Limousin.

Because the ParWSTO(t) series is a random series (or very close to), it can be regenerated by a random number generator. The shape of the random distribution is adjusted dynamically and parametrically to the observed one by analysing the organization of the variance, skewness and kurtosis of ParWSTO(t).

The upgrade of the determination of climate extremes is the result of the whole process which can be summarized as a separation between organized and random variability.

4) Biding farewell to the 30-year average ...

On one side, the 30-year average is an easily explained notion, which needs only simple calculations and is universal. To abandon it will be indeed a difficult human and social process. On the other side the climate expectancy is a quite open concept, delicate to understand at first sight and that can lead to long and uneasy calculations. However its integration into the toolbox of climatologists has to be started soon because of the strengh and the inertia of the global warming phenomenon. Its usability at very different scales of time (from hourly to centenial datas at the least) should facilitate a rapid consensus.

P-1113-04

Climate change and extreme weather events in Mediterranean Sea: studies with WRF atmospheric model

G. Emmanouil (1) ; M. Vlachogianni (1) ; A. Sfetsos (1)
(1) Demokritos, Athens, Greece

Extreme weather events are becoming more frequent the last years. This fact along with its relation to the possible climate change, are two major issues of scientific study. In this work, WRF-ARW atmospheric model is used to simulate extreme weather conditions in Mediterranean Sea, focusing in the Greek peninsula. Sensitivity tests with different model configurations will be presented, as well as evaluation of the results against in-situ observations. The results show good agreement with observations and prove to be a very useful tool for studying, forecasting and trying to limit down the consequences of such events.

P-1113-05

Extreme Rainfall Events in Asia: Projected Changes and Uncertainties

N. Freychet (1) ; A. Duchez (2) ; CH. Wu (1) ; HH. Hsu (1) ; CA. Chen (1) ; A. Forryan (2) ; B. Sinha (2) ; JJM. Hirschi (2) ; AL. New (2)
(1) Academia Sinica, RCEC Research Center for Environmental Change, Taipei, Taiwan; (2) National Oceanography Center (NOC), Southampton, United Kingdom

Extreme precipitation (and drought) are one of the main concern for society and environment, because they can lead to severe flood (and lack of water supply). In warmer environment, atmospheric moisture is expected to increase, and could thus create more favorable conditions to trigger extreme rainfall. However, the change in dynamics can also play a major role in the change of distribution of precipitation. The modification of the land-sea thermal gradient, the vertical structure of the atmosphere, or the latent heat released by the precipitation, can all impact the large scale circulation, and thus the rainfall distribution.

In this study, focussed on the East Asia region, we analyzed the results from two high resolution models (HiRAM-C192 and HadGEM3-GC2), and from the CMIP5 ensemble, to investigate the projected change in extreme rainfall events (either extreme precipitation or long drought). The role of the SST is also investigate. HadGEM3-GC2 is fully coupled with ORCA025, while HiRAM-C192 is forced by prescribed SST. The SST forcing for this model is determined by a cluster analysis from the CMIP5 projection. Three main patterns of SST are used, providing three different projections for this model. We also emphasize the correlation with the dynamics to explain the internannual variability of the extremes events.

In both CMIP5 ensemble and high resolution models the signal of extreme precipitation strongly increase during the summer. On the other hand, the signal on the drought spell is not clear. HadGEM3-GC2 show a decrease during winter of East Asia, while the three HiRAM runs show an increase during this same season. It could be due to a difference of sea-land contrast. The East Asia 200 hPa Jet intensity impacts significantly the variability of extremes precipitation, while the winter 850hPa winds show a strong correlation with the dought over East Asia. The results on CMIP5 ensemble also show a significant impact of the change in vertical motion (with a tendency to slow down), that could act as a counterbalance to increase of atmospheric moisture. But large uncertainties remain between different models, and impact strongly the confidence on the extreme projection.

P-1113-06

Climate change impacts on social well-being of fishers' communities in the Bangladesh Sundarbans

MM. Islam (1)
(1) Sylhet Agricultural University, Department of Coastal and Marine Fisheries, Sylhet, Bangladesh

Social well-being concept has garnered much interest in recent years as a multi-dimentional, holistic approach to understand and measure progress and problems. Though the concept of social well-being has operationalized across different disciplines, there are very few studies using this concept to show how climate change is affecting well-being of fishing communities. To fill this knowledge gap, this study employs social well-being approach to study the impacts of climate change on the livelihoods of mangrove fishers' communities in the Bangladesh Sundarbans. Qualitative data collection tools were employed; a semi-structured questionnaire was used to collect the empirical data from four fishing communities. Given that, in recent past two consecutive cyclones- Sidr (hit Bangladesh coast on 15th November, 2007), and Aila (struck Bangladesh coast 25th May, 2009) affected a major part of the Sundarbans mangrove ecosystem with great devastation. In addition, the region faces other environmental degradations such as saline water intrusion, occasional droughts as well as degraded resources base of the forest. Thus, ongoing environmental changes in the Sundarbans and its effects on the communities provide a suitable setting to study the impacts on climate changes on the well-being of the residing population. Following the WeD framework of wellbeing, social well-being has three dimensions, material, subjective and relational that together constitutes human welfare. Cyclones Sidr and Aila caused loss of different 'material' values for the fishing communities in several ways. Rising tidal waves, associated with cyclones washed away productive assets, housing, and standing crops in the field, employment opportunities in alternative occupations were also severely squeezed, that altogether rendered in income loss of the communities. Immediate aftermath of cyclone Aila, most fishers took shelters in makeshift built on embankments that severely degraded their standard of living. Increased salinization after cyclone struck caused acute crisis of drinking water and loss of biodiversity that reduced overall environmental quality of region. Many fishers expressed their shocks, fears after seeing that rising water washing away their belongings before their eye. Living in constant economic hardship, depending on external supports for survival for longer period, school drop out and increased child labour undermined fishers' aspirations and confidence for a secured future. In case of relational values, 'social cohesion' of fishers' communities traditionally served as buffer during the period of crisis. However, individual competition to receive relief at the cost of others' interest negatively affected the community bonding and dispelled social capital to certain extend. The

responses from the government mostly gave emphasis on of materialistic rehabilitation of the affected communities. Following this new understandings through social well-being lens, the present study submits for a more holistic, more responsive policy making in Bangladesh by taking consideration into multiple dimensions of human welfare that are affected by climate change impacts.

P-1113-07

Characterization of extreme rain events and assessment of Regional Climate Models in Morocco

K. Khomsi (1) ; M. Gil (2) ; M. Sinan (3) ; M. Snoussi (4)
(1) Direction de la Météorologie Nationale, Casablanca, Morocco; (2) Université Montpellier 2, Hsm/ird, MONTPELLIER, France; (3) Ecole Hassania des Travaux Publics, Casablanca, Morocco; (4) Université Mohammed V-Agdal, Faculty of Sciences, Rabat, Morocco

At a global scale, more than half of the costliest disasters are weather related and our planet is facing more devastating extreme events mainly those related to rain. In Morocco, the floods between the 21st and the 25th November 2014 in the south of the country had caused the death of 32 people. In Casablanca, the flood of the 29th-30th November 2010 had caused enormous human and material losses. In the province of Settat, the flood of the 23th and 24th December 2001 have caused the death of eight people and flooded several industrial units and Douars in the region, adding to many other tragedies in the flood areas. Also in Ourika, the floods of the 17th August 1995 had caused more than 230 deaths, 500 missing, 200 damaged cars and other property damage. Thus, there is a real need for understanding and anticipating weather extreme events mainly those related to intense rains, that may leads the way in risk assessment and development of mitigation strategies.

The aim of this work is to characterize the frequency and the trends of rain extreme events and to assess simulations of regional climate models for these extreme events in the watersheds of Tensift and Bouregreg (Morocco), during the last decades. First, the work analyzes the observed trends in daily rainfall time series, than it identifies rare, very rare and exceptional rain events, using percentile-sampling thresholds, and studies the trends of their frequencies. Finally it evaluates an ensemble of regional climate models from the European project ENSEMBLES, with regard to the found trends in order to recognize models that best describe observed rain regime, in the studied catchments.

P-1113-08

Relationship between the Tropical South Atlantic SST and drought over West Africa from CORDEX

NAB. Klutse (1) ; A. Babatunde (2) ; M. Adeniyi, (3) ; F. Nkrumah (4)
(1) Ghana Atomic Energy Commission, Remote sensing, gis, climate, ghana space science and technology institute, Accra, Ghana; (2) Univesrity of Cape Town, Environmental And Geographical Science, Cape Town, Western , South Africa; (3) University of Ibadan, Department of physics, Ibadan, Nigeria, Federal Republic of; (4) University of Cape Coast, Department of physics, Cape Coast, Ghana

Droughts in West Africa are not only an environmental problem but also a social and economic concern. However, droughts research has not obtained the necessary attention in West Africa. Moreover, the dynamics of West African drought are not fully understood and among the studies that have considered droughts of West Africa, only a few have considered the link between Tropical South Atlantic (TSA) Sea Surface Temperature (SST) and drought over West Africa. In this study, we look at how CORDEX models represent the relationship between the TSA SST and drought, precipitation and temperature over West Africa. Studies on drought done over West Africa used only precipitation in Standardised Precipitation Index (SPI) to measure drought index. The use of precipitation alone is inadequate to give information about drought as evapotranspiration has a direct influence on drought. We recognize that evapotranspiration is an important process of water loss. Here, we use the Standardised Precipitation Evapotranspiration Index (SPEI) where evapotranspiration is included in the calculation of the drought index.

P-1113-09

Drought Hazard Analysis over India and Its Impact on Climate Using Applying Multivariate Technique for Composite Indicators

P. Kumar, (1) ; K. Swati (2)
(1) Banasthali University, Remote sensing, jaipur, India; (2) Banasthali University, Remote Sensing, Tonk, India

Drought being complex and least understood disaster affects multidimensional parameters of social and economic structure of society. It is said to be hydro-meteorological disaster having prolonged period of below average precipitation causing drought whose severity is largely determined by the amount of rainfall. The objective of this study to carryout drought hazard analysis in India with a combination of drought indices in geospatial environment using meteorological drought hazard analysis has been carried out effectively by the generation of Drought Hazard Index (DHI). Meteorological drought hazard analysis was performed by analyzing rainfall and its distribution pattern and drought occurrences. The current study of this research is to develop a composite index capturing spatial variations of drought hazard by taking into account the spatial and temporal occurrence of meteorological drought and to map the drought hazard in India. The present research involves generation of drought hazard index formed by compilation of individual indicators based on meteorological parameters into single index which is further used for the analysis of namely meteorological drought hazard in the country India. The study uses Climate Precipitation Center (CPC) rainfall time series at 10 x10 km grid for south west monsoon season (June-September) for 12 years 2001-2012 shown in Figure 1. DHI proposed in this study is a major initiative towards generating hazard indices for disasters with the composite index approach. DHI has fairly well represented the drought hazard pattern in the country by capturing the spatial variations in drought hazard across India. The DHI has thus effectively captured the spatial variations in drought hazard across India. The spatial patterns of drought hazard are reasonable and justify the strength of the index. The procedure for generating DHI can be further improved by adding more number of indicators. The strengths of the methodology are using a composite index method, analysis in spatial perspective, inclusion of a wide range of inputs and covering a large geographic area. Indicators selection and weights generation are the possible areas for further work.

P-1113-10

Determining climate indicators to assess the impact of extreme weather events on road accidents in Hungary

M. Lakatos (1) ; E. Vincze (1) ; Z. Bihari (1) ; T. Szentimrey (1)
(1) Hungarian Meteorological Service, Climate Department, Budapest, Hungary

The Special Report of IPCC on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (2011) concluded that there is evidence from observations gathered since 1950 of change in some extremes. A set of climate indices are used in several projects on climate change as prevailing indicators of changes in extremes.

The main focus of the presentation is preparing climate indicators to impact and vulnerability assessment of roads accidents, as critical infrastructure, within extreme weather events in wintertime periods based on existing dataset of the National Adaptation Geographical Information System (NAGIS) in Hungary. The daily grid for period 1961-2010 in 0.1° spatial resolution for several basic meteorological variables and climate indicators were created in CARPATCLIM (Climate of Carpathian Region) project is integrated to the NAGIS system for the territory of Hungary. The common used methods and software in the CARPATCLIM project was the method MASH (Multiple Analysis of Series for Homogenization; Szentimrey) for homogenization, quality control, completion of the observed daily data series; and the

method MISH (Meteorological Interpolation based on Surface Homogenized Data Basis; Szentimrey and Bihari) for gridding of homogenized daily data series. It is a relevant climate database for studying climate extremes and climate change in the region.

Different climate indicators are defined and quantified to mapping of exposure and sensitivity such as zero crossing days, precipitation amount in a specific period, ice days, snow cover, wind speed, cold/wet days, daily mean temperature < 25th percentile, and daily precipitation > 75th percentile for example. These climate indicators are the input values to impact studies that will be developed through the integration of the exposure and sensitivity mapping layers to the NAGIS system. Mapping of exposure will be based on measurement data and climate modelling results of Hungarian Meteorological Service (OMSZ), while the transport accident data recorded at the central body of disaster management will serve as a basis for sensitivity mapping. Among others these climate indicators will be used to assess the vulnerability due to climate change, which will foster the development of adaptation strategies and objective decision making.

P-1113-11

Changes in nature of extreme rainfall in southern Africa

C. Lennard (1)
(1) University of Cape Town, Climate System Analysis Group, Cape Town, South Africa

Extreme rainfall, usually expressed through local or regional weather events, is driven by synoptic-scale forcings as well as other factors like moisture availability, lapse rate etc. Rainfall and especially small-scale extreme rainfall associated with convection is poorly simulated by numerical models (general circulation models - GCMs) and regional climate models (RCMs). However, numerical models are able to simulate large-scale circulation states so in this study we characterize circulation states to investigate projected changes in extreme rainfall over Southern Africa.

Downscaled evaluation and projection data from two CORDEX regional models and four global models were examined and changes in the occurrence of rainfall and extreme rainfall investigated in three sub-regions over southern Africa. Synoptic states associated with extreme rainfall were identified in each region. Over teh evaluation period we find that the regional models performed adequately in capturing the general rainfall characteristics over the region but did not capture the characteristics of extreme rainfall well. However, synoptic states associated with rainfall and extreme rainfall were captured and characterized.

In the near-term (2036-2065) and far-term (2065-2099) under both RCP4.5 and RCP8.5, synoptic states that are associated with drier conditions are projected to increase, while synoptic states that enhance precipitation are projected to decrease over time. Furthermore, the synoptic states associated with extreme precipitation are projected to increase.

Given the current threat posed by extreme rainfall in the regions these results speak directly to the necessity to develop effective and implementable adaptation strategies to reduce the impact of extreme rainfall on vulnerable communities.

P-1113-12

Summer temperature extremes over Europe obtained from an ensemble of regional climate models

S. Lidija (1) ; I. Güttler, (1) ; K. Cindri□ Kalin, (1) ; □. Brankovi□, (1)
(1) Meteorological and Hydrological Service, Department for Climatological Research and Applied Climatology, Zagreb, Croatia

European summer temperature extremes from simulations of six EURO-CORDEX regional climate models are analysed for the 20-year period, 1989-2008. The models were driven by ERA-Interim reanalysis at 50 and 12.5-km horizontal resolutions. Three categories of extreme temperature indices - absolute, percentile and duration - are derived from daily data. The results are compared with extreme temperature indices calculated from the gridded daily E-OBS data over Europe and for Croatia, where the indices are derived from daily observations at 20 Croatian meteorological stations. The ensemble spread is large, but the biases at 12.5-km simulations are smaller than at 50 km. When compared with validation data, model simulated temperatures and their percentiles are mostly overestimated over southern Europe and underestimated over northern Europe. Over Croatia, spatial distribution of indices at 12.5 km is closer to observed distribution than at the 50-km resolution.

P-1113-13

Standardized Precipitation Index (SPI) and Its Use to Assess Drought Occurrences in Cameroon over Recent Decades

F. Mkankam Kamga (1)
(1) Université des Montagnes, Bangangté, Cameroon

The standardized precipitation index (SPI) is computed and analyzed using 55 years of precipitation data recorded in 24 observation stations in Cameroon along with University of East Anglia Climate Research Unit (CRU) spatialized data. Four statistical distribution functions (gamma, exponential, Weibull, and lognormal) are first fitted to data accumulated for various time scales, and the appropriate functions are selected on the basis of the Anderson-Darling goodness-of-fit statistic. For short time scales (up to 6 months) and for stations above 10°N, the gamma distribution is the most frequent choice; below this belt, the Weibull distribution predominates. For longer than 6-month time scales, there are no consistent patterns of fitted distributions. After calculating the SPI in the usual way, operational drought thresholds that are based on an objective method are determined at each station. These thresholds are useful in drought-response decision making. From SPI time series, episodes of severe and extreme droughts are identified at many stations during the study period. Moderate/severe drought occurrences are intra-annual in short time scales and interannual for long time scales (greater than 9 months), usually spanning many years. The SPI calculated from CRU gridded precipitation shows similar results, with some discrepancies at longer scales. Thus, the spatialized dataset can be used to extend such studies to a larger region—especially data-scarce areas.

P-1113-14

Analysis of extreme temperature indices of long-term homogenised temperature series in South Africa

M. Nxumalo (1) ; A. Kruger, (2)
(1) South African Weather Service, Climate department, Pretoria, South Africa; (2) South Africa, Climate department, Pretoria, South Africa

Homogenized data reduces the risk of significantly biased results in historical climate trend analysis. This study utilises for the first time long-term homogenised maximum and minimum daily temperature data sets for South Africa, spanning from the period 1931 to 2014. Previous extreme temperature trend analyses for South Africa only covered periods from 1961, which makes the current analyses significant in terms of the period of analysis, but also the number of stations that could be utilised. Whereas previous studies covered the analyses of the time series of fewer than 30 stations, the combinations of data from different stations in single time series through homogenisation increased the number of time series to 36. The time series were analysed using the extreme temperature indices developed by the WMO-ETCCDI team, which makes it possible to compare the results to other analyses across the world. Examples of the index trends analysed are the annual number of cool days, annual number of warm days, Diurnal temperature range, annual maximum and minimum temperatures, warm and cold nights and annual maximum warm spells, amongst others. This analysis forms part of the ongoing study in historical temperature trends in South Africa from in-situ measurements, by the South African Weather Service.

P-1113-15

Characterizing and understanding the

Sahelian heat waves

B. Oueslati (1) ; B. Pohl (2) ; V. Moron (3) ; S. Rome (4)
(1) Centre de Recherches de Climatologie-BIOGEOSCIENCES, Université de Bourgogne, dijon, France; (2) CNRS, Centre de Recherches de Climatologie-BIOGEOSCIENCES, Université de Bourgogne, Dijon, France; (3) Aix-Marseille Université, CEREGE UM 34 CNRS, France, Geography, Aix-en-Provence, France; (4) Université Grenoble Alpes, LTHE UMR 5564 UJF-CNRS-IRD, Grenoble, France

Large efforts are made to address the heat waves (HW) in developed countries because of their devastating impacts on human health. This interest increased after the intense event over Europe during summer 2003. However, HWs are still understudied over developing countries. This is particularly true in West Africa, and especially in the Sahel, where temperatures recurrently reach critical values, such as during the 2010 HW event. Understanding the Sahelian HWs and associated health risks constitute the main objective of ACASIS, a 4-year project funded by the French Agence Nationale de la Recherche.

Our work contributes to this project and aims at characterizing the Sahelian HWs and understanding the mechanisms associated with such extreme events.

There is no universal definition of a HW event, since it is highly dependent on the sector (human health, agriculture, transport...) and region of interest. In our case, we chose to define a HW as a period of at least 3 consecutive days of extremely high (90th percentile) daily heat index (Rome et al. 2015). This index combines temperature and relative humidity in order to determine the human-perceived equivalent temperature (Steadman, 1979).

Intrinsic properties of Sahelian HW are next analyzed from the Global Summary of the Day (GSOD) synoptic observations and ERA-interim and MERRA reanalyses over 1979-2012 during boreal spring seasons (April-May-June), the hottest period of the year in the Sahel. Reanalyses capture well the observed interannual variability and seasonal cycle at the regional scale, as well as the 1979-2012 increasing linear trend of springtime HW occurrences in Central and Western Sahel.

Reanalyses however overestimate the duration, spatial extent of HW, and underestimate their intensity. For both GSOD and reanalyses, we show that, over the last three decades, Sahelian HWs tend to become more frequent, last longer, cover larger areas and reach higher intensities. The mechanisms associated with HWs are analyzed to assess the respective roles of atmospheric dynamics, radiative and turbulent fluxes, in the establishment of such events.

P-1113-16

Changes in the occurrence of cold and heat waves in France toward the end of the century assessed using a stochastic model to downscale climate model simulated temperature

S. Parey (1) ; T. Hoang (1)
(1) EDF/R&D, MFEE, Chatou, France

As cold and heat waves have a major impact on society and economy, these events are widely studied in climate change simulations for different parts of the world. This study may be viewed as another of such studies, but its originality lies in the adopted methodology. The aim here is to assess changes in cold or heat wave frequency distribution in France at the station, or grid point level in order to avoid any smoothing of the time series which could alter the extremes. Thus 22 robust temperature time-series provided by Meteo-France in the framework of the national research agency project SECIF and designed as SQR (for Reference Daily time Series in French) are first used to estimate the distributions of cold or heat waves of different durations, from one single day to more than 15 consecutive days. Then a stochastic model for temperature (Parey et al. 2014), designed to correctly reproduce extreme values, is used to simulate 100 equivalent temperature time series with potentially more severe extremes, so that a distribution of such frequencies can be derived for each station. As the stochastic model simulates the random part of temperature, after removing the deterministic parts (seasonality and trends) of the mean and the standard deviation, these 100 simulations are also used to reconstruct 100 time-series from each climate model simulation for different periods and greenhouse gas emission scenarios. The climate model biases are corrected by reconstructing the future seasonalities as the observed ones, to which the future changes given by the climate models are added (Smf = Smo + (Smf - Smp) ; Svf = Svo*Svmf/Svmp where subscripts o is for observation, f for future and p for present). Then, the full climate model non parametric trends in mean and standard deviation are considered. In this way, distributions of the cold or heat waves frequencies can also be obtained for climate model simulations and thus the significance of the changes can be more robustly assessed. The results obtained with two climate models (CNRM-CM5, IPSL-CM5A-MR), two RCP scenarios (RCP4.5 and RCP8.5) and two future periods, the first and second half of the 21st century will be presented.

Study of Extreme Rainfall Events over Odisha using observation and simulation

S. Payoshni (1) ; KC. Gouda (2) ; P. Goswami (3)
(1) CSIR 4PI, BANGALORE,KARNATAKA, India; (2) CSIR 4PI, Cemp, BANGALORE,KARNATAKA, India; (3) CSIR FOURTH PARADIGM INSTITUTE (FORMERLY CSIR CMMACS), Cemp, BANGALORE KARNATAKA, India

The state of Odisha lies in the eastern part of India with a broad coast line of around 480 km. The climate of state fully depends on the Indian summer monsoon and being the coastal state always the disaster due to hydro meteorological events like tropical cyclone, extreme rainfall events (ERE) and flood etc. are important to monitor and model for the real time mitigation and disaster management. In this study first the extreme rainfall analysis is being carried out using the rainfall data from multiple sources like the India Meteorological Department (IMD) daily gridded data, APHRODITE and Tropical Rainfall Measuring Mission (TRMM) data. Firstly the EREs defined with the criteria of a grid point receiving 10cm or more rainfall per 24hour, are counted over the continental part of Odisha state domain (18-22.5oN, 82-87oE) at the daily scale for the period 1951 to 2014. The inter annual variability in the number of ERE over the state are presented and which clearly shows there is an increasing trend in the ERE of about 0.23 events/year. Because there is a positive trend of the ERE in the second part the ERE distributions are being analyzed and clearly indicates there is increase in the ERE over the south, central and eastern part of Odisha while the trend is normal in the northern part. The possible impact of climate change is also quantified. To simulate the ERE the Mesoscale Meteorological Research Institute, Japan Non Hydrostatic Model (NHM) is calibrated for the Odisha region and about 10 such events are simulated and the model is well capable of simulating the EREs before 48-72 hours. Some sensitivity studies also carried out with the model for the optimized configuration of the model for the meso scale forecasting of the EREs over Odisha. This model configuration and the observational studycan be used for the investigation of the ERE mechanisms in particular over Odisha region and the medium range forecasts can be useful for different sectors like agriculture planning, water management, disaster management etc. for the state of Odisha

P-1113-18

Uses and limits of thermal indices: the case of Sahel

S. Rome (1) ; V. Moron (2) ; B. Oueslati (3) ; B. Pohl (4) ; B. Fontaine (4) ; A. Diedhiou (5)
(1) Université Grenoble Alpes, LTHE UMR 5564 UJF-CNRS-IRD, Grenoble, France; (2) Aix-Marseille Université, CEREGE UM 34 CNRS, France, Geography, Aix-en-Provence, France; (3) Centre de Recherches de Climatologie-BIOGEOSCIENCES, Université de Bourgogne, dijon, France; (4) CNRS, Centre de Recherches de Climatologie-BIOGEOSCIENCES, Université de Bourgogne, Dijon, France; (5) Institute of Research for Development (IRD), LTHE - University Grenoble Alpes, Grenoble Cedex 9, France

Our main goal here is to analyse extreme heat waves

(HWs) in the Sahel (13°N–18°N; 16°W–30°E), using different thermal indices. In the ACASIS project funded by the French "Agence Nationale de la Recherche", HWs analyses are characterized for the first time during the hottest season in the Sahel, using the Global Summary of the Day (GSOD) synoptic observations during April–May–June 1973–2013. Such extreme high temperatures are usually defined by 3 criteria: 1/ Their low probability of occurrence: less than the 10% of the days. The use of absolute thresholds, associated with heat budget and physiological impacts, could be an alternative (Seneviratne et al., 2012). 2/ Their intensity, i.e. their amplitude in terms of standard deviations from the local climatology (Goubanova, 2007), or otherwise excesses over absolute intensity thresholds. 3/ Their severity: extreme events causing socio-economic or human losses, the notion of impact is thus of major importance for their definition (Beniston et al., 2007).

According to prior IPCC assessments (TAR, AR4 and SREX), it is very likely that increased maximum temperatures and enhanced probabilities of hot days occurrences will occur at the global scale. There is also medium confidence that warm spells/heat weave frequencies, lengths or intensities will increase in many regions (Cubasch et al., 2013). Because of its latitude, Sahel is especially concerned, with diurnal temperatures often exceeding 40°C in boreal spring and, to a lesser extent, autumn. AR4 concluded that global land-surface air temperature (LSAT) had increased over the instrumental period of record, with the warming rate approximately double that reported over the oceans since 1979. AR5 confirms previous estimates: Global LSAT increased: 0.1005°C ± 0.01925°C per decade over 1901–2012 period while the rise reaches 0.262°C ± 0.05°C per decade over 1979–2012 time period, according to the observations of CRUTEM4.1.1.0, GHCNv3.2.0, GISS and Berkeley dataset average (Hartman et al., 2013). Changes in the length of the spells are observed and they are likely to increase but this needs to be investigated further over Sahel where severe heat can have damaging consequences for societies.

For instance, in Niamey (Niger) in April 2010 whereas Tmax reaching 47°C (Ringard et al., 2015), increased morbidity and mortality rates were observed, especially among the elderly and young children. Moreover, in some places, HWs can be associated with increased rates of atmospheric pollution.

Terminology is large: a "hot spell" implies the hottest temperature during an extreme of temperature with a small duration (a few hours), small extension (around the station) and a high frequency; a "warm spell" should be less frequent and covers a larger area; a "heat wave" (HW) exceeds thresholds of temperature most frequently and covers at least a whole region (~ 500–1000 km²). These thresholds can be absolute (T° fixed locally) or relative, exceeding 5 °C as local standards for example for Expert Team on Climate Change Detection and Indices (ETCCDI, 2013). ACMAD (African Centre of Meteorological Applications for Development) classifies the extreme temperatures following five high-impact weather events; they broadcasts a mail alert when Tmax> 40°C. In ACASIS, Sahelian HW is defined (Rome et al. 2015) as a period of at least 3 consecutive days of extremely high (above the local 90th percentile) daily heat index. The Heat Index (HI) (Steadman 1979, 1994), combining temperature and relative humidity, appears as the most appropriate index, suitable for tropical climate, which takes into account the human-perceived equivalent temperature. The role of humidity is rather small in boreal spring across the Sahel, when high incoming solar radiation is combined with extremely dry soils, preventing cooling effect associated with latent heat flux. As for global scales, results show a clear warming trend over the last three decades, with a clear trend for HW events to become more frequent, last longer, cover larger areas and reach higher intensities (see also Oueslati et al. 2015). We then observe a decrease in cases of "Caution" HI and an increase in cases of "Danger" and "Extreme Danger" HI values.

P-1113-19

Future changes of extreme events of sea cooling in the Black Sea region in winter period of end of XXI century

A. Savchenko (1)

(1) Marine Hydrophysical Institute of NAS of Ukraine, Interaction of atmosphere-ocean, Sevastopol, Ukraine

The study of climate change at the end of the XXI century with increasing human intervention around the world is important and necessary. In particular, it is argued that the unprecedented magnitude of the positive trend in surface air temperature, observed since the mid XX century, largely due to the concentration of greenhouse gases in the atmosphere associated with human activities. Moreover, this warming will continue in this century, and by the end of the century will be 2 - 5 °C. At the same time, the spatial resolution of global models, despite their continuous improvement remains insufficient to display a regional atmospheric circulation. The method of «dynamical downscaling» takes an additional argument in regions with underdeveloped network of meteorological stations and difficult terrain. In the current global climate models do not take into account the Crimean Mountains, the Caucasus Mountains height not exceeding 2 km, and the Black Sea is posed less than 10 points calculation area. In this study, we used input data of global model INMCM4, which is a joint in international project CMIP5. Experiment of downscaling was carried out for area Black-Caspian Sea region to further revised data, i.e. the transition from large-scale calculations of global fields to regional estimates to obtain regional climate characteristics (temperature, turbulent heat fluxes, etc.), directly with the influence of regional factors with a spatial resolution of 25 x 25 km. Thus, for the Black Sea region were calculated turbulent heat fluxes in winter 2071-2100 (scenario RCP8.5). By control period used a data set of observations for the period 1971-2000 years. In the Black Sea basin was selected region's largest winter heat fluxes from the sea surface, which is the north-western basin. This water area is interesting that in the selected area of river runoff about 80% of the total annual flow into the Black Sea. According to the scenario RCP8.5 average temperature in winter over the Black Sea basin will increase by 2 - 3 °C at the end of XXI century. The following integral characteristics of the north-western shelf of the Black Sea are in the area of the sea bounded by the 44 - 47° N and 28 - 34° E. In the future heat fluxes of winter periods will change as follows: sensible heat flux will decrease by 3%, and latent heat flux will increase by 22% compared to the control period. Also Bowen ratio was calculated for the average winter values that will decrease in the future to 0.34 although it was 0.43 in control period. This ratio was calculated in order to look at the share of sensible and latent heat in the total heat flux (sensible heat flux + latent heat flux = total heat flux) and look at their quantitative changes. Most interesting were the calculations of extreme events P = 95% (5% of winter days with the largest values of total heat flux of the winter period) and their change in the future period. Thus it appears that the total flux extreme heat rise by 15% compared with the control period, but it is interesting that the most extreme P = 99% (1% of winter days with the highest values of total heat flux of the winter period), which in the future will rise by 40%. It was also interesting to see the changes in the synoptic situation during extreme cooling P = 95% of north-western part of Black Sea in the winter, where a total heat flux used to build composites. Composite fields showed that after clustering atmospheric situation in Europe have been identified 2 main types (clusters). So the first type - a anticyclone on the Baltic sea, and the second type of synoptic situation - a cyclone in the district of the Caspian Sea. So in the future period the number of extreme events P = 95% in each cluster was approximately 50% to 50%. And compared to the control period, the number of events first type was little over 20% and second type almost 80% of all events P = 95%. That is, it can be concluded that the change not only the quantitative characteristics of extreme cooling, but also qualitative changes in the synoptic situation in Europe during extreme cooling of sea surface of Black Sea. The greatest danger in the future period(2071-2100) in Black Sea region are extreme events for P = 99%, while increasing total heat flux almost 40% compared to the control period and result in potential losses in fishing, oil (gas) industry, agriculture and the other in this region. Thus these results require further verification and analysis of possible risks in the future for the economy of the Black Sea region.

Climatological analysis of trend of rainy days in Bangladesh using Mann Kendall Test

MR. Uddin (1) ; J. Begum (2) ; S. Ahmed (3)
(1) Bangladesh University of Engineering and Technology, Department of physics, Dhaka, Bangladesh; (2) Southeast University, Department of textile engineering, Dhaka, Bangladesh; (3) Comilla Victoria Govt. College, Department of physics, Comilla, Bangladesh

The impact of climate change on rainy days has received a great deal of attention by scholars worldwide. Many studies have been conducted to illustrate that changes in annual rainy days is becoming evident on a global scale. Bangladesh is likely to be one of the most vulnerable countries in the world due to climate change. This study focuses on detecting the trend of rainy days for 13 Bangladesh Meteorological Department rain gauge stations using Mann Kendall test, which was run at 5% significance level during the period 1950–2009. Seasonal and yearly trend of rainy days (greater than 01 mm/day) are studied. Variation of three threshold rainy days named: Moderated Heavy (22–44 mm/day), Heavy (45–88 mm/day) and Very Heavy (greater than 88 mm/day) are also studied. The country is divided into two regions named: wet region and dry region. All the stations showed increasing trend of rainy days except in Srimongal. The trend of Dhaka, Cox's Bazar, Srimongal and Chittagong stations are not statistically significant. All the four seasons (winter, pre-monsoon, monsoon and post-monsoon) showed statistically significant increasing trends except post-monsoon. The country's averaged threshold rainy days also showed statistically significant increasing trend except Very Heavy rainy days. The yearly rainy days indicate statistically significant increasing trend. The yearly rainy days in the wet region (122 days) were higher than that of dry region (105 days). The wet (dry) region showed negative (positive) trend of rainy days during 1950–1979 whereas wet (dry) region showed positive (negative) trend of variation of rainy days during 1980–2009. The country's averaged rainy days showed negative trend during 1950–1979 and positive trend during 1980–2009. These changes indicate that the climate of Bangladesh is changing. The yearly averaged increase of rainy days was 0.35 days.

Climate Change Signal in the 2012 Central U.S. Record (Flash) Drought

SSY. Wang (1)
(1) Utah State University, Climate Center, Logan, Utah, United States of America

The summer drought of 2012 in the central United States is instructive regarding one unique feature, that is, its rapid intensification during the early summer, evolving over a mere month from moderate to severe status. The timing of this drought's rapid intensification coincided with a subseasonal feature of widespread drying. The seasonal transition from June to July saw precipitation in the central U.S. decrease by about 25%, and this precipitation decrease is observed to have intensified since 1979. Such an intensification could enhance spring drought occurrences in the central U.S., where conditions evolved quickly from being abnormally dry to exceptionally dry, likely within a mere month from June to July. In this study, various atmospheric and land reanalysis datasets were analyzed to examine the trend calculated from 1979 to 2012 in the June-to-July seasonal transition. It was found that the change in precipitation deficit was accompanied by increased downward shortwave radiation flux and tropospheric subsidence, enhanced evaporative fraction, as well as an elevated planetary boundary layer height. The change in the tropospheric circulation encompassed an anomalous ridge over the western U.S. and a trough on either side; this wave-form circulation pattern is known to induce dry conditions in the central U.S. Such trends in the June-to-July seasonal shifts in precipitation, surface drying, and tropospheric circulation could have intensified and accelerated drought that took place in spring. The knowledge of the trends allows one to anticipate the evolution of spring onset of drought into the summer.

P-1113-22

Extreme North America Winter 2013-15: California drought and cold East Coast

SSY. Wang (1) ; JH. Yoon (2) ; R. Gillies, (3)
(1) Utah State University, Climate Center, Logan, Utah, United States of America; (2) Pacific Northwest National Laboratory , Department of energy, Richland, WA, United States of America; (3) Utah State University, Logan, UT, United States of America

The ongoing California drought was initiated by an anomalous high-amplitude ridge system in the winter of 2013-2014. The anomalous ridge was investigated using reanalysis data and the Community Earth System Model (CESM). It was found that the ridge emerged from continual sources of Rossby wave energy in the western North Pacific starting in late summer and subsequently intensified into winter. The ridge generated a surge of wave energy downwind and deepened further the trough over the northeast U.S., forming a dipole. The dipole and associated circulation pattern is not linked directly with either El Niño-Southern Oscillation (ENSO) or Pacific Decadal Oscillation; instead, it is correlated with a type of ENSO precursor. Multi-model analysis using CMIP5 model outputs indicated that the connection between the dipole and ENSO precursor has become stronger since the 1970s, and this is attributed to increased greenhouse gas loading as simulated by the CESM. Therefore, there is a traceable anthropogenic warming footprint in the enormous intensity of the anomalous ridge during winter 2013-2014 and the associated drought. When projecting for the future, the large-member ensemble simulations of CESM indicated increases in fire counts and extreme drought occurrences, both of which are increasingly linked to the ENSO cycle.

Furthermore, the extent to which climate oscillations will modulate wildfire occurrences in the changing climate is examined. The consensus of climate model has projected a generally wetter climate for California towards the latter part of the 21st century, a scenario that seems to counter the projections of more fires in a wetter climate. Using CESM that directly outputted fire parameters, it is found that both the mean fire probability and annual precipitation in California are projected to increase slightly towards the end of the 21st century. However, the fluctuation in annual precipitation will amplify leading to a robust increase in the variation of vegetation and fire probability. The increased fluctuation of fire probability is associated with the amplified ENSO cycle at the 4-5 year frequency. This association suggests a potential for increasingly severe wildfires to occur more regularly in the future.

P-1113-23

Early and late winter cold spells over the Euro-Mediterranean region

E. Xoplaki (1) ; A. Toreti (2) ; J. Luterbacher (1)
(1) Justus-Liebig-University Giessen, Geography: Climatology, Climate Dynamics and Climate Change, Giessen, Germany; (2) European Commission, Joint Research Centre, Ispra, Italy

Temperature extremes have a strong impact on ecosystems, societies and economies; for instance in terms of impacts on agriculture, human health, energy consumption among others. Warm summer extremes and their impacts, i.e. summer heat waves, have extensively been investigated and characterised in several studies focusing on either recent past-current time or climate projections for the next decades. Less efforts have been, instead, devoted to cold spells occurring in the Euro-Mediterranean region, although also these extreme events can have significant impacts especially in a future warmer climate. Especially for the European south, sensitivity to cold weather is greater than the northern, cooler regions, while mortality is found to increase to a greater extent with a given fall in temperature in regions with warmer winters. This study aims at characterising future changes in the occurrence, intensity, and duration of cold spells and their spatial variability over the Euro-Mediterranean region. The focus is on early and late cold season events (December and March, respectively), especially conditional on the occurrence of a presiding warmer autumn (winter for the late season events). Mid- and late 21st century potential changes are investigated by using the recently released Euro-Cordex regional climate simulations both under the mid-range mitigation emission scenario RCP4.5 and the high emission scenario RCP8.5.

1114 - Global emissions and their implications for climate targets

ORAL PRESENTATIONS

K-1114-01

Short Lived Promise? Short-lived climate pollutants, cumulative carbon and emission metrics

M. Allen (1)
(1) University of Oxford, School of geography and the environment, Oxford, United Kingdom

The relative priority given to reducing carbon dioxide emissions versus other forms of anthropogenic climate pollution, such as the Short Lived Climate Pollutants (SLCPs) methane and soot, could be a significant issue for many countries in the preparations for COP21. The decision to allow countries to adopt their own metrics to add up the role of different gases in their contributions to the overall emission reduction goal highlights the need for clarity on these issues. This talk will review the findings on cumulative carbon and emission metrics in the IPCC 5th Assessment, and present a new Policy Brief from the Oxford Martin School, with the same title, that discusses and elucidates these issues.

Any strategy to prevent dangerous anthropogenic interference in the climate system must limit cumulative emissions of the main long-lived climate pollutant, carbon dioxide (CO2). To limit the warming they cause to 2°C, for example, CO2 emissions must be limited to a cumulative budget of about one trillion tonnes of carbon, over half of which has already been released. That said, other climate drivers are likely to contribute to peak warming, and hence reduce the carbon budget consistent with 2°C of total anthropogenic warming. Current emissions of both CO2 and SLCPs also affect the rate and magnitude of climate change over the next few decades, although it is important to note that the climate benefits of reduced emissions on these short timescales could be comparable to, and hence potentially outweighed by, natural climate variability, particularly on regional scales.

Reductions in SLCP emissions could be achieved at relatively low cost and with substantial co-benefits but, I will argue, implementing these reductions immediately would have little impact on peak warming unless CO2 emissions are substantially reduced at the same time. Hence any decisions on policy priorities between CO2 and SLCPs, and any country's choice of emission metric to relate them, represents in essence a matter of intergenerational prioritisation: Advancing measures to reduce SLCP emissions could provide some climate benefit to the current generation through reduced warming over the next few decades, while immediate reductions in CO2 emissions also deliver a more substantial climate benefit to future generations.

Any emission trading system or climate policy that addresses emissions of several different greenhouse gases together in a single 'multi-gas basket' requires some form of metric to specify what a given amount of one greenhouse gas is 'worth' in terms of another. The choice of metric to compare the impact of emissions of methane and other SLCPs with the impact of CO2 depends on the timescale of interest. If the policy goal is to limit peak warming, it also depends on the ambition and success of future mitigation measures.

The standard '100-year Global Warming Potential' metric (GWP100) provides (despite its name) an approximate indication of the relative importance of emissions of different gases to the increase in global temperatures over the next 20 to 40 years. GWP100 is therefore a measure of impact on peak warming if and only if temperatures are expected to be approaching stabilization within 40 years, for which CO2 emissions need to approach zero on a comparable timescale.

As long as CO2 emissions continue to rise, policies that allow SLCP measures to be exchanged, traded or offset against CO2 emission reductions using GWP100 overvalue the impact of SLCP measures on peak warming and hence risk discouraging the CO2 emission reductions that are required to stabilize temperatures. Replacing GWP100 with a different metric would not solve this problem because any metric that is suitable for long-term impacts would be misleading for short-term impacts and vice versa. Using a metric that changes over time would help, but introduces greater complexity and uncertainty.

Rather than discussing a change of metric within a single 'multi-gas basket' framework, policymakers should focus instead on introducing additional instruments, safeguards or measures to ensure that cumulative emissions of CO2 are limited to an overall budget consistent with meeting the 2°C goal. A simple precaution would be to avoid trading or offsetting between CO2 and SLCP emission reductions until global CO2 emissions are falling fast enough to allow a robust and realistic assessment of the remaining time to peak warming.

O-1114-01

The changing face of global fossil fuel carbon dioxide emissions

R. Andres (1) ; T. Boden (2)
(1) OAK RIDGE NATIONAL LABORATORY, LOS ALAMOS, NM, United States of America; (2) OAK RIDGE NATIONAL LABORATORY, OAK RIDGE, TN, United States of America

Global fossil fuel carbon dioxide emissions have been persistently increasing for the last 250 years. This increase is a primary driver of the atmospheric disequilibrium impacting and changing atmospheric, terrestrial, and oceanic systems.

The Carbon Dioxide Information Analysis Center (CDIAC) at Oak Ridge National Laboratory (ORNL), U.S.A., has been estimating fossil fuel carbon dioxide emissions for more than 20 years. These emission estimates are based on fuel statistics, carbon contents, and the fraction of fuel oxidized. This has resulted in an annual time series of emission estimates from the year 1751 to the present. Annual updates add another year to the time series as well as revising data in previous years. Over the years, this basic time series has been supplemented by mapping the emissions at one degree latitude by one degree longitude, describing the time series in terms of stable carbon isotopic (â13C) signature, parsing the time series from annual to monthly time steps, and describing the uncertainty of the global total FFCO2 emissions. Underway now is an uncertainty evaluation of the annual and monthly mapped emissions.

This time series reveals interesting trends when disaggregated by country, fuel type, and source. For example, the proportion of emissions from Kyoto Protocol Annex B and non-annex B countries has changed since Protocol signing to today. The role of coal in fueling global energy systems has changed from being the primary fuel to becoming secondary to liquid fuels to again becoming the primary fuel. The practice of flaring excess gas in oil fields, as a proportion of total energy production, has decreased by more than a factor of two since the year 1950. Release of carbon during cement production has increased by more than a factor of four since 1950 and now equates to about 5% of global carbon dioxide emissions from fossil fuel production.

The global fossil fuel carbon dioxide uncertainty analysis resulted in a 2σ range of 1.0 to 13%, which can be greatly simplified to 8.4% (2σ). This uncertainty in the magnitude of global fossil fuel carbon dioxide emissions has become an important component to our overall understanding of the global carbon cycle. The uncertainty in the magnitude of mapped fossil fuel carbon dioxide emissions will become a limitation to our understanding of local carbon cycles in the absence of detailed local inventories and observations.

The emission time series has been used by the Global Carbon Project in its annual evaluation of the global carbon budget. The budget is a high level check on the

understanding of carbon flows throughout the Earth system. Uncertainty propagation through the budget constrains our knowledge about the carbon system.

O-1114-02

Potential emissions of CO2 and methane from proven reserves of fossil fuels in the context of the global remaining carbon budget

R. Heede (1) ; N. Oreskes (2)

(1) Climate Accountability Institute, Snowmass, CO, United States of America; (2) Harvard University, and Climate Accountability Institute, Department of the history of science, Cambridge, MA, and Snowmass, CO, United States of America

Scientists have argued that no more than one-third of proven recoverable fossil fuel reserves can be extracted and consumed by 2050 if we are to avoid exceeding the 2°C temperature target agreed to in Copenhagen (IEA 2012). The remaining carbon budget is ≤275 gigatonnes of carbon (GtC) (assuming a 66% probability of staying below 2°C; IPCC 2014), whereas recoverable fossil fuel reserves contain an estimated 733 GtC (based on BP 2014; IPCC 2014 cites reserves of 1.0–1.9 TtC). Global reserves are based on national assessments without reference to reserve ownership or productive capacity. The studies that do identify corporate owners are limited to investor-owned companies listed on major securities exchanges. We identify the largest seventy investor-owned and state-owned companies that possess the financial and technical capacity (and the ownership or production rights) to exploit and produce the majority of the world's recoverable reserves of oil, natural gas, and coal. We quantify the potential emissions of CO2 and methane for each entity's reserves, and compare the emissions to the global remaining carbon budget.

This presentation will report on recent estimates of the potential emissions of CO2 and methane from the proven reserves declared by the world's largest producers of oil, natural gas, and coal, focusing on the seventy companies and eight government-run industries that produced 63 percent of the world's fossil fuels from 1750 to 2010 (Heede 2014). Full production of these reserves (accounting for non-energy uses and flared and vented CO2) is estimated to result in emissions of 440 GtC of carbon dioxide — or 160 percent of the remaining 275 GtC carbon budget. Of the 440 GtC attributed, the 42 investor-owned oil, gas, and coal companies hold reserves with potential emissions of 44 GtC, whereas the 28 state-owned entities possess reserves of 210 GtC — equivalent to 16 percent and 76 percent of the remaining carbon budget, respectively. Government-run industries possess reserves of 185 GtC (16% of the remaining budget).

This analysis shows that 1) the profound risk to the future arises not so much from the proven reserves in the hands of publicly-traded corporations, but from their on-going exploration for and development of new fossil fuel resources, and 2) that while the investor-owned companies may be most vulnerable to investor and consumer pressure, effective action to control climate change must also include the state-owned companies and governments that hold the preponderance of reserves. This work will inform climate scientists, energy and emission scenario modelers, climate negotiators, national climate and energy policy leaders, and investors in fossil fuel companies with practical data on the potential consequences of fossil fuel reserves held by specific companies with the capacity, financial resources, and incentives to extract, refine, and market carbon fuels. These supra-national companies may play a critical role in delivering solutions to reduce net emissions from the fossil fuel sector.

O-1114-03

Net Carbon gain and loss in the world's tropical vegetation: New estimates for the 2012 – 2014 period

A. Baccini (1) ; W. Walker (2) ; L. Carvalho (3) ; D. Sulla-Menashe (4) ; RA. Houghton (2)

(1) The Woods Hole Research Center, Woods Hole, United States of America; (2) The Woods Hole Research Center, Woods Hole Research Center, United States of America; (3) Boston University, Dept. of mathematics and statistics, Boston, United States of America; (4) Boston University, Geography, Boston, United States of America

Tropical forests store 471 Pg C, 55 % of global forest stocks, and emissions from land use and land cover change (LULCC) are the second largest anthropogenic source of carbon dioxide to the atmosphere. Despite the near convergence of emissions estimates for the tropics as a whole, estimates for individual regions are much more variable, particularly at national and subnational scales. Forest disturbance and successional processes determine the magnitude and distribution of sources and sinks of atmospheric carbon dioxide, which influence climate. Tracking terrestrial carbon fluxes and predicting how tropical forests will respond to continuous global change relies on accurate estimates of annual changes in the density and distribution of carbon stocks at local to global scales. Thus, determining the magnitude and distribution of sources and sinks at annual time steps with measurable uncertainty is of scientific and political importance. While significant progress has been made in the quantification of single-epoch carbon storage across large areas of the globe, robust assessments of aboveground carbon dynamics remain lacking. Existing evidence for tropical forests as a carbon sink is based on a limited number of repeated in situ measurements that have been scaled to characterize sequestration dynamics across large regions of the tropics. Advancing the work of Baccini et al. (2012), we combine wall-to-wall satellite image data, Light Detection and Ranging (LiDAR) measurements and field data to empirically examine aboveground biomass dynamics (i.e., gains and losses) and quantify net changes in carbon density (i.e., rates of carbon sequestration and emissions) at annual intervals for the period 2002 to 2014 using a hierarchical statistical model that segments annual time series measurements of carbon density according to piecewise linear trends. Thirteen years (2002–2014) of pantropical satellite data serve to provide direct, measurement-based evidence that the world's tropical forests are a net carbon source on the order of 420 Tg C yr −1. This net release of carbon consists of net losses of 548 Tg C yr−1 and net gains of 128 Tg C yr−1. The gains result from forest growth, afforestation and reforestation; losses result from natural disturbance processes as well as both anthropogenic reductions in forest area attributed to deforestation and in biomass density within forests resulting from degradation. While the changes are widely distributed throughout the tropics, the forests of tropical America account for 75 % of the net loss. Advantages of this new approach to emissions estimation over traditional methods that rely on emission factors (carbon density) and activity data (forest area change) include (1) providing spatially explicit, consistent and accurate estimates of net emissions from forest biomass change that eliminate the need for error prone land cover classifications or area change products, (2) accounting for gains and losses without the need to explicitly define or delineate forest degradation and (3) tracking of changes in net forest carbon emissions on an annual basis with quantified uncertainty that is suitable for use in national and international policy making on REDD+ and associated mitigation actions.

Global methane budget and natural gas leakage based on long-term □13CH4 measurements and updated isotopic source signatures

S. Schwietzke (1) ; O. Sherwood, (2) ; PP. Tans, (1) ; MS. Englund (2) ; G. Etiope, (3) ; A. Ionescu, (4) ; JB. Miller, (1) ; EJ. Dlugokencky, (1) ; LMP. Bruhwiler, (1)

(1) National Oceanographic and Atmospheric Administration, ESRL/GMD, Boulder, CO, United States of America; (2) University of Colorado at Boulder, Institute of arctic and alpine research, Boulder, CO, United States of America; (3) Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy; (4) Babes-Bolyai University, Cluj-Napoca, Romania

Methane (CH4) is a greenhouse gas (GHG) with the second largest global radiative forcing contribution after CO2. Its atmospheric abundance has increased by about 150% since the industrial revolution. Given the critical role of CH4 in global climate change, it is important to better understand its sources and sinks. Improving the estimates of individual source magnitudes – such as fossil fuels, agriculture, and other anthropogenic and natural sources – helps prioritizing CH4 emissions mitigation efforts

and modeling future climate change. Policy-makers rely strongly on accounting-based national and international emissions inventories to inform mitigation regulatory action. However, recent field studies indicate that emissions inventories may significantly underestimate fossil fuel CH4 emissions (those associated with extraction and use of natural gas, oil, and coal). In this work, atmospheric measurements from the National Oceanographic and Atmospheric Administration (NOAA) Global GHG Reference Network spanning the past three decades are used to derive long-term estimates of global CH4 emissions from fossil fuels and other sources in comparison with inventories and other estimates. Atmospheric measurements include global CH4 and the stable isotope 13CH4, which are used in a global box-model to constrain source magnitudes. First, probability distribution functions of the key model parameters are derived including literature isotopic source signatures, isotopic fractionation factors, atmospheric CH4 lifetime, and fossil fuel hydrocarbon gas compositions. Our isotopic source signature distributions are based on the largest literature survey to date, which suggests significant corrections compared to previous studies. Second, a Monte Carlo simulation of the box-model is performed to quantify confidence intervals of individual emissions sources. We find that attributing the majority of increased CH4 levels over the past three decades to microbial sources is consistent with 13CH4. The sum of CH4 emissions from the fossil fuel industry and geological seepage is significantly larger than previous estimates, which is compatible with pre-industrial isotopic ice core records. Third, recently published estimates of global CH4 emissions from oil and coal production are subtracted from our global fossil fuel CH4 results to quantify global CH4 leakage from the natural gas industry during extraction, processing, transport, and distribution of the fuel. Natural gas CH4 leakage as a fraction of total production has decreased steadily over the same period indicating industry efficiency improvements. The results highlight a major gap in our understanding of global CH4 emissions. This motivates increased collaboration efforts between the physical sciences and regulatory agencies to explain and reconcile the differences between atmospheric measurements and emissions inventories.

Arctic Deposition of Black Carbon from Biomass Burning in Northern Eurasia from 2002 to 2012

WM. Hao (1) ; N. Evangeliou (2) ; Y. Balkanski (3) ; S. Urbanski (1)

(1) US Forest Service, Missoula Fire Sciences Laboratory, Missoula, MT, United States of America; (2) Norwegian Instiitute for Air Research, Atmospheric and climate research, Kjeller, Norway; (3) Institut Pierre et Simon Laplace, Laboratoire des sciences du climat et de l'environnement, Gif sur Yvette Cedex, France

Black carbon (BC) in smoke plumes in Northern Eurasia can be transported and deposited on Arctic ice and accelerate ice melting during certain times of the year. Thus, we examined daily BC emissions from fires in this region at a 500 m x 500 m resolution from 2002 to 2012 and modeled the BC transport and deposition in the Arctic. Black carbon emissions were estimated based on MODIS land cover maps and detected burned areas, the Forest Inventory Survey of the Russian Federation, and biomass specific BC emission factors. Annual burned areas in Northern Eurasia varied considerably with an average of 260,000 km2 for the study period. Grassland dominates the total burned area (61%), followed by forest (27%). For grassland fires, about three-quarters of the area burned occurred in Central and Western Asia and about 17% in Russia. More than 90% of the forest burned area was in Russia. Annual BC emissions from Northern Eurasian fires varied enormously with an average of 0.85 Tg. In contrast to burned area, BC emissions from forest fires accounted for about two-thirds of the emissions, followed by grassland fires (15%). More than 90% of the BC emissions from forest fires occurred in Russia. Central and Western Asia is the major region for BC emissions from grassland fires (53%). Overall, Russia contributed 83% of the total BC emissions from fires in Northern Eurasia.

The transport and deposition of BC on Arctic ice from all the global sources was estimated using the LMDz-OR-INCA global chemistry-aerosol-climate model at the LSCE. Overall, about 55% of emitted BC was deposited on the Arctic ice. Biomass burning over Northern Eurasia was the dominant source (54%) of the BC deposition in the Arctic. Anthropogenic sources in Northern Eurasia accounted for 24% of BC deposition in the Arctic, while all sources from North America and southern Asia comprised the balance. Seasonally, biomass burning contributed 68% of the BC sources in the Arctic in the spring and 81% in the summer, while anthropogenic sources contributed 73% in the winter and 67% in the fall. About 49% of total BC deposition in the Arctic originated from Asia and only 5% was from Europe. Geographically, in Asia, Siberia was the major source (59%) for the BC deposition in the Arctic, followed by Kazakhstan (18%) and Mongolia (8%).

These results are critical to understanding the contribution of black carbon from biomass burning to accelerated melting of Arctic ice under future climate conditions.

Lagrangian modeling of global atmospheric methane (MAIOLICA II project)

F. Arfeuille (1) ; S. Henne (1) ; D. Brunner (1)

(1) EMPA, Dübendorf, Switzerland

In the MAIOLICA II project, the Lagrangian particle dispersion model FLEXPART is used to simulate the global atmospheric CH4 over the 1990-2010 period. In this Lagrangian framework, 3 million particles are permanently transported based on wind fields from ERA-interim. The history of individual particles can be followed allowing for comprehensive analysis of transport pathways and timescales and to establish a link between sources (emissions) and receptors (measurement stations) in a straightforward manner, a prerequisite for source inversion problems. FLEXPART was extended to incorporate the methane loss by reaction with OH. CH4 mass is further lost by soil uptake and stratospheric loss reactions with prescribed Cl and O(1D) radicals.

Sources are separated into 245 different tracers, depending on source origin (anthropogenic, wetlands, rice, biomass burning, termites, wild animals, oceans, volcanoes), region of emission, and time since emission (5 age classes). The inversion approach applied is a fixed-lag Kalman smoother similar to that described in Bruhwiler et al. [2005].

Results from the FLEXPART global methane simulation and from the subsequent inversion will be presented.

Methane is the second anthropogenic greenhouse gas after carbon dioxide. Atmospheric methane has contributed 20% of the climate forcing by long-lived greenhouse gases since pre-industrial times but also influences the oxidizing capacity of the atmosphere. With a lifetime around 10 years in the atmosphere and a diversity of emission types, methane is an important target for climate change mitigation. Observations of atmospheric methane began in 1978, reached global coverage after 1983, and now include a large variety of in-situ and remote-sensed observations. After the loss of SCIAMACHY (2002-2012), two space missions are currently producing methane

weighted-columns, GOSAT (since 2009) and METOP-IASI (since 2007).

Although sources and sinks of methane are identified, large uncertainties remain in their spatio-temporal quantification. Here, we present a synthesis of methane emissions and sinks since 2000 using an integrated approach to combine: atmospheric measurements, chemistry-transport models, ecosystem models, emission inventories, and climate-chemistry models. The results of an ensemble of atmospheric inversions (top-down) and of process-based models (bottom-up) are presented and compared. Global and regional methane budgets and their changes are presented and discussed for the period 2000-2012. Possible scenarios are presented to explain the increase of atmospheric methane after 2006, after almost a decade of stagnation. Year-to-year changes are also analysed after 2006 in order to identify robust changes as opposed to still uncertain ones.

P-1114-03

Fossil fuels ultimate recovery appraisal, clue to climate change modelling

B. Durand (1)
(1) retired from ENS de Géologie, Geology, Arvert, France

According to ICCP report, Climate Change 2013 (the Physical Science Basis), as shown by figure SPM.10 of Summary for Policymakers, temperature of the earth's surface at the end of the century would depend primarily on the cumulative quantity of CO2 from anthropogenic sources emitted since 1860. Because roughly 80 % of these emissions are produced by fossil fuels combustion, according to this modelling, fossil fuels ultimately recoverable quantities are the main drivers of climate change during this century and the followers.

Since production histories of fossil fuels are already long, it is now possible, as shown in this paper, to predict with a good approximation their quantities to be ultimately produced. This is done by statistical methods, using mainly the construction of creaming curves of technical reserves discoveries and Hubbert's production linearization.

These quantities are such that a temperature increase till the end of the century as high as described by RCP 8,5 and 6, is highly improbable even in a Business As Usual scenario. And staying below a 2 °C temperature increase from 1860 on remains obviously possible, provided that use of coal is now strongly restricted. This is the responsibility of the main coal consumers.

10 of them, China, the USA, India, Japan, South Africa, Russia, South Corea, Germany, Poland and Indonesia, consume nearly 90 % of the world's total coal production. As a result, these 10 countries also produce for the moment most of the world CO2 emissions. Therefore they are, according to ICCP modeling, the main drivers of climate change. They should definitely cooperate to undertake immediate and strong action.

Exploitations of bituminous shales, methane hydrates, or of coal by underground gasification are not considered here. They are for the moment highly hypothetical at a large scale. Nevertheless they should not be encouraged.

P-1114-04

Extending the relationship between global warming and cumulative carbon emissions to multi-millennial timescales

T. Froelicher (1)
(1) ETH Zurich, Zurich, Switzerland

Climate model simulations and theoretical arguments indicate an approximately linear relationship between cumulative carbon emissions and projected global mean temperature over the 21st century and beyond in a wide set of future carbon emissions scenarios. This Transient Climate Response to cumulative carbon Emissions (TCRE) is estimated to likely (> 66% likelihood) be in the range of 0.8-2.5°C/1000 Gt carbon. TCRE is defined for peak temperature and is nearly independent of the rate of carbon emissions. Any global temperature target therefore implies a limited carbon emissions budget. TCRE is a simple and useful policy framework and may play an important role in the post-Kyoto political negotiations for a new global agreement on future carbon emissions.

A recent modeling study (Frölicher et al. 2014) using carbon pulse experiments of a comprehensive global atmosphere-ocean general circulation model (AOGCM) finds that global mean temperature may continue to increase on multi-centennial timescales even after stopping carbon emissions. In other words, there may be a significant amount of warming expected from past carbon emissions. These results imply that the linear relationship between global warming and cumulative carbon emissions breaks down when the carbon emissions are tapering off. This is in contrast to a large body of studies suggesting that global mean surface temperature stays roughly constant for a couple of centuries at the value attained when carbon emissions are stopped. These earlier studies, however, use climate models of intermediate complexity, which simplify the complexities of many processes such as cloud feedbacks.

These results call for an extension of the TCRE concept. Here I use climate models of different complexities to show that the temperature response to cumulative carbon emissions can be characterized by three different timescales or phases and that the TCRE concept is only valid during the first phase, when emissions are steadily increasing. For longer time-scales, when emissions are tapering off, two new metrics will be introduced that better characterize the time-dependent temperature response to cumulative carbon emissions, namely the Peak Climate Response to cumulative carbon Emissions (PCRE) and the Equilibrium (multi-millennial) Climate Response to cumulative carbon Emissions (ECRE). I will explain why the PCRE is generally larger than the TCRE in the fully coupled AOGCMs and why the models of intermediate complexity as a class don't simulate an increase in global mean temperature after carbon emissions stoppage. The implications of these results for allowable carbon emissions required to remain below a specific global warming target will be discussed.

Frölicher, T. L., M. Winton, J. L. Sarmiento, 2014, Continued global warming after CO2 emissions stoppage, Nature Climate Change, 4, 40-44.

Hydrological and biogeochemical constraints on terrestrial carbon cycle projections

S. Mystakidis (1) ; N. Gruber (2) ; LE. Davin (1) ; S. Seneviratne (1)
(1) ETH Zurich, Institute for atmospheric and climate science, Zurich, Switzerland; (2) ETH Zurich, Institute of biogeochemistry and pollutant dynamics, Zurich, Switzerland

Terrestrial ecosystems are playing a crucial role in the climate system by absorbing about one third of the total anthropogenic emissions of CO2, thus providing a valuable ecosystem service to mankind. How this ecosystem service will evolve in the coming decades is still a subject of debate. This evolution depends on the response of biogeochemical cycles and ecosystems to a changing climate with more frequent and severe extreme events in some regions as well as to increased CO2 concentrations. Earth System Models which are explicitly represent the

ecosystem behavior such as the exchange of carbon and water with the atmosphere are used to study the future evolution of the land and ocean carbon cycle sinks. However, the estimates of these carbon fluxes are clearly subject to significant uncertainties. Observationally-based constraints on these simulated fluxes should therefore facilitate reduce uncertainties in future terrestrial carbon cycle projections performed for AR5 (CMIP5).

Gross Primary Production (GPP) is the total amount of carbon that is taken up by plants during photosynthesis and it is one of the main components of the land carbon cycle and driver of the carbon uptake by land. We show that over many regions models simulating high present-day GPP and Evapotranspiration (ET) tend to simulate higher increase in future GPP. Using these emergent relationships combined with present-day estimates of ET and GPP we constrain future changes in GPP. We find that the inter-model spread in future GPP is reduced by at least 50% while the increase in future GPP in northern latitudes is higher than previously thought. Our results for future changes in Water Use Efficiency (WUE), a highly significant determinant of primary production of terrestrial ecosystems, show similar behavior. Applying the observational constraints on the future land sink (NBP) reveals higher than previously thought decrease in the land sink. The inter-model spread in the land sink is reduced by more than 30% and in most of the constrained ensembles the terrestrial biosphere is even turned into a net carbon source by the end of the century. Our findings therefore have several implications on the future productivity of ecosystems and the atmospheric CO2 concentrations.

P-1114-06

Air Pollution Emissions and Potential for Co-Benefits in Megacities of South Asia

BR. Gurjar (1)
(1) Indian Institute of Technology Roorkee, Civil Engineering Department, Roorkee, India

The South Asian region is highly and densely populated and includes 5 megacities (each with population more than 10 million) and hundreds of large and medium size cities. Megacities in South Asia are namely – Delhi, Mumbai and Kolkata (India), Dhaka (Bangladesh) and Karachi (Pakistan). Constantly increasing energy-intensive urban activities in burgeoning cities areas are responsible for a large share in the unacceptably high emissions of those air pollutants, which are responsible for poor air quality, adverse health effects and also climate change. High levels of Air pollution in South Asia came into highlight by the South Asian haze called Atmospheric Brown Cloud (ABC). The annual premature deaths due to ABC were estimated equal to 100,000s in the South Asian region. Whereas, recent estimates of the burden in India show approximately 1.04 million premature deaths and 31.4 million disability-adjusted life years (DALYs) to be attributable to household air pollution (HAP) resulting from solid cooking fuels. Numerous policy measures and technological interventions are being tried in India and other countries to curb the air pollution. However, there is a growing interest in adopting those measures which can reduce air pollution emissions resulting in not only air quality improvement and health benefits but also in climate change related co-benefits.

This presentation would provide an analysis of the urban pollution emissions and potential for health and climate change related co-benefits in South Asian megacities. Most of the South Asian countries are in the stage of developing or emerging economies, and India is the fasted growing economy among them. Given the increasing trend of energy use and emissions in South Asian cities, present study is a step to make governments and people aware of the extent and intensity of ambient as well as indoor air pollution problem. The analysis presented in this study is expected to help initiate appropriate policy measures and suitable action plans to limit air pollution emissions and adopt ways based on co-benefits approach that can promote the sustainable development – especially in South Asia.

P-1114-07

Cumulative carbon emissions modulated by policy options for limiting warming to below 1.5 and 2°C

J. Rogelj (1) ; M. Schaeffer, (2) ; M. Meinshausen, (3)
(1) IIASA, Laxenburg, Austria; (2) Climate Analytics, Berlin, Germany; (3) University of Melbourne, Australian-german college of climate & energy transitions, school of earth sciences, Melbourne, Australia

Cumulative emissions of carbon dioxide, or so-called carbon budgets, have recently received increasing attention in the climate policy arena. Not only are they part of the headline statements of the most recent assessment of the Intergovernmental Panel on Climate Change (IPCC), they have also been proposed as guidance for long-term emission reduction goals within the international climate negotiations under the United Nations Framework Convention on Climate Change (UNFCCC). For example, directly following from the concept of a carbon budget is that as soon as 2055 to 2070, global net emissions of CO2 will have to be phased-out to zero in order to stay below 2°C warming with a likely chance.

A thorough understanding of the interplay between policy choices and the amount of carbon emissions compatible with specific temperature limits gains therefore in importance, in particular because the amount of future carbon emissions compatible with limiting warming to below the 1.5 or 2°C thresholds is vanishing quickly with time. Mitigation costs are related to the size of the carbon budget and can increase significantly with a delay of strong decarbonisation, as weaker reduction ambition early on comes with the necessity of much stronger reduction rates later.

We provide key insights that link the theoretical concept of carbon budgets to a real-world context, by quantifying policy-relevant emission-scenario aspects that increase or decrease cumulative carbon emissions compatible with limiting warming to below specific temperature limits, like 1.5 or 2°C relative to preindustrial. To achieve this, we explore dimensions not previously assessed by the IPCC.

First, we show that the choice of methodology to derive compatible carbon emissions from integrated multi-gas emission scenarios plays a non-negligible role. Both the influence of non-CO2 forcing variations and the timescales of the Earth system response lead to lower compatible carbon emissions when derived from low instead of high emission scenarios. Second, as non-CO2 forcing has the potential to modulate carbon budgets, we assess the potential influence of the mitigation of so-called short-lived climate pollutants (SLCP, like methane, soot, or hydrofluorocarbons) on the size of compatible carbon emissions. We show how, due to technological linkages between the sources of CO2 and some SLCPS, the potential impacts can vary strongly across species. Third, we explore how socio-economic developments and technological policy choices can influence the size and cost of a carbon budget for meeting a specific temperature goal by, often inadvertently, influencing the proportion of CO2 to non-CO2 forcing. Finally, by using multi-gas characteristics of a large set of emission scenario as well as theoretical phase-out pathways we explore the implications for the timing of global net zero carbon emissions.

P-1114-08

Speciation of anthropogenic VOC emissions from observations in contrasted urban environments: a basis for emission inventory evaluation and the definition of CMIP (Coupled Model Intercomparison Project) historical emission inventory

T. Salameh (1) ; A. Borbon, (1) ; C. Afif, (2) ; S. Sauvage, (3) ; N. Locoge, (3) ; C. Granier (4)
(1) Laboratoire Interuniversitaire des Systèmes Atmosphériques (LISA),IPSL,CNRS,UMR7583,UPEC and UPD, Créteil, France; (2) Unité Environnement, Génomique Fonctionnelle et Études Mathématiques, Saint Joseph University, Beirut, Lebanon; (3) Mines Douai, Sciences de l'Atmosphère et Génie de l'Environnement (SAGE), Douai, France; (4) CNRS, LATMOS/IPSL, Paris, France

Having accurate trace species emission estimates is critical in the development of basic scientific knowledge and to assess atmospheric chemistry, air quality, and climatic conditions at present and in the future. In addition, detailed emissions data are also required at high resolution for the design of feasible controls aimed at reducing emissions of pollutants, and for the evaluation of the efficiency of

the implemented policies. Therefore, concerted efforts in emission inventory development are necessary to improve the quality of the emission estimates and to be able to reproduce air quality conditions in models. In this context, the CMIP project was established to provide a basic support for the IPCC future report (AR6). The CMIP Panel has requested further improvements on the emissions data by using observations, as well as on the emissions spatial and temporal resolution. Among others, a high priority is given to the development of anthropogenic hydrocarbon and particle speciation.

Non-Methane Volatile Organic Compounds (NMVOCs), emitted from various sources, are of particular interest since they affect urban air quality and regional climate change by contributing to the formation of tropospheric ozone, PAN and Secondary Organic Aerosols. According to Shindell et al. (2012), NMVOC reductions could help slow the near-term rate of climate change because of their influence on short-lived climate forcers (e.g., ozone, methane, aerosols). Thus, reducing NMVOC emissions provides regional to global benefits to air quality and climate (Fry et al. 2014). Some studies have shown that the NMVOC composition depends on the regional characteristics, even among the northern mid-latitude megacities (Borbon et al., 2013). These discrepancies may be more important if we consider the UNFCC Non-Annex 1 countries.

Here, we propose to make an assessment of the spatial and temporal variability of the composition of NMVOC anthropogenic emissions from recent and decadal observations in urban areas in order to define more accurate and representative NMVOC emission sources profiles. The main objectives are: (1) the establishment of NMVOC emission sources profiles from in-situ observations or by near field measurements, (2) the analysis of seasonal and interannual variability of NMVOC emissions composition, and (3) the evaluation of the anthropogenic emission inventories.

This work is based on the most recent results of several long-term (air quality networks) and intensive measurement campaigns (MEGAPOLI - Paris, 2009, CalNex,) in post-industrialized regions (northern mid-latitude cities) and in the Eastern Mediterranean Basin within the TRANSEMED initiative. According to the ACCMIP and RCPs inventories, the total anthropogenic emissions of NMVOCs in the MEA region were constantly increasing reaching ~15 Tg in 2010 whereas in USA and Europe, the NMVOCs emissions were decreasing reaching ~10 Tg in 2010 (ECCAD database). A very detailed and unique multipollutant database was generated in a city of the Middle East, Beirut, with a focus on the organic carbon, and in Istanbul. Since, the current NMVOC speciation applied in models needs updating, source profiles were determined with field measurements close to the main potential emitters (Salameh et al. 2014).

Black Carbon emission and its climate implication in Pakistan

I. Shahid (1)
(1) Institute of Space Technology, Islamabd, 1-Islamabad highway near Rawat Toll plaza ISlamabad, Islamabad, Pakistan

Black carbon (BC) is a product of incomplete combustion (burning that gives off smoke). It is the solid, mostly pure carbon component of soot that is capable of absorbing light at all wavelengths. Black carbon emissions in South Asia are primarily derived from four sectors: residential, industrial, transportation, and biomass burning (field burning, cook stove burning). The residential sector represents the largest single source of black carbon emissions in South Asia. The transportation and industrial sectors are also significant contributors (US EPA 2012). Black carbon deposited on snow and ice darkens the surface and decreases reflectivity, thereby increasing absorption and accelerating melting. Kopacz et al., (2011) reported the role of BC in Himalaya glacier melting and change of radiative forcing in the region due to BC.

Emission inventories and analyses of aerosol samples indicate that more than half of the black carbon emitted in South Asia comes from the burning of biofuels, especially in traditional cook stoves. Shahid et al., (2015) reported that burning of different wood species for cooking emits 22% BC of the total amount of biomass burned. Other large sources include burning of coal (for example in brick kilns), exhaust from diesel vehicles and generators, waste burning, and forest fires. Many sources of black carbon also co-emit other substances that are less light-absorbing, or that scatter light, including brown carbon, organic carbon, and sulfate. Emissions from diesel trucks have a higher percentage of pure black carbon than emissions from open fires. The overall effect of BC in any region will therefore be a result of local / regional / global emission, climate and geography. For example, in the Himalayas BC can amplify the effects of enhanced global warming while, in addition, causing surface dimming which can reduce crop productivity. There have been efforts to build emission inventories in Pakistan, however, this has been sporadic and specific. Three local efforts, one in 1990, another in 1994 and the latest in 2009 have all focused on greenhouse gases (GHG), and BC carbon was ignored. In global and regional emission inventories scarce information is available for Pakistan. In this study BC emissions have been estimated from different sectors using Atmospheric Brown Cloud emission inventory manual with emphasis of biomass burning for cooking and field burning (crop Residue). Unfortunately no sector specific emission factors are available. Thus we used emission factors that have been already published and closely related to Pakistan environment. During the year 2013-14, 16.923 x 106 Hectare area was cultivated for crop production, and 116 x 106 tonnes of crops were produced which inturn produced 40 x 106 tonnes of dry mass that was burnt in field. Thus single source of crop residue buring emits about 24 mega tonnes of BC along with other pollutants. Based of this data emission maps will be generated for gridded emissions over Pakistan.

These are the preliminary results,work is going on and hopefully will be able to finish till June.

P-1114-10

National and regional contributions to global climate change

RB. Skeie (1) ; JS. Fuglestvedt (1) ; M. Allen () ; T. Berntsen (1) ; GP. Peters (1)
(1) CICERO, Oslo, Norway

According to the "Brazilian Proposal" from 1997 the industrialized countries should reduce emissions proportional to their contribution to temperature increase. The emissions of Greenhouse Gases (GHG) and Short-Lived Climate Forcers (SLCFs) have changed dramatically over the last decade with large regional differences, suggesting that previous estimates are outdated. In this work we update earlier estimates of the contributions to global mean temperature change from countries and regions, and perform deeper analysis of various scientific and policy related choices. Which time period should be accounted for when calculating the countries' contributions? We show the importance of the start year, end year, and evaluation year on countries' contributions. Another choice is which forcing components that should be included in the analysis. First we consider only CO2 from fossil fuels and then we explore how the results are affected when all Kyoto gases and CO2 from land use change are included, and then non-Kyoto gases together with SLCFs. Time series of emissions of GHGs, aerosols and its precursors for countries/regions are constructed and a simple climate model is used to calculate the temperature response. Another policy choice is for which stage in the emission chain the contributions should be calculated (extraction, production (territorial), consumption). Finally, we will discuss how the historical responsibilities of countries/regions can be seen in relation to attribution to extreme events based on work in the EU-project EUCLEIA.

Biogenic CH4 and N2O emissions overwhelm land CO2 sink: implications for climate change mitigation

The stabilization of greenhouse gas (GHG) concentrations in the atmosphere requires reducing net anthropogenic GHG emissions and increasing the capacity of carbon sinks in the biosphere. Although global terrestrial CO2 uptake partially mitigates global warming, its contribution may be offset or even overturned by the increasing biogenic emissions of methane (CH4) and nitrous oxide (N2O). Of particular importance to climate change mitigation policies is the ability to evaluate the net balance of these three GHGs in the terrestrial biosphere. Here we synthesized multiple estimates of CO2, CH4 and N2O from various studies to investigate the net biogenic GHG budget (NBGB) on global and regional scales. Based on 22 bottom-up studies using terrestrial biosphere models, empirical and inventory-based approaches and 7 top-down studies using atmospheric inverse models, we conclude that global terrestrial ecosystems had a net positive NBGB, indicating net greenhouse gas release to the atmosphere. After subtracting pre-industrial GHG emissions from land ecosystems, we found the global land uptake of anthropogenic CO2 (-7.7 to -9.2 Pg CO2 eq/yr) was offset by 129% to 147% due to anthropogenically-caused emissions of CH4 and N2O. Among them, agricultural CH4 and N2O emissions (7.0 to 8.0 Pg CO2 eq/yr) play the most important role, offsetting 85% - 103% of the global land sink of anthropogenic CO2. It is clear that biogenic CH4 and N2O emissions had overwhelmed the global land CO2 sink, contributing to a net climate warming effect of all the GHG exchanged to or from the land biosphere. Our results indicate that effective agricultural management strategies are very much needed to alleviate biogenic GHG emissions, while sustaining food and bioenergy production.

Emissions metrics and evaluating methane-emitting natural gas as a bridge fuel

J. Trancik (1) ; M. Edwards (1) ; M. Klemun (2) ; M. Roy, (3)

(1) MIT, Cambridge, MA, United States of America; (2) Massachusetts Institute of Technology, Engineering Systems Division, Cambridge, United States of America; (3) MIT, Cambridge, United States of America

Climate change mitigation is a multi-gas problem. Mitigation policies that focus on CO2 reductions alone may result in increased emissions of other gases such as CH4, leading to overshoots of climate policy goals. For example, policies aimed at reducing CO2 emissions may encourage a transition from coal to natural gas electricity, enabled by increased production of unconventional gas, but could also lead to higher CH4 emissions due to leakage in the natural gas supply chain. Therefore, it is important to consider multiple gases in making emissions reduction commitments and in evaluating technology options to meet these goals. Here we present an approach to evaluating policies and technologies based on their multi-gas emissions.

Evaluating technology options on a common scale, or setting a national target for overall GHG emissions reductions, requires some means of comparing different gases on a common scale. This comparison is challenging because of the dissimilar removal dynamics of different GHGs. Emissions equivalency metrics are a commonly used approach, and the global warming potential (GWP) is the most prevalent metric. The GWP converts masses of non-CO2 GHG emissions to a CO2-equivalent value based on a time-integrated radiative forcing comparison over a fixed horizon of 100 years, leading to a conversion factor that is constant over time. This static approach can lead to significant overshoots of climate policy goals, such as radiative forcing stabilization targets, because it doesn't take into account how close in time emissions occur relative to an intended stabilization year.

Here we present an alternative set of dynamic emissions equivalency metrics that evaluate emissions impacts relative to an intended radiative forcing stabilization level [1]. Our approach results in a lower impact value on shorter-lived greenhouse gases, like CH4, early on, but increases this value as emissions approach an intended stabilization time. The metrics are relatively independent of the future emissions and energy consumption scenario to be followed, and therefore can be used to evaluate policies and technologies despite the inherent uncertainty about the future. Applying the metrics to set emissions reduction targets and evaluate technologies results in substantially lower overshoots of climate policy targets than the GWP. Furthermore the metrics points to methane mitigation timelines that can allow for greater energy consumption while meeting climate policy goals [2].

How might dynamic metrics be used in setting policy targets? We will discuss a specific example by examining the US Environmental Protection Agency's Clean Power Plan target of 30% reduction in power sector CO2 emissions by the year 2030 (from 2005 levels). This policy incentivizes a shift to natural-gas based electricity generation, and could result in significant increases in power sector CH4-emissions. Applying the time-sensitive metrics mentioned above, overall GHG reductions (counting both CO2 and CH4) may only reach 10-20% by 2030, instead of the targeted 30%, without additional methane regulation. However, as shown by applying the proposed dynamic metrics, reduction rates of 11-13% per year would allow the 30% by 2030 GHG reduction target to be met [3]. As demonstrated by this US example, capturing the full climate benefit of coal-to-gas technology transitions requires substantial CH4 mitigation to complement CO2-focused climate policy frameworks. The alignment of CO2 abatement and CH4 leakage reduction goals is an important problem that needs to be addressed as nations globally prepare policy proposals for the 2015 United Nations Climate Change Conference in Paris (COP21. The method proposed here provides an approach to setting coupled CO2 and CH4 reduction targets, and evaluating mitigation technologies.

A global estimate of carbon stored in the world's mountain grasslands and shrublands, and the implications for climate policy

A. Ward (1) ; P. Dargusch (2) ; S. Thomas (2) ; Y. Liu (2) ; E. Fulton (3)

(1) University of Queensland, Brisbane, Australia; (2) University of Queensland, Brisbane, Queensland, Australia; (3) Commonwealth Scientific and Industrial Research Organisation, Hobart, Australia

Carbon market and climate finance schemes (e.g. the CDM, REDD+ and the Green Climate Fund) are being investigated for their ability to achieve enhanced sustainability outcomes in terrestrial forests, lowland grasslands and marine ecosystems, all which store large amounts of carbon (C). To date however climate policy discourse has largely overlooked the conservation of existing C stored in mountain grasslands andshrublands. These ecosystems provide critical ecological goods and services to humanity yet are increasingly at risk from anthropogenic stressors including agricultural intensification, mining and climate change. The absence of a global estimate for these C stocks is likely to be one reason for their exclusion from climate change policy discussions, both on a political and scientific basis. This represents a missed opportunity in two respects: firstly, by conserving and restoring existing C stocks the impacts of climate change can be lessened; and secondly, carbon finance and climate finance might provide financial support to address the aforementioned stressors. Here we use spatial analysis and estimate there to be between 60.5 Pg C and 82.8 Pg of C contained within biomass and soils of the world's mountain grasslands and shrublands. To put this in perspective, globally tropical Savannas andgrasslands, temperate forests and tropical peatlands are estimated to contain 326–330 Pg C, 159–292 PgC and 88.6 Pg C respectively. Our review of existing empirical studies and of United Nations FrameworkConvention on Climate Change (UNFCCC) national greenhouse accounts suggests that this C is not reliably accounted for in international carbon budgets. Our estimate is the first to provide a global point of reference, useful in developing future research and in climate policy discussions. We conclude by briefly discussing how climate finance might be leveraged to support the sustainable management of these C stocks, and in so doing uphold the other important socio-economic benefits provided to humanity.

Global and China's admissible emissions pathways under various warming targets

Y. Zhu (1) ; Z. Wang (1)
(1) Institute of Policy and Management, Chinese Academy of Sciences, Beijing, China

Using the adaptive control model with climate system, this paper projected and compared the global admissible emission pathways under various warming targets, namely, warming 2℃ above pre-industrial level, and the average level of 1850–1900, 1861–1880, 1961–1990, 1980–1999 and 1986–2005 that mentioned in IPCC-AR5 WGI report. Our study shows that the admissible emission is required to reduce by 20%, 35%, 50% and 62% until 2020, 2030, 2050 and 2100 respectively so as to limit the global warming within 2℃ above the preindustrial level. This indicates that the Copenhagen agreement is hard to achieve without some breakthrough in low-carbon energy technology since the global emission is ever-increasing. Corresponding to the RCP 4.5 and RCP 6.0 in IPCC AR5 report, the admissible emissions pathways for the 2℃ targets above the average level of 1850–1990 and 1861–1880 indicates that it can still rise until 2040–2045 following the historical trend and then reduce. Therefore, they are not effective targets to abate the emissions promptly. Moreover, taking 1961–1990, 1980–1999 and 1986–2005 as the base year means the admissible emission is far more than what is needed.

In view of the difficulty to achieve these targets, we further proposed three viable warming limit schemes after appraising the feasibility of the aforementioned targets, which are (1) warming 2.5℃ relative to pre-industrial level, (2) warming 1℃ relative to 1986–2005 and (3) 1.5℃ relative to 1850–1900. The first one is a mild reduction target, which requires the global emission to stop increasing immediately and starts to reduce since 2020 gradually, finally reach a level slightly less than that in 2005 by 2100. This target is in accordance with the current abatement commitments of major countries/regions. The second one is a moderate target, which indicates the global emission should decrease at once with a smooth dropping rate. It matches the average warming expectation of RCP 2.6 scenario in IPCC report and should be a reference for each country to make further commitment. The last one is a strong target, which requires the global emission to reduce immediately with the rate similar to its growth rate during 2000–2012, indicating greater efforts need to make.

Finally, the emission rights are analyzed with different principle of allocation. The sovereignty principle is to the benefit of developed countries such as United States, European Union and Japan; some populous countries like China and India are in favor of the egalitarianism principle; the developing countries will get more emission right under the principle of ability-to-pay. China will acquire about one fifth of global emissions under all the three principles, indicating the current emission level in China is compatible with its population and economy. But with all these principles, the admissible emission for China will shrink gradually under the three aforementioned warming targets and the emission gap between emission demand and supply will enlarge accordingly.

The Greenhouse gases Observing SATellite (GOSAT) has been operating for more than five-and-a-half years since January 2009. Over that period, the NIES GOSAT Project provided researchers and the general public with the retrieved column-averaged concentrations of carbon dioxide (XCO2) and methane (XCH4) (SWIR Level 2 data products), which helped ascertain the global distributions of the two global warming gases and their variability with time and space. Further, with those concentration data that filled gaps in the existing surface monitoring networks, the monthly estimates of regional sources and sinks of CO2 and CH4 (Level 4 data products) were produced with smaller uncertainties. Although there are some issues still left that need to be handled, such as region- and time-dependent biases and low retrieval success rates over the tropics, the GOSAT Project has contributed significantly to advancing the global carbon cycle studies through providing useful space-based GHG data. The Orbiting Carbon Observatory 2 (OCO-2) was launched successfully in July 2014, and now and finally, there are two CO2 monitoring platforms in space, as originally planned ten years ago. GOSAT is expected to operate and continue its observation for the next several years, even after its five-year nominal operation period ended in early 2014. Evaluating and inter-comparing data from the two platforms will yield valuable findings that can further advance the space-based GHG monitoring techniques. We will present the overview of the latest GOSAT data products and some of important research outcomes brought by the GOSAT Research Announcement researchers, and show our views on the future of space-based carbon cycle study by worldwide research collaboration.

The Integrated Carbon Observation System (ICOS RI) – a European Research Infrastructure on greenhouse gases and the global carbon cycle

WL. Kutsch (1) ; A. Vermeulen, (2) ; T. Johannessen, (3) ; I. Levin, (4) ; D. Papale, (5) ; L. Rivier, (6) ; A. Watson, (7)

(1) 10 Integrated Carbon Observation System (ICOS RI), Head Office, Helsinki, Finland; (2) Integrated Carbon Observation System, Carbon Portal, Lund, Sweden; (3) University of Bergen, Bergen, Norway; (4) Universität Heidelberg, Institut fuer umweltphysik, Heidelberg, Germany; (5) University of Tuscia, Viterbo, Italy; (6) LSCE, Gif sur Yvette, France; (7) University of East Anglia, Exeter, United Kingdom

Greenhouse gases contribute to radiative forcing and therefore their concentrations in the atmosphere influence climate of the Earth. The mission of ICOS RI is enabling research for understanding present state and predicting future behavior of the global carbon cycle and greenhouse gas emissions. ICOS RI does this by providing long-term observations through a distributed infrastructure with station networks designed to monitor GHG concentrations in the lower atmosphere and ocean as well as GHG exchange between terrestrial ecosystems or oceans and the atmosphere. By knowing the dynamics of GHG in the atmosphere and their fluxes, ICOS RI will provide independent data to improve and verify GHG emission inventories for international conventions.

This fusion of streams of (big) data from observational infrastructures with advanced earth system models is the next step in developing integrated knowledge on global carbon and greenhouse gas budgets. By using the complex model-data fusion systems currently under development, these observations will enable us to verify greenhouse gas fluxes on regional and national levels at unprecedented resolution in time and space.

Potential of in-service aircraft based greenhouse gas observations within IAGOS for constraining regional carbon budgets

S. Verma (1) ; J. Marshall (1) ; C. Roedenbeck (1) ; C. Gerbig (1)
(1) Max Planck Institute for Biogeochemistry, Biogeochemical Systems, Jena, Germany

Spatial and temporal variations of atmospheric greenhouse gas concentrations contain information about their sources and sinks as well as the exchange processes between the atmosphere and the surface of the earth. However, the potential use of these observations in inverse models for accurate estimation of surface fluxes is hindered by the fact that they are both insufficent and unevenly distributed. The use of passenger aircraft for obtaining information about atmospheric composition and physical and chemical processes is a relatively new concept. Within the recently established European Research Infrastructure IAGOS (In-service Aircraft for a Global Observing System), highly accurate and precise in-situ observation of greenhouse gases is foreseen in the near future. Detailed and continuous measurements are made during long distance flights by hi-tech instruments deployed on board, thus providing a view of the horizontal and vertical distribution of the measured trace gases on global scale and over long periods of time. The project IGAS (IAGOS for GMES Atmospheric Service) serves as a vital link between the data collected on board civil aircraft through IAGOS and the Copernicus atmosphere monitoring service (previously known as GMES) that utilizes these measurements for applications in the field of modeling, weather forecasting and air quality forecasting.

This study is focussed on assessing the impact of measurements from IAGOS on the constraint on the regional carbon budget and quantifying the reduction in uncertainty in the inverse source-sink estimates of CO2 and CH4, brought about by the use of this newly developed data stream. Anticipating the deployment of five GHG observing systems within IAGOS, the flight tracks from five in-service aircraft within MOZAIC (Measurement of OZone and water vapour by Alrbus in-service airCraft), a predecessor project of IAGOS, are used in an inversion system to assess the constraint on the carbon budget and quantify the potential for reduction in posterior flux uncertainties. These measurement locations and times are used to evaluate the impact of data from aircraft on the reduction of flux uncertainties compared to that based on the existing global observation network, and furthermore to identify areas where the addition of these measurements would be of greatest impact. We use the Jena Inversion System that employs the Global Atmospheric Tracer Model TM3 for atmospheric transport, focussing on the period 1996-2004. The vertical aircraft profiles are input into the inversion as two partial-column averages instead of point measurements, the lower partial column completely containing (and exceeding) the boundary layer. This is a novel approach, the advantage being that the error due to imperfect model representation of the boundary layer height and hence the vertical tracer transport near the surface can be diminished, which results in the reduction of the overall model-data mismatch error. The experimental design is such that in each simulation the existing measurement network is augmented by pseudo-observations from up to five simulated IAGOS aircraft. Uncertainty reduction from each of these simulations is compared to the uncertainty reduction from simulations employing only the existing observation network. We find that for both CO2 and CH4, the additional constraint on the carbon budget brought about by the use of IAGOS measurements is highest for the tropical regions, the magnitude of the change in uncertainty reduction being about 20 percent.

O-1115-03

Cost-effective guidelines for measurement of agricultural greenhouse gas emissions and removals

M. Richards (1) ; T. Rosenstock (2) ; K. Butterbach-Bahl, (3) ; M. Rufino (4) ; E. Wollenberg, (5)
(1) CGIAR Research Program on Climate Change, Agriculture and Food Security, Low Emissions Agriculture, Burlington, VT, United States of America; (2) World Agroforestry Centre (ICRAF), Nairobi, Kenya; (3) International Livestock Research Institute (ILRI), Nairobi, Kenya; (4) CIFOR / CCAFS, Nairobi, Kenya; (5) Gund Institute for Ecological Economics, School of environment and natural resources, Vermont, United States of America

As COP21 approaches, many non-Annex 1 countries are for the first time developing mitigation targets in the form of Intended Nationally Determined Contributions. Mitigation activities in the agriculture, forestry, and land use (AFOLU) sector are likely to be in developing countries because they provide up to 70% of the technical potential for AFOLU-based mitigation. However, decision-makers in these countries are currently limited by the lack of scientific information on emissions and mitigation potentials from the agricultural systems common in tropical developing countries.

For example, direct measurements of methane from livestock—perhaps the most significant agricultural GHG source in sub-Saharan Africa—are lacking. Measurements of soil carbon sinks from land rehabilitation and carbon storage in aboveground woody biomass are also notable gaps. The emission factors and models used in the absence of such data (IPCC Tier 1) rely on measurements largely from temperate, developed countries and their precision and accuracy in tropical developing countries is unknown.

Here we describe the SAMPLES measurement guidelines and data platform, two web-based resources for improving the availability of agricultural GHG information from tropical developing countries. Developed by scientists within the CGIAR Research Program on Climate Change, Agriculture, and Food Security (CCAFS), the guidelines provide a critical assessment of various methods that can be used to quantify GHG emissions within a developing country context. As the cost of measurement is often a constraint, the guidelines compare the available methods for each GHG driver (e.g., land use change) and source (e.g., soil emission or biomass accumulation) in terms of cost and accuracy. They recommend methods that produce reliable, robust data considering factors common to developing country farming systems such as heterogeneity of farming systems and seasonality of feed supply and quality (e.g. for enteric methane emissions). The guidelines also emphasize informed sampling design in order to aggregate GHG measurements to larger scales without unnecessary replication of measurement.

The SAMPLES data platform is the first international, publicly accessible compilation of GHG flux and carbon stock change data from tropical developing countries. While it is currently houses data from CCAFS experiments in several countries, the data platform is open to contributions from agricultural emissions studies worldwide. The platform provides a resource for compilers of national inventories, designers of monitoring and verification systems and researchers to share and access data for developing Tier 2 emission factors and calibrating models.

These two new resources provide decision-makers and the global scientific community with a means of developing and sharing the information necessary to assess, monitor and verify the GHG impacts of agricultural policies and technologies.

Reconstruction of super resolution oceanic pCO2 from remotely sensed data and multiresolution analysis: an application in the South Eastern Atlantic

V. Garçon (1) ; I. Hernandez-Carrasco (1) ; J. Sudre (1) ; H. Yahia (2) ; C. Garbe (3) ; A. Paulmier (4) ; B. Dewitte (4) ; S. Illig (4)

(1) CNRS, LEGOS, Toulouse Cedex 9, France; (2) INRIA, Geostat, Bordeaux, France; (3) University of Heidelberg, Interdisciplinary center for scientific computing, Heidelberg, Germany; (4) IRD, Legos, Toulouse Cedex 9, France

The knowledge of green house gases (GHG) fluxes at the air-sea interface at high resolution is crucial to accurately quantify the role of the ocean in the absorption and emission of GHGs. We present here a novel method to reconstruct maps of surface ocean partial pressure of CO2, pCO2, and air-sea CO2 fluxes at super resolution (4 km) using Sea Surface Temperature (SST) and Ocean Colour (OC) data at this resolution, and CarbonTracker CO2 fluxes data at low resolution (110 km). Inference of super-resolution of pCO2, and air-sea CO2 fluxes is performed using novel nonlinear signal processing methodologies that prove efficient in the context of oceanography. The theoretical background comes from the Microcanonical Multifractal Formalism which unlocks the geometrical determination of cascading properties of physical intensive variables. As a consequence, a multiresolution analysis performed on the signal of the so-called singularity exponents allows the correct and near optimal cross-scale inference of GHGs fluxes, as the inference suits the geometric realization of the cascade. We apply such a methodology to the study offshore of the Benguela upwelling system. The inferred representation of oceanic partial pressure of CO2 improves and enhances the description provided by CarbonTracker, capturing the small scale variability. The methodology is validated using in-situ measurements by means of statistical errors. Mean absolute and relative errors in the inferred values of pCO2 with respect to in-situ measurements are smaller than for CarbonTracker.The potential of the approach with other gases such as DMS is illustrated.

O-1115-05

Top down estimates of the European emissions of hydrofluorocarbons and comparison with bottom up inventories

M. Michela (1) ; F. Graziosi, (1) ; U. Giostra, (1) ; J. Arduini, (1) ; F. Furlani, (1) ; P. Bonasoni, (2)

(1) University of Urbino, Basic Sciences and Foundations, Urbino, Italy; (2) National Research Council, Institute for the study of the atmosphere and climate, Bologna, Italy

Hydrofluorocarbons are strong greenhouse gases included in the United Nations Framework Convention on Climate Change (UNFCCC) Kyoto Protocol.

Under the Protocol, Parties are required to submit to UNFCCC their annual emission inventories. Such emissions are normally assessed through "bottom-up" methods aggregating various local statistics. However, emissions measured by their accumulation in the atmosphere, can significantly disagree with reported bottom-up emissions.

Top-down emission estimates based on in situ long-term high frequency observations combined with inverse modelling have proved to be a powerful and important tool for the quantification of emissions and the verification of bottom-up inventories for many trace gases. Here we present regional (European) emission estimates of nine hydrofluorcarbons characterised by extremely high Glabal Warming Potentials (GWPs).

Emissions estimates are obtained through a combination of observations and models. For this study we used high frequency, long term observations conducted via gas chromatography-mass spectrometry in four WMO-GAW Global stations in Europe that are part of the AGAGE (Advanced Global Atmospheric Gases Experiment) network. The obtained data undergo a rigorous quality control, following the procedures adopted within AGAGE. FLEXPART 20-d backward trajectories and a Bayesian inversion method are then used in order to derive annual emissions from the European Geographic Domain, divided into eight macro-regions, strarting from 2001 onward.

Then, we compared our estimates with the bottom-up inventories submitted by the single countrie to the UNFCCC. Such comparison revealed not negligible discrepancies between the inversion results and the inventories, thus showing the effectiveness of this approch as a verification tool for declared emissions

The estimates provided by this analysis are relevant non only for constraining the atmospheric budget of these gases on a regional scale, but also also to improve the accuracy of their emissions quantification on a global scale.

O-1115-06

Observational Determination of Surface Radiative Forcing by CO2 and CH4

W. Collins (1) ; D. Feldman (2) ; MS. Torn (2)

(1) UC Berkeley / Berkeley Laboratory, Earth & Planetary Science / Climate Sciences, Berkeley, California, United States of America; (2) Berkeley Lab, Climate sciences, Berkeley, California, United States of America

Earth's background atmospheric CO2 and CH4 concentrations have been steadily rising due to anthropogenic emissions, and these increases since 1750 have implications for the radiative balance of the Earth's atmosphere. The physics governing how atmospheric CO2 and CH4, both well-mixed greenhouse gases (WMGHGs), influence atmospheric infrared energy balance, and thus climate, are well established, but the impact of recent atmospheric WMGHG trends on the surface energy balance has not been experimentally confirmed in the field.

Using infrared WMGHG absorption bands and controlling for atmospheric temperature and water vapor, spectra from the DOE ARM Program's Atmospheric Emitted Radiance Interferometers (AERI) yield the first direct observational evidence of the time-series of WMGHG surface radiative forcing directly attributable to recent increases in WMGHGs, in this case between 2000-2010. The time-series shows a secular trend of in the radiative forcing from both CO2 and CH4. This data record provides the first comprehensive observational evidence of upward trends in surface radiative forcing by WMGHGs, confirming theoretical predictions of the anthropogenic atmospheric greenhouse effect. These data support predictions of enhancements to the greenhouse effect from future WMGHG emissions.

Evolution of CO2 storage in karstic cavities by changes in climate in semiarid regions: Rull Cave (Alicante, Spain)

D. Benavente (1) ; C. Pla (1) ; C. Grossi (2) ; E. Garcia-Anton (3) ; S. Cuezva (3) ; A. Fernandez-Cortes (4) ; S. Sanchez-Moral (3) ; J. Cañaveras (1)

(1) University of Alicante, Earth and Environmental Sciences, Alicante, Spain; (2) University of East Anglia, Norwich, United Kingdom; (3) CSIC, Museo nacional de ciencias naturales, Madrid, Spain; (4) Royal Holloway, University of London, Department of earth sciences, Surrey, United Kingdom

The global carbon cycle in the Earth's surface-troposphere boundary depends on feedbacks among a number of sources and sink processes that operate on both short and long time scales. Soil and subsurface cavities in the vadose zone may contain large amounts of CO2 compared to the exterior air. CO2 concentrations in the vadose zone show significant seasonal and even daily variations, which involves the exchange of large amounts of this greenhouse gas with the lower troposphere. The main source of the CO2 contained in the caves is the organic production from

soil although the abiotic contribution can be important in warm seasons. CO2 from soil can be transported into the caves as a gas or dissolved in seepage waters and the final cave air CO2 concentration air is broadly the result of the mixing of background atmospheric CO2 with soil-produced CO2. Tourism can also increase CO2 concentrations in cave-air by an order of magnitude. The cavities CO2 outputs are mainly due to ventilation processes that depend on cave morphology, the number and configuration of cave openings, and microclimatic relationships with the exterior climate.

Our study has been carried out in the Rull cave during two annual cycles (November 2012 – January 2015). The karstic cavity is located in the northeastern sector of Alicante province, a semiarid region on the Spanish Mediterranean coast (30 km far from the coast line). Indoor trace gases (CO2 and 222Rn) showed that cave acts as both CO2 sink and source for the whole period, although some differences were found between the two registered cycles. For the first cycle (December 2012 – November 2013), average value of indoor T and RH were 15.9ºC and 97.2% respectively. Indoor T reached a maximum value of 16.6 ºC. CO2 mean concentration was 2054 ppm but this value varied from 463 ppm (minimum value, registered in January 2013) to 4065 ppm (August 2013). In 2014, indoor T and RH average values were 16.1ºC and 97.8% respectively but indoor T reached a maximum value of 17.9 ºC. Mean CO2 concentration was 1937 ppm but ranged from 565 ppm (February 2014) to 3731 ppm (August 2014). The gaseous recharge of the cavity occurs when the outdoors temperature is higher than the cave air temperature as consequence of the air density differences. For the second studied cycle (2014) the recharge of the cavity took place some days before than for the first cycle as outdoor temperature exceeded the temperature of the cavity slightly earlier than in 2013. This fact confirms that relationship between both temperatures is a key factor in the dynamics of this cavity. Furthermore, air cave CO2 changed for the both cycles and was closely related to rainfall since it contributes to biotic and abiotic processes. For the first cycle (2013) total annual rainfall was 471 mm, while it was 280 mm for 2014. Rainfall drop is mainly responsible of a lower CO2 concentration in the cavity for 2014 due to: (i) a lower organic production as consequence of reduction in soil moisture; (ii) a lower amount of seepage waters that finally reach the cavity containing dissolved CO2; (iii) when the soil-epikarst system suffers for a reduction in moisture (due to the scarce rainfalls) a major connection between the underground and the exterior environment is accomplished as consequence of an opening of the soil porous system and the fractures-fissures of the epikarst, which is responsable for a higher gaseous exchange.

The isotopic signal δ13C of CO2 is widely used as a proxy of the origin of the CO2. The light values of δ13CO2 inside the cavity point to an organic origin of the CO2. δ13CO2 average annual value for outdoor atmosphere, soil and cave are -10.1, -21.9 and -22.0 ‰ respectively. CO2 in soil was measured for the whole year in 2014. Maximum values (2948 ppm) occur while the cave is in gaseous recharging (April 2014) while the lowest concentration (735.5 ppm) is found in August 2014, when the soil production is buffered due to the high temperatures and scarce water.

Results highlight the narrow existing dependence between climate conditions and CO2 dynamics in the cave-soil-atmosphere system. The output of the CMIP5 multi-model ensemble, under the RRCP4.5 and RCP8.5 scenarios, predicts a relevant increase of temperature and a decrease in precipitation and relative humidity at the geographical coordinates of the cave surface throughout the current century. We are using this CMIP5 output to model the expected shift in season ventilation-recharge pattern and a potential reduction of the CO2 storage capacity in this semiarid region.

P-1115-02

The use of GHGs as tracers of the coupling/uncoupling between natural processes and human activities in a Mediterranean Delta system

L. Cañas Ramírez (1) ; E. Vazquez, (1) ; A. ÀGueda, () ; P. Occhipinti, (1) ; C. Grossi, (1) ; R. Curcoll (1) ; M. Nofuentes Ramos () ; O. Batet, (1) ; S. Borràs, (1) ; X. Rodó () ; JA. Morgui (1)

(1) Institut Català de Ciències del Clima, Lab atmosphere & oceans, Barcelona, Spain

Delta ecosystems are important in many environmental aspects as they act like a buffer between terrestrial and marine ecosystems. Moreover, human activities control the basing hydrology and the overall watershed economy from the water in a resource perspective. Furthermore, the Delta environmental patchiness favors a high biodiversity standing on a delicate equilibrium.

The high sensibility of these ecosystems to small changes in environmental conditions, already under the pressure of human exploitation, might lead to abrupt changes on demographic dynamics of the inhabiting species, the migrant ones and the invasive ones. Under the threats of climate change, like reduced water discharge and the consequent salinization, increased temperature, increase in the incidence of droughts, etc., might amplify the effects of natural occurring cycles.

The detailed and continuous study of greenhouse gas emissions (GHGs) like CO2, CH4 and N2O as tracers of ecosystemic metabolic fluxes is a useful tool to discern the changes occurring along different temporal scales, from less than hours to years. Thus, they offer an excellent dataset to assess management, adaptation and mitigation policies on endangered deltas.

The Ebre River Delta is one of the largest wetland areas (over 300 Km2) in the North-Western Mediterranean region. This area presents a high diversity of ecosystems with rice fields, natural lagoons and marshes along the shoreline, conforming a highly patched landscape. Water management plays a relevant role in agricultural activity, birdlife habitat protection and GHGs sources and sinks.

A GHGs measurement station has been established at the Ebre River Delta Natural Park with the aim of studying climate interactions between land-surface and atmosphere by the Institut Català de Ciències del Clima (IC3) within the framework of the ClimaDat project (www.climadat.es, funded by Obra Social "la Caixa") and InGOS.

GHGs data obtained in this location provide thorough knowledge of the Ebro river delta and the coupling and uncoupling of human activities and natural cycles.

A dedicated monitoring network for greenhouse gases: SNO ICOS-France

M. Delmotte, (1) ; M. Ramonet (1) ; V. Kazan, (1) ; C. Vuillemin, (1) ; PE. Blanc (2) ; B. Burban (3) ; S. Conil, (4) ; A. Diawara (5) ; F. Gheusi, (6) ; JM. Metzger (7) ; JM. Pichon, (8)

(1) LSCE, Gif-sur-Yvette, France; (2) CNRS, St Michel l'Observatoire, France; (3) INRA, Cayenne, French Guiana; (4) ANDRA, Observatoire pérenne de l'environnement, Bure, France; (5) University Felix Houphouet Boigny – Cocody Abidjan, Physic, Abidjan, Ivory Coast; (6) Laboratoire d'Aérologie, Observatoire midi pyrénées, Toulouse, France; (7) CNRS & Universite de La Reunion, Osu-reunion, Saint Denis de la Reunion, France; (8) Laboratoire de Météorologie Physique, Opgc, Clermont-Ferrand, France

Greenhouse gases (GHG) have been identified as the main actors of current climate change. Evolution of the atmospheric composition will drive our future climate and it is therefore essential to increase our knowledge of the global carbon cycle, to refine the carbon budget from global to regional and/or national scale and to precisely monitor the composition of the atmosphere.

Since the pioneer CO2 observation study conducted at Mauna Loa in the late fifties, atmospheric monitoring stations have been progressively deployed over most of the earth, mainly focusing on CO2 specie. Over the last decade a significant effort has been engaged to build real operational monitoring network including more monitored species (CO2, CH4, CO, N2O) and continuous recording (instead of flasks samples). In Europe, these efforts resulted in the foundation of the Integrated Carbon Observation System (ICOS) research infrastructure which is based on a harmonized and operational monitoring network including 16 countries.

As member and contributor to the ICOS infrastructure, France has a major role on the atmospheric component of the project through the GHG national network (SNO ICOS-France) and the atmospheric thematic center installed

at LSCE. The French monitoring network consists of 12 observation stations including ground stations and high tower equipped with several sampling levels.

We will present the French monitoring network for GHG:

- Network design and station location,
- station set up and specifications,
- instrumental set up and characteristics,
- data treatment and quality control.

We will also give some example of scientific results obtained from chosen observations within the French monitoring network (altitudinal gradients, characteristic synoptic events, trends and seasonal variability on long term records).

P-1115-04

Methodological Discrepancies in Measuring Agricultural Greenhouse Gases for Precise Estimation of National Emissions

Ml. Khalil (1) ; B. Osborne (1)
(1) University College Dublin, Ucd earth institute, Dublin 4, Ireland

The main agricultural greenhouse gases (GHGs) – nitrous oxide (N2O) and methane (CH4) –account for 10–12% of anthropogenic emissions globally, corresponding to ~ 60% and 50% of total anthropogenic emissions, respectively. Agricultural systems are highly diversified and complex, and that measured data covering all practices are very limited to estimate GHG emissions accurately at entity scales/system boudaries and thereby national levels, which is vital. This is to provide robust data for accounting, modeling, finding policy options and mitigation solutions with confidence, leading to achieve environmental sustainability and greater resilience in agricultural production. Special equipment, technical capacity and infrastructure required to measure actual GHG emissions from the source into the atmosphere are insufficient at global scales. These are associated with cost and complexity of methodologies as well as huge difficulty in measurement under field conditions. These result in large uncertainty due to sampling errors and the impact of soil, weather and other environmental variables including management-induced changes relative to background pools and fluxes.

Soil N2O emissions are extremely variable in time and space linking particularly to the practices that affect its fluxes in one soil alone or in association with climate/site-year more than in another. Accordingly, development/selection of existing but globally recognized methodology appropriate for a country should be chosen. It is to estimate changes in emissions accurately at the entity level but sufficiently generalizable for upscaling. There are several existing methods to measure N2O and CH4 emissions for example are: (i) intact soil cores under artificial environment without vegetation and simulated management practices, (ii) closed or open chamber measurements that are limited primarily by timing and frequency of gas samplings, (iii) automated chamber that represents the vegetation canopy and management practices inadequately, (iv) micrometeorological shows difficulty in differentiating the impact of land use and management practices at entity/boundary scales, and (v) isotope technique, which is very delicate and expensive.

Recently, tiered measuring approaches are proposed to capature both temporal and spatial variability of agricultural GHG fluxes including livestock and manure management systems coupling with the generation of ancillary data related to key variables in these systems. For precise estimation of national GHG emissions using practice-based scaling factors, a new hybrid approach i.e. coupling model with a measurement network of stratified monitoring sites with due consideration to key factors for example soil properties, land use type, nutrient and water management and climate influencing GHG emissions is likely to be most feasible and robust way forward to minimize uncertainty. Given the regulatory roles of the key influencing factors and variables, each measurement method has its advantages and disadvantages in providing the quantity of GHG emissions closer to reality. This paper illustrates the above issues to find a universally acceptable appropriate methodology to accurately measure and monitor GHGs from agricultural systems.

A proposed open international standard for GHG emissions and offsets

L. Mckee (1) ; D. Bart (2) ; M. Jackson, (3)
(1) Open Geospatial Consortium (OGC), Wayland, Massachusetss, United States of America; (2) Open Geospatial Consortium (OGC), Antwerp, Belgium; (3) University of Nottingham, Professor of geospatial science, faculty of engineering, Nottingham, United Kingdom

The diversity of carbon calculators, protocols and registries currently makes it difficult to publish, discover, assess, access, aggregate, analyze and share geospatial and statistical information about GHG emissions and offsets. In recent years, facing similar diversity, the hydrology, aviation meteorology, climatology and geology communities have all developed consistent international open geospatial standards (WaterML 2.0, WXXM, netCDF and GeoSciML) for encoding those four types of data. Those standards are based on a shared framework of geospatial and temporal standards that make maximum use of Internet and Web technologies. GHG markets, treaties, science, and taxation and regulator regimes all await an expansion of that standards framework to encompass GHG emissions and GHG offset projects. International standards for geospatially consistent digital characterization of GHG emissions and offsets would add rigor to GHG science and management analysis and transparency to GHG transactions and compliance. The standards would also increase the value of GHG data immeasurably by fully leveraging the computational and communication power of the Internet and Web.

Virtually all of the data involved in GHG measurement and management activities has geospatial and temporal elements. The not-for-profit standards organizations Open Geospatial Consortium (OGC) and World Wide Web Consortium (W3C) are already engaged together along with ISO with many other organizations in developing a unified platform of spatial environmental standards.

We propose that public and private sector climate organizations commit a very small fraction of their budgets to developing open international encoding and interface standards that would enable efficient and effective integration of GHG data. Much of what needs to be measured and communicated has already been captured in current GHG standards, registries, protocols and calculators. The next step is to agree on common conceptual models for this data, using something like UML (Universal Modeling Language) diagrams. There will probably need to be a separate data model for each greenhouse gas, though the models will share many features and borrow significantly from standards such as WaterML 2.0. The conceptual models would provide a basis for different but interoperable implementation standards for computing platforms such as XML, JSON and REST, or CSV.

Our talk, perhaps a keynote, would be focused on standards for encoding GHG data, but it wold also show how this proposed standard or set of standards is necessary for all types of environmental accounting. We would explain the methodology for developing such standards and explain why such standards are urgently needed as we enter «the environmental age».

The terrestrial biosphere interacts strongly with the climate, providing both positive and negative feedbacks due to biogeophysical and biogeochemical processes. To understand and predict the evolution of the climate, it is critical to understand both the contribution of vegetation to the greenhouse gases (GHG) budget and the response of the terrestrial biosphere to the changing climate.

The Integrated Carbon Observation System (ICOS), a new European monitoring network, offers a unique way of documenting and quantifying long term changes in the GHG balance of ecosystems. The ICOS research infrastructure includes atmospheric, ecosystem and marine station networks. The Ecosystem station network (ESN) of ICOS is based on a large number of monitoring stations that will be maintained for the next 20 years. The ESN uses a large set of standardised instruments to perform continuous and intensive measurements of meteorological and micrometeorological variables. A central part of this measurement set is the eddy covariance measurement, that allows a continuous monitoring of the flux exchanged between vegetation and atmosphere. All together these standardised observations allow a better understanding of the functioning of ecosystems in relation to climate and management practices.

ICOS Ecosystems France, the French part of ESN is a cooperation of three research institutes: INRA, CNRS and ANDRA. ICOS Ecosystems France is extensive and includes eight observation stations (4 Class 1, 4 Class 2). In addition seven associated stations also contribute to the network. The network samples a wide range of ecosystems (forest, crop and grassland), of management practices and climates (from cold mountain climate to tropical humid in Guyana, including wet oceanic and dry Mediterranean climate).

We will provide an overview of the stations and the measurement system (sensors and data flow). We will equally present the current status of the network, recent measurements and preliminary findings.

P-1115-07

Ground-based monitoring of greenhouse gases emissions over continental ecosystems: the ecosystem part of the ICOS European infrastructure

D. Loustau (1) ; S. Lafont (1) ; I. Janssens, (2) ; D. Papale, (3) ; R. Valentini (3) ; B. Gielen, (2) ; M. Op De Beek (2) ; TMT. Nguyen (2) ; R. Ceulemans, (2)
(1) INRA, ISPA, Villenave d'Ornon, France; (2) University of Antwerpen, Antwerpen, Belgium; (3) University of Tuscia, Viterbo, Italy

Since the discovery in the early nineties of a missing terrestrial sink of carbon in the global carbon cycle (Tans et al. 1990), there was a tremendous effort of observation of the continental part of the carbon cycle.

The most recent estimate of its magnitude proposed by the Global Carbon Project reaches 10.6 GtC $CO2 \pm 2.9$ in 2014. The continental ecosystems contribute to attenuate the anthropogenic greenhouse gases enhancement by 29%.

This terrestrial sink is characterized by the large amplitude of its inter-annual variations and its ample uncertainty which makes it difficult to predict the future of the continental sink of carbon.

Inversion of atmospheric concentrations in greenhouse gases (GHG) and their temporal variations combined with atmospheric transport model allows characterizing the GHG exchanges at the continental surface at typical scale of 10 to 100 km.

Point measurements of the full GHG budget at half hourly resolution together with ancillary measurements on vegetation, management practices and soil permit to characterize the biogeochemical processes involved and their drivers. They are of utmost importance for understanding the GHG cycle and its sensitivity to environmental drivers on the long term.

Thus far, however, the inhomogeneity of methods, protocols and instruments used across ground observation networks have limited strongly our capacity to detect and observe the effects of environmental changes that are assumed to provoke changes in the GHG cycle. Indeed, the rate of pollutants deposition (Ozone, Nitrogen compounds), solar dimming, climate change and CO2 concentration enhancement not mentioning the secondary drivers are not monitored with sufficient accuracy and neither co-located in a sufficient number of stations for attributing clearly changes in the GHG budget of the main terrestrial ecosystems.

From this conclusion, the European research strategy implemented through the ESFRI roadmap was to build a new world class infrastructure having the capacity to coordinate and harmonise networks of ocean-, atmospheric- and ground-based stations equipped with identical instruments and operated according to the sale common protocols and standards, that is the ICOS infrastructure.

This communication will present the ICOS ecosystem network of stations and the Ecosystem Thematic Centre which collects and processes the measurements that are being operated across the station network. It will give few examples of the data obtained so far and show how they are being used for establishing robust GHG budgets of different ecosystems and their sensitivity to the environment, management practices and interaction.

A Multi-Model Regional Decomposition of CO2 Emissions: Socio-Economic Developments vs Energy Efficiency and Carbon Intensity Improvements

MM. Malpede (1)
(1) Fondazione Eni Enrico Mattei (FEEM), Milan, Italy

This study explores the regional distribution of total CO2 emissions.

Kaya and Yokoburi (1997) decompose carbon dioxide emissions into 4 different components, namely Population, GDP per capita, Energy Efficiency and Carbon Intensity.

Ang (2004) shows that a difference in an aggregate indicator can be decomposed into the sum of the effects by differences in explaining factors and residual terms. Therefore changes of CO2 between time t and t-n is defined as the sum of the differences of each of the drivers and a residual term:

By making use of the Long Mean Divisia Index (LMDI) and the Refined Laspeyres Decomposition (RLD), the purpose of the paper is to quantitatively analyze how those components affect total CO2 emissions for different regions of the world, over time and across different socio-economic scenarios. In particular, socio-economic scenarios considered to perform this analysis are the 5 SSPs developed by National Center for Atmospheric Research (NCAR).

The reason of that is to determine the implications of each of the 4 drivers in evaluating the impacts of climate policies on global and regional economic systems and exploring the differences between short-term (2010-2030), medium-term (2010-2050) and long-run (2010-2100) effects.

By drawing data from the IIASA Database, this study considers 6 Integrated Assessment Models used to analyze climate mitigation and impact of different policies in regional economic systems, i.e. AIM-CGE, REMIND, MESSAGE, GCAM, IMAGE and WITCH and by making use of the Principal Component Analysis it evaluates their performances in explaining regional CO2 variations, and in which degree they differ.

The main findings of this study are the following:

REGIONAL VARIATIONS OF CO2 EMISSIONS:

- Index Decomposition Analysis, performed by utilizing

the LMDI method suggests a convergence and eventually divergence in total CO2 emissions over time for developing countries with respect to advanced economies. This is mainly due to more robust GDP per capita and Population growth rates relatively to those shown by the USA and Europe.

- However this is not the case of Latin America countries which thanks to a relative high rate of carbonization and less GDP per capita growth will show a minor average growth of total CO2 emissions with respect to that of the USA.

IMPACT OF EACH FACTOR IN EXPLAINING CO2 OVER TIME AND ACROSSSCENARIOS:

- GDP per capita and Population are shown to have a positive impact on total CO2emissions, in particular for developing regions. Energy Efficiency, in contrast, is the main determinant in dragging down total CO2 emissions variations across different economic scenarios. This is valid for all regions considered expect for Latin America countries in which decarbonization plays the biggest role.

- While the impact of Energy Efficiency is more stagnant over time, the pattern shown by the Carbon Intensity Effect suggests an increasing trend over the course of the years. Nevertheless the implications of such components differ from region to region and scenario considered.

PERFORMANCES OF INTEGRATED ASSESSMENT MODELS IN EVALUATING REGIONAL CO2 EMISSION VARIATIONS:

- Principal Component Analysis suggests that although the 6 models achieved a considerable degree of homogeneity, the main source of difference stems from the components of Primary Energy (i.e. Fossil, Biomass, Nuclear and Non Biomass Renewables), while showing a similar pattern for Carbon Intensity, Population and GDP per capita. In particular IMAGE and MESSAGE incorporate more optimistic assumptions on total CO2 variation in the short-term relatively to WITCH, GCAM, AIM and REMIND.

P-1115-09

Influence of Tropospheric and Stratospheric Air Pollution on Climate Change over the Indian Subcontinent

S. Palve (1)
(1) Research Scholar University of Pune, PUNE, MAHARASHTRA, India

India is home to an extraordinary variety of climatic regions, ranging from tropical in the south to temperate and alpine in the Himalayan north, where elevated regions receive sustained winter snowfall. India is characterised by strong temperature variations in different seasons ranging from mean temperature of about 10°C in winter to about 32 °C in summer season. Monsoonal and other weather patterns in India can be wildly unstable, epochal droughts, floods, cyclones, and other natural disasters are sporadic, but have displaced or ended millions of human lives. Ongoing and future vegetative changes and current sea level rises and the attendant inundation of India's low-lying coastal areas are other impacts, current or predicted, that are attributable to global warming. Over the past two decades India has undergone rapid industrial and economic development with increasing emissions of gaseous pollutants. The main tropospheric pollutants (O3, NO2, CO, formaldehyde (HCHO) and SO2) and two major greenhouse gases (tropospheric O3 and methane (CH4)) and important parameters of aerosols, which play a key role in climate change and affecting on the overall well-being of subcontinent residents. In the light of considering these facts this paper aims to investigating possible impact of air pollutants on climate change over the subcontinent. Atmospheric aerosols can impact the local and regional radiation heat budget. Black carbon aerosols absorb incident solar radiation and heat the atmosphere more effectively than dust, sulfates, and organic carbons, which reflect more radiation and cool the atmosphere. The population 1.25 billion in India has led to a significant demand on natural resources. Biofuels such as wood fuel, dung, and crop waste are the primary contributors of aerosols in rural areas of India. Satellite derived column aerosol optical depth (AOD) is a cost effective way to monitor and study aerosols distribution and effects over a long time period. Aerosols have an impact on cloud formation process largely affecting monsoonal rainfall distribution over Indian subcontinent especially in the Ganga basin. Aerosols are found to be substantially increasing in the Ganga basin. Indo-Asian aerosols have impact on radiative forcing that cause negative forcing (cooling) at surface and positive effect (warming) at top of atmosphere.AOD is found to be increasing rapidly since 2000 in summer season that may cause adverse effect to the agricultural crops and also to the human health. Increased aerosol loading may likely affect the rainfall which is responsible for the observed drought conditions over the Indian subcontinent.Carbon monoxide is emitted into the atmosphere by biomass burning activities and by various other anthropogenic activities. The MOPITT CO retrievals at 850 hPa show large CO emission from the IG region. MOPITT CO distributions are able to capture at least part of the surface CO pollution, particularly where the sources are strongest in the Indian region. MOPITT CO daytime retrievals are able to provide significant information on the vertical transport of CO associated with the deep convective activities during the Asian Summer Monsoon and horizontal transport during the winter monsoon. The development of convective activity associated with the ASM leads to large scale vertical transport of the boundary layer CO from the Indian region into the upper troposphere. Ozone (O3) plays an important role in the global weather and climate even though the total atmospheric composition of ozone is less than that of other trace gases. The total ozone column (TOC) in the tropical atmosphere depends on both chemical and dynamical processes and has been studied extensively during the past few decades.TCO over the Indian subcontinent has a systematic and gradual variation, spatial as well as temporal. Higher amount of TCO in the northern latitudes and simultaneous lower TCO at near equatorial latitudes indicates depletion of ozone near the equator and accumulation at higher latitudes within the subcontinent. Winds at tropospheric and stratospheric heights may be just one of the principal factors of spatial variation of TCO that transports atmospheric constituents from one region to another. The Asian monsoon affects the chemical composition of the troposphere. In addition, changes in stratospheric ozone and atmospheric abundances of aerosols alter the energy balance of the climate system.

P-1115-10

A Roadmap for Monitoring GHG Emissions Reduction in Brazil

M. Poppe, (1) ; M. Rocha, (2)
(1) Centre for Strategic Studies and Management in Science, Technology and Innovation (CGEE), Sustainable development, Brasilia – DF, Brazil; (2) Fabrica Ethica, Piracicaba – SP, Brazil

The Brazilian government is developing and implementing a modular system to monitor, analyze and manage the greenhouse gases (GHG) emissions reductions achieved through the National Mitigation Plans (NMP) – SMMARE (in Portuguese: Sistema Modular de Monitoramento e Acompanhamento das Reduções das Emissões de Gases de Efeito Estufa).

Since the NMP are in different stages of implementation and are substantially different in terms of mitigation actions, each NMP will have a Monitoring Module (MM) that will be implemented in different points of time. All MM will be based on the 2006 IPCC Guidelines for National Greenhouse Gas Inventories, taking into consideration relevant national circumstances.

CGEE (a non-profit organization with the mission of rendering Science, Technology and Innovation as Brazil's best allies for economic growth, competitiveness and well-being) has coordinated, under the supervision of the Environmental Ministry, a group of experts with wide experience on national GHG inventory planning, implementation and review, to develop each MM.

SMMARE was conceived during a one-year process with extensive and continuous dialogue with all the Ministries responsible for each NMP; and is being implemented based on 2 scenarios:

- Possible scenario: in which, based on the existing data and/or data that can be easily obtained, the monitoring of GHG emissions reduction could be done in the short-term at the national level;
- Ideal scenario: in which it would be necessary to improve the data collection in order to make the GHG emissions

reduction monitoring in a more disaggregated level (e.g. emissions reduction at the territorial-unit level, due to decrease in deforestation; emissions reduction at the plant level due to implementation of a specific technology; etc.).

Finally, SMMARE is designed to be a tool to help the international consultation analysis (ICA) process to be conducted under UNFCCC, with the aim to increase the transparency of mitigation actions and their effects.

An Example of a Monitoring Module – One of the NMP that have been implemented and is obtaining good results is the Action Plan for Protection and Control of Deforestation in the Amazon (PPCDAm), under the responsibility of the Ministry of Environment. Since its implementation in 2004, deforestation rates in the Amazon region have been decreasing (a 84% reduction in 2012). With the aim of monitoring the GHG emissions reduction associated with the actions implemented by the PPCDAm, a specific MM is being developed based on a generic spatially explicit modeling framework to estimate carbon emissions from deforestation developed by the Brazilian Institute for Space Research (INPE-EM). An indicator for monitoring the GHG emissions reduction achieved by PPCDAm will be tons of CO2 reduced per hectare of avoid deforested areas. Preliminary results indicated that the total potential CO2 emission reduction from PPCDAm could be around 580 million tones by 2020, with an average value of 200 tones of biomass per hectare.

P-1115-11

Greenhouse gas emissions from energy consumption and mitigation of a mining project in Padcal, Benguet Province, Philippines

E. Racelis (1) ; D. Racelis, (1)
(1) University of the Philippines Los Banos, College of Forestry and Natural Resources, College, Laguna, Philippines

The mining industry is one of the most economically important sectors in our society particularly for developing countries. It is a major foreign exchange earner and provides employment opportunities to thousands of people. However, the industry is viewed as among the primary causes of environmental degradation. One of the potential adverse impacts of mining operation is greenhouse gas emission that contributes to global warming and climate change. To minimize the impacts, accurate assessment of greenhouse gas emitting activities is necessary not only to identify them but more importantly to find ways to minimize if not totally avoid their adverse consequences.

A study was conducted to determine the amount of GHG emissions of a mining project focusing on its energy consumption. Using 2014 as base year, the study showed that under Scope 1, the fuel used for both mobile and stationary sources amounted to a total of 5,081,995.10 liters of diesel and 8,317.00 liters of gasoline. The total fuel usage has an equivalent amount of 14,021.09 Mg of CO2e. While under Scope 2, the company consumed a total of 280,142.01 megawatts of electricity in its mine and milling operations including those of ancillary services and staff housing needs. The amount of electricity consumed has an equivalent of 238,400.85 Mg of CO2e emissions.

To sum it up, the company's GHG emissions from energy usage yielded a total of 252,421.94 Mg of CO2e. This would mean that the project has to mitigate their CO2 emissions. One of the easiest and economical ways of sequestering carbon is through plantation maintenance and establishment in which the company has intensively done since then. A Pinus kesiya plantation has an average sequestration rate of 12.7 Mg C ha-1 year-1 or 46.57 Mg CO2 ha-1 year-1 based on studies conducted from different age classes. P. kesiya is a common and most dominant species in the Cordillera Region. Hence, to offset the company's current emissions, it would need a minimum of 5,420.3 hectares of pure Pinus kesiya and mixed P. kesiya plantations to maintain per year. This could also be supported by other mitigating measures to compensate emissions from other sources.

P-1115-12

Interannual variability of atmospheric CO2 and CH4 in Western Europe

M. Ramonet (1) ; M. Schmidt, (2) ; M. Lopez, (1) ; F. Apadula, (3) ; S. Conil, (4) ; AH. Elyazidi (1) ; M. Delmotte, (1) ; F. Gheusi, (5) ; O. Laurent, (1) ; F. Meinhardt, (6) ; JM. Pichon, (7) ; G. Spain, (8) ; J. Helle, (1) ; V. Kazan, (1) ; C. Vuillemin, (1) ; C. Yver-Kwok, (1) ; JD. Paris, (1) ; L. Rivier, (1) ; P. Ciais (1)
(1) LSCE, Cea/cnrs/uvsq, Gif-sur-Yvette, France; (2) Institut für Umweltphysik, Heidelberg, Germany; (3) Research on Energy Systems, Environment and sustainable development department, Milano, Italy; (4) ANDRA, Observatoire pérenne de l'environnement, Bure, France; (5) Laboratoire d'Aérologie, Observatoire midi pyrénées, Toulouse, France; (6) Umweltbundesamt, Kirchzarten, Germany; (7) Laboratoire de Météorologie Physique, Opgc, Clermont-Ferrand, France; (8) National University of Ireland, Galway, Ireland

The space-time variations of trace gases in the atmosphere reflect the distribution of surface emissions, mixed by horizontal and vertical atmospheric transport. By using atmospheric tracers or/and models to quantify the intensity of the mixing, surface emissions can be resolved from the atmospheric measurements. The objective of our study is to characterize the CO2 and CH4 variations observed over Europe. We have analyzed the CO2 and CH4 molar fractions gradients between the continental stations in Western Europe and the Atlantic Ocean. The marine selected data from Mace-Head, Ireland, was used as a reference to define Atlantic Ocean background conditions. Long term (> 10 years) time series of DCO2 and DCH4 were calculated from Shauinsland, Plateau Rosa and Puy de Dôme. New monitoring stations set up in France provide a more detailed view of the gradients for the most recent years. The signals are characterized by a high year-to-year variability (up to 6 µmol.mol-1 for CO2), with a strong correlation between most of the stations. The latest winter (2013-2014) shows relatively low gradients at all sites, similarly to 2007-2008 winter season. Both winters correspond to a warm anomaly, associated to stronger Westerlies. Stronger advection and vertical mixing due to higher Westerlies seems to be the main reason for the low gradients observed in 2008 and 2014. However the interannual variability of the climate in Western Europe, also induce variations in trace gases exchange with terrestrial ecosystems and fossil fuel emissions. The objective of our analysis will be to discriminate between the contributions of atmospheric transport and surface emissions in the observed variability of DCO2 and DCH4 over Europe.

P-1115-13

Recovery, recycling and destruction of F-gases in Georgia

S. Suladze (1) ; S. Shekeladze (2) ; L. Kvinikadze (3)
(1) Georgian Refrigerant Recovery and Recycling Centre, Tbilisi, Georgia; (2) Georgian Rerigerant Recovery and Recycling Centre, Tbilisi, Georgia; (3) Tbilisi State University, Tbilisi, Georgia

Introduction of a sustainable system for recovery, disposal and destruction of contaminated artificial refrigerants, which are F-Gases with very high GWP (Global Warming Potential), is a direct contribution to the reduction of emissions of GHG into the atmosphere especially for developing countries.

Refrigerating, Air-conditioning and Heat pump (HRAC) sector is only consumer of industrial GHGs in Georgia. These substances have been widely introduced as alternatives to ODS (Ozone Depleting Substances) refrigerants during the last twenty years since Georgia ratified the Montreal Protocol on Substances that Deplete the Ozone Layer. By this reason annual consumption of the industrial GHGs has grown up sharply and reached two hundred thousand metric tons now. Therefore the Introduction of an effective monitoring system together with recovery, disposal and destruction of F-gas refrigerants is urgent issue today in the country.

This study gives feasibility assessment of such system for Georgia taking into account the experience of the Georgian Refrigerant Recovery & Recycling Centre in recovering, recycling or destruction of the ODS.

In order to make the feasibility assessment the preconditions for generating unwanted refrigerants bank were studied.

Based on the gathered and analyzed data the recommendations were formulated for designing a sustainable monitoring system of new and used GHG refrigerant in the country. The recommendations include introduction of measures to support the sustainability looking at available F-gases waste that can be collected through two Recovery & Recycling centers operating in the country in cooperation with service companies, importers, car dismantling and metal scrapping companies in longer run with future waste disposal deploying in-country generated sources of finance.

This is very urgent issue because like in other developing countries there are no technical facilities of destruction of F-gases waste in Georgia. So the collected unwanted GHG refrigerants have to be saved for trans-boundary transportation where they can be safely destroyed. Financial mechanism for sustainable system of F-gases waste permanent collection and destruction has been studied and shown that several methods for accumulation of funds inside the country can be acceptable for Georgia.

Transferring concern with climate mitigation to Institutional Sustainability: A case study applying carbon accounting as a tool for resource management in a desert environment

K. Tarabieh (1) ; R. Tutwiler (2) ; T. Jaskolski (2) ; M. Rauch (3)

(1) The American University in Cairo, Construction and Architectural Engineering Dept, New Cairo, Egypt; (2) The American University in Cairo, Research institute for a sustainable environment, New Cairo, Egypt; (3) The American University in Cairo, Sustainability office, New Cairo, Egypt

As a result of climate change and the potential risk of global warming, an emerging interest across academic institutions to develop a comprehensive inventory of greenhouse gas emissions is on the rise. Higher education institutions are often faced with the challenge to develop a process that will accurately assess the campus' resource consumption in a timely, economical, and informative manner. This type of assessment is not typical and relies heavily on the availability of data and institutional capacity to carry such exercise accurately and report the findings, benchmark against peer institutions and establish the institutional mechanisms to sustain this type of data intensive work. In response to the previous principals and faced with a number of environmental challenges in a desert environment, the American University in Cairo (AUC) recently completed the first phase of carbon accounting and issued a Carbon Footprint Report which highlights the strategies adopted by the sustainability team to reduce energy consumption on campus. The report measured the University's carbon footprint, which is the annual total of carbon dioxide (CO2) and other significant greenhouse gases emitted into the atmosphere as a result of daily activities and campus operations. AUC was the first higher education institution in the Middle East and North Africa to conduct such a comprehensive study of its own impact on climate change. As part of its ongoing efforts to maintain and improve its operational sustainability, AUC has witnessed a one-third reduction in overall energy consumption on the New Cairo campus over the past two years, decreasing the cost of utilities by 35%, thanks to an energy-saving plan designed and implemented by the University's sustainability team. This proposal presents the method, challenges, strengths and areas of improvement of the method used and outlines the present strategies developed to manage the campus resources as a result of this exercise. It also presents the efforts taken to institutionalize the method so it becomes campus culture and to transition the work from research to a daily practice.

Assessing the role of megacities on atmospheric CO2: results for Paris from the CO2-MegaParis project, France

I. Xueref-Remy (1) ; E. Dieudonné, (1) ; C. Vuillemin, (1) ; M. Lopez, (1) ; C. Lac, (2) ; M. Delmotte, (1) ; F. Ravetta (3) ; O. Perrussel (4) ; FM. Bréon (1) ; G. Broquet, (1) ; M. Schmidt, (5) ; F. Chevallier (1) ; V. Masson (2) ; P. Ciais (6) ; M. Ramonet () ; C. Ampe, (7) ; L. Ammoura, (6) ; V. Gros (1) ; A. Baudic, (1) ; B. Bonsang, (1)

(1) LSCE, Ipsl, Gif-sur-Yvette, France; (2) CNRM, Toulouse, France; (3) LATMOS, Ipsl, Paris, France; (4) AIRPARIF, Paris, France; (5) IUP, Heidelberg, Germany; (6) LSCE, Ipsl, Gif sur Yvette, France; (7) Airparif, Pars, France

On average, atmospheric CO2 increases in the atmosphere at a rate of about 2 parts per million (ppm) per year, due to the accumulation of about half of the anthropogenic CO2 emissions in the atmosphere (mostly from the combustion of fossil fuels), while the other half is being re-absorbed by the ocean and the continental biosphere. Today, more than 70% of global fossil-fuel CO2 emissions come from punctual sources such as megacities. Paris is the third megacity in Europe and it emits about 15% of the total French emissions, while it covers only less than 2% of the national territory. Currently, most of the estimates of urban CO2 emissions are given by bottom-up CO2 emissions inventories, which rely on activity proxies and benchmarked emission factors. The associated uncertainties can be as high as several tenths of percents, especially when it comes to discriminate the CO2 urban emissions by emission sectors. Therefore, there is an urgent need for developing new methods to better Monitoring, Reporting and Veryfying (MRV) CO2 emissions from megacities, dedicated to provide robust results to policy makers for taking efficient decisions and actions in matter of controling CO2 anthropogenic emissions and mitigating climate change. Since 2009, the CO2-Megaparis project aims to quantify CO2 emissions from Paris using top-down approaches based on a synergy between atmospheric observations and modeling. For the first time, a mini-network of 3 greenhouse gases (GHG) monitoring stations was developed by LSCE in Paris agglomeration within the infrastructure of the regional air quality monitoring agency, AIRPARIF, completing 2 other GHG stations from the ICOS European greenhouse monitoring network. One of our urban station was located on top of the Eiffel tower above Paris megacity. The analysis of one year of data showed that Paris CO2 emissions lead to a mean increase of the atmospheric CO2 concentration in the mid-afternoon of 2 to 3 ppm, and is strongly season, windspeed and wind direction dependent: the CO2 urban plume is characterized by a very large spatio-temporal variability and can reach about 60 ppm at low windspeeds on top of the Eiffel tower. In addition, analysis of correlations between CO2, CO and 14C02 were carried out from field measurements and allowed an independent assessment of the inventories emission sectors. Furthermore, direct modeling of CO2 at a very fine resolution (2x2 km2, 1h) was performed and matched well with the observations. Last but not least, inverse modeling efforts at the same resolution allowed a significant improvment of the regional inventory from Airparif. Finally, a campaign conducted during springtime and based on lidar facilities revealed that due to the effect of the urban heat island, the boundary layer height (that can be seen on the first degree as the man dilution factor of CO2 emissions in the atmosphere), is 10 to 40% time higher in Paris than in surrounding rural areas: this is an important result that supports the implementation of urban canopy models in future fine scale urban CO2 modeling framework. A synthesis of the different results will be presented, as well as an attempt of defining the strengths and weaknesses of the atmospheric approach to quantify urban CO2 emissions. Contributions from sister studies (MultiCO2 - IPSL, Le CO2 parisien - Ville de Paris 2030, CarboCount-City - KIC Climat...) will also be mentionned.

1116 - Biogeochemical Feedbacks to Climate Change

ORAL PRESENTATIONS

Observational constraints on biogeochemical feedbacks

C. Le Quéré (1)
(1) University of East Anglia, Tyndall Centre for Climate Change Research, Norwich, United Kingdom

Tremendous efforts are underway to use a wider range of observations to inform model projections. Efforts range from enhanced coordination of repeat observations, the collection of quality controlled data in public databases, the development of new data interpolation methods, and extensive model-data comparison efforts. This presentation will provide an overview of efforts by the carbon cycle research community to constrain, using a range of observations, our quantitative understanding of how the carbon cycle works. It will use the trends and variability observed during 1959-2014 in a range of observations to examine how the land and ocean carbon sinks have responded to changes in increasing atmospheric CO2 and climate change and variability at the global and regional level, and comment on the qualities and limitations of models to project changes in the 21st century and beyond. This presentation will be based on the 'Global Carbon Budget' annual update by the Global Carbon Project. It includes an assessment of the annual change in land and ocean carbon sinks from three ocean data products, seven ocean models, eight dynamic global vegetation models, three atmospheric inversions, plus indirect constraints from CO2 emissions and measured atmospheric CO2 growth rate. The presentation will also include additional data and model analysis from the marine environment and discuss the marine biogeochemical feedbacks related to ocean deoxygenation and to the response of marine ecosystems to climate change and ocean acidification.

The loss of carbon from ecosystems as they adjust to a warmer climate may act to amplify climate change. Permafrost-affected ecosystems may be particularly vulnerable to such carbon losses because of the huge amounts of organic carbon that have been preserved in frozen soils, which may thaw and decompose more rapidly as a result of climate warming. In the IPCC fifth assessment report, the models of the Earth system that were used to estimate the magnitude of these terresrial carbon-climate feedback processes did not include key representation of the CO2 and CH4 release from permafrost thaw. Recent progress has been made to synthesize observations of permafrost carbon dynamics and develop the representation of these processes in global carbon cycle models, to better estimate the amount and timing of greenhouse gas emissions from permafrost. I will discuss a variety of approaches to project the feedback from warming permafrost, from highly simplified and data-constrained soil models to detailed ecosystem models that include vegetation-permafrost-nutrient interactions. Such approaches suggest that the carbon-climate feedback from permafrost is an important process on the 50-300 year timescale, and that the magnitude of ecosystem carbon losses is highly sensitive to the future trajectory of fossil fuel emissions, with much larger losses under high emission scenarios such as RCP8.5 than on mitigated emissions pathways such as the RCP4.5 scenario.

Biogeochemical feedbacks to climate change: Insights into soil moisture controls on soil heterotrophic respiration

C. Chenu (1) ; F. Moyano (2) ; P. Garnier (3) ; I. Virto (4)
(1) Agroparistech, Umr ecosys, Grignon, France; (2) CNRS, Bioemco, Grignon, France; (3) INRA, Umr ecosys, Grignon, France; (4) Universidad Pública de Navarra. Escuela Superior de Ingenieros Agrónomos, Departamento de ciencias del medio natural, Pamplona, Spain

Soils contain the largest C terrestrial pool and even small changes in soil organic C (SOC) can have a significant impact on the atmospheric CO2 concentration. The C cycle feedback to climate will largely depend, in magnitude and timing, on the response of soil C to climate changes. However, there is still considerable uncertainty regarding such effects.

While the effect of temperature on soil C mineralization has been the subject of much work and considerable debate, much less attention has been paid to the effect of changes in water regime, another predicted component of climate change. However, soil moisture has a key role in regulating soil respiration. Here, we synthesise work regarding the relation between soil moisture and soil C dynamics, focusing on the underlying mechanisms, on the interaction with soil properties and other components of global changes, and discuss how mechanisms and the complexity of soils can be integrated into models.

The effect of soil moisture is complex to predict because, unlike that of temperature, it is strongly dependent on soil characteristics. Soil moisture effect on heterotrophic respiration is represented in most current carbon cycle models by empirical functions, which are often based on limited experimental data. We performed a data-driven analysis of soil moisture respiration relations and showed how these are consistently affected by soil properties such as clay content, organic C content, bulk density. We developed empirical models including the effects of soil texture, soil organic carbon and bulk density which improve the functions currently used in different soil biogeochemical models.

Partially responsible for the present state of knowledge may be the idea that, in biogeochemical models, time- and spatially averaged or approximate relationship of microbial activity with moisture is sufficient to reliably predict C fluxes. But soil microorganisms live in a complex 3-D framework of mineral and organic particles defining pores of various sizes, more or less inter-connected, which result in a variety of microhabitats. Most promising perspectives in this area are based on mechanistic approaches, where theoretical linkages between substrate and gas diffusivity in soil pores and heterotrophic respiration are explored in different soil matrices. A new generation of biogeochemical models is based on an explicit representation of soil architecture at a fine scale, which provides in-depth mechanistic understanding, and should help to define relevant descriptors of soil characteristics to improve how larger scale models account for the effects of soil moisture.

The complex interplay between biological, biogeochemical and physical processes is apparent when considering the variability of soil C storage upon a widely used cropping practice: not tillage, where soil moisture also regulates the flows of C between soil litter and mineral layers. The interactions between soil moisture and other components

of global change, i.e. land use, cropping practices, temperature, will also result in biogeochemical feedbacks to climate change.

O-1116-01

Positive future climate feedback due to changes in oceanic DMS emissions

J. Tjiputra (1) ; K. Six, (2) ; Ø. Seland (3) ; C. Heinze (4)
(1) Uni Research, Uni climate, Bergen, Norway; (2) Max Planck Institute for Meteorology,, Hamburg, Germany; (3) Norwegian Meteorological Institute, Oslo, Norway; (4) University of Bergen, Geophysical institute, Bergen, Norway

The global ocean is the largest natural source of dimethylsulphide (DMS) gas to the atmosphere. DMS is produced by phytoplankton and is released to the surface ocean if cells are degraded. Once it enters the atmosphere, it might contribute to the nucleation particles important for cloud formation, which then effect the Earth's radiation budget and climate. Future global warming and ocean acidification is projected to alter marine DMS production and emission. However the none of the models assessed in the last IPCC report includes the DMS-climate feedback.

Recent study indicated that under high CO2 emissions future, the oceanic DMS emission is projected to decrease by 12 to 24% by the end of this century, potentially leading to an equilibrium temperature response of 0.1K to 0.76K.

Here, for the first time using a fully interactive Earth system model including a microphysical aerosol module with sulfur chemistry, we perform simulations on future climate projection with coupled DMS feedback. Under the highest pH sensitivity, our simulation shows that projected DMS production and emission decrease relative to the preindustrial state by 50% and 36%, respectively toward the end of the 21st century under the RCP8.5 emissions scenario. The largest emission reduction is simulated in the Southern Ocean. On contrast, emissions at polar latitudes increase owing to the sea ice retreat. This large change in marine sulfur emisson leads to an additional global warming of 0.3K relative to the reference simulation without DMS-climate feedback at the end of the 21st century. Both simulations also produce similar trajectories in atmospheric CO2 concentration, consistent with little change in the cumulative oceanic and terrestrial carbon sinks.

High northern latitudes are predicted to warm rapidly during the 21st century. The tundra, boreal forests and peatlands found in these regions are recognised to contain substantial stores of organic matter. Permafrost soils are particularly important in this context, storing as much carbon as all the rest of the world's soils put together, and more than twice as much carbon as the atmosphere. The IPCC AR5 report emphasises that there is high confidence that warming in the Arctic and Boreal will lead to a reduction in permafrost extent. However, while some estimates suggest that the potential for carbon release from thawing permafrost soil could be the single most important climate-carbon cycle feedback, the AR5 report also emphasises that there is low confidence in predicting rates of soil carbon loss, and also whether the carbon will be released mainly as carbon dioxide or the more powerful greenhouse gas, methane. Importantly, the permafrost feedback is not currently included in the models evaluated in the IPCC CMIP programme, and thus a potentially critical feedback is missing.

This presentation will focus on how recent studies, making detailed in situ observations, and running manipulative field and laboratory experiments, have improved understanding of the permafrost feedback. In particular, the presentation will: 1) explain the role of different high-latitude plant communities, including understudied groups such as mosses, in both controlling rates of thaw and potentially mitigating against some of the expected carbon release, 2) outline the important role radiocarbon dating has played in detecting the contribution of the decomposition of old, previously-frozen organic matter to rates of carbon release following permafrost thaw, and 3) discuss the potential for substantial amounts of permafrost carbon to be released in the form of methane.

Research has shown that in boreal forest, thick moss layers may insulate soils to such an extent that disturbances (e.g. fire) may be required before warming promotes deep permafrost thaw. Therefore, tundra and peatland ecosystems may thaw more rapidly due to wetter conditions or reduced thickness of insulating moss layers. Overall, it appears that there is indeed considerable potential for increased carbon dioxide production from thawing permafrost, especially from highly organic soils, and where soils are not permanently waterlogged post thaw. The latter issue requires a fuller consideration of water flow paths within permafrost landscapes. Given the potential for large soil carbon losses, it may be unlikely that these could be fully compensated for by increased plant growth, at least in tundra ecosystems where plant biomass is low. There does though remain the potential for increased soil carbon inputs from plants to reduce rates of soil carbon losses. On the other hand, rates of methane production from thawing permafrost may not be as high as first predicted. Rather, the direct effect of climate warming on rates of methanogenesis associated with the decomposition of contemporary carbon inputs in northern wetlands, is likely to be more important.

The permafrost feedback remains potentially one of the most important carbon cycle feedbacks to climate change, but requires considerable further study. Improving understanding of the proportion of previously-frozen organic matter that will decompose aerobically following thaw, and the extent to which nutrient release from thawing permafrost can increase plant growth and soil carbon inputs, should be considered as key ongoing research priorities.

(ssai), Greenbelt, MD, United States of America; (3) NASA Goddard Space Flight Center, Universities space research association (usra), Greenbelt, MD, United States of America; (4) NASA Goddard Space Flight Center, Earth system science interdisciplinary center (essic), Greenbelt, MD, United States of America; (5) Vanderbilt University, Nashville, TN, United States of America; (6) South Dakota School of Mines & Technology (SDSMT), Rapid City, SD, United States of America; (7) University of Nebraska, Lincoln, NE, United States of America; (8) University of Missouri, Kansas City, MO, United States of America; (9) Desert Research Institute (DRI), Reno, NV, United States of America; (10) Howard University, Washington, DC, United States of America; (11) Centre for Scientific and Industrial Research, Natural resources and the environment, Pretoria, South Africa

One of the most vulnerable tropical regions of the world is the northern sub-Saharan African (NSSA) region, which is bounded on the north and south by the Sahara and the Equator, respectively, and stretching East-West across Africa. This is so because of the highly active

environmental and meteorological processes associated with its unique location and human activities. Over the years, this region has suffered frequent severe droughts that have caused tremendous hardship and loss of life to millions of its inhabitants due to the rapid depletion of the regional water resources. On the other hand, the NSSA region shows one of the highest biomass-burning rates per unit land area among all regions of the world. Because of the high concentration and frequency of fires in this region, with the associated abundance of heat release and gaseous and particulate smoke emissions, biomass-burning activity is believed to be one of the drivers of the regional carbon and energy cycles, with serious implications for the water cycle and climate. This extensive biomass-burning phenomenon contributes to environmental change, whose effects on the regional climate variability can be significant, with far-reaching implications for societal adaptation. An interdisciplinary research effort sponsored by the United States National Aeronautics and Space Administration (NASA) is presently being focused on the NSSA region, to better understand possible connections between the intense biomass burning observed from satellite year after year across the region and the water cycle, through associated changes in certain essential climate variables (ECVs) including land-cover, albedo, soil moisture, evapotranspiration, and atmospheric composition, which can drive changes in additional ECVs such as atmospheric water vapor and wind patterns, precipitation, surface runoff, and groundwater recharge. A combination of remote sensing and modeling approaches is being utilized to investigate these multiple processes to establish possible links between them. We are finding appreciable relationships between biomass burning and many of the above-listed ECVs. In this presentation, we will discuss interesting results as well as the path toward improved understanding of the interrelationships and feedbacks between the water cycle components and the environmental change dynamics due to biomass burning and related processes in the NSSA region.

The biggest terrestrial tipping point or a potential carbon sink? 124 experts weigh in on the permafrost carbon feedback

B. Abbott (1) ; E. Schuur (2) ; JB. Jones, (3) ; FS. Chapin Iii (3) ; .. Permafrost Carbon Network (2)

(1) Observatoire des Sciences de l'Univers de Rennes, Rennes, France; (2) Northern Arizona University, Center for ecosystem science and society, Flagstaff, AZ, United States of America; (3) University of Alaska Fairbanks, Institute of arctic biology and department of biology & wildlife, Fairbanks, United States of America

Arctic tundra and boreal forest contain approximately half of all terrestrial organic carbon. As the permafrost region warms, more of this immense carbon pool will be exposed to decomposition, combustion, and hydrologic export. This permafrost carbon feedback has been described as the largest terrestrial feedback to climate change as well as one of the most likely to occur; however, it is not included in current emissions negotiations and estimates of its strength vary by a factor of thirty. Models predict that some portion of this release will be offset by increased Arctic and boreal biomass, but the lack of robust estimates of net carbon balance increases the risk of further overshooting international emissions targets with serious societal and environmental consequences. Because precise empirical or model-based assessments of the critical factors driving carbon balance are unlikely in the near future, we collected expert judgments from 124 permafrost-region scientists of the response of high-latitude carbon balance to four warming scenarios. Experts provided quantitative estimates of CO2 and CH4 release, change in biomass, wildfire CO2 emissions, and hydrologic carbon flux by 2040, 2100, and 2300. Results suggest that, contrary to current model projections, total permafrost-region biomass could decrease due to water stress and disturbance. Assessments indicate that end-of-the-century organic carbon release from Arctic rivers and collapsing coastlines could increase by 75% while carbon emissions from wildfire could increase four-fold. For the business as usual scenario (RCP 8.5), experts hypothesized that the permafrost zone could emit 14 to 40% of the carbon necessary to push the climate system beyond the 2C threshold by the end of the century (140 to 240 Gt CO2 equivalent) with cumulative net emissions reaching 320 to 510 Gt by 2300. However, because lower warming scenarios resulted in less carbon release from soils and more carbon uptake by Arctic and boreal biomass, results suggest that 65 to 85% of permafrost carbon release can still be avoided if human emissions are rapidly reduced.

P-1116-02

Constraining the strength of the terrestrial CO2 fertilization effect in Earth system models

V. Arora (1)

(1) Canadian Centre for Climate Modelling and Analysis, Environment Canada, Victoria, Canada

The response of the global carbon cycle to future atmospheric emissions of carbon dioxide (CO2) is paramount to projecting the future atmospheric CO2 concentrations and the resulting climate change. Yet, the current generation of Earth system models (ESMs) show widely varying responses of the global carbon cycle to future increases in anthropogenic CO2 emissions. A large fraction of the differences in response of the ESMs is due to the land carbon cycle. The response of the ocean carbon cycle, to changes in atmospheric CO2 and changing climate, is much more consistent across ESMs. Over land, the strength of the CO2 fertilization effect is biggest source of uncertainty that contributes to the large differences in response of the land carbon cycle. Here, using results from the three generations of the Canadian Earth System Model (CanESM1, CanESM2, CanESM 4.2) it is shown that the net land carbon uptake over the historical period and the amplitude of the annual cycle of the atmospheric CO2 concentration may be used together to constrain the strength of the terrestrial CO2 fertilization effect. Uncertainty exists in land use change emissions over the historical period, and thus the estimate of historical land carbon uptake, and monthly global atmospheric CO2 data go back only to the 1980s. These limitations imply that both the net land carbon uptake over the historical period and the amplitude of the annual cycle of the atmospheric CO2 concentration provide not-too-strong, but still meaningful, constraints on the strength of the CO2 fertilization effect of the land carbon cycle.

P-1116-03

What you see is not what you get: the permafrost carbon feedback in the context of climate stabilization and reversibility

E. Burke (1) ; C. Jones (1) ; P. Good (1)

(1) Met Office Hadley Centre, Exeter, United Kingdom

Permafrost soils contain large amounts of relatively inert soil carbon, a proportion of which is projected to thaw and become vulnerable to decomposition under future climate change. This paper utilises a series of idealised scenarios – where the surface temperatures are increased, stabilised and reduced – to highlight the implications of the timescale of response of the permafrost carbon to changes in climate and the potential for (ir)reversible loss of carbon. Patterns of warming are based on the HadGEM2-ES climate model. Uncertainty ranges in permafrost carbon loss are estimated using a simple model that accounts for uncertainties in the distribution of soil carbon, its lability and different plausible decomposition mechanisms. Under scenarios of steadily increasing temperature only a proportion of the carbon vulnerable to decomposition is emitted at any given time, because of a time lag in decomposition. The proportion of vulnerable carbon released at any given level of warming depends on the rate of past warming. Faster transient warming causes less of the vulnerable carbon to be emitted than a slower increase. In a scenario where the global warming reaches 2.6 K over a period of 70 years only about 30 % of the 70 – 230 Gt C vulnerable to decomposition has been emitted. However, if temperatures are stabilised, then the majority of the remaining vulnerable carbon will be emitted over the next 200 years causing an eventual additional temperature increase of 0.1–0.6 K. If the permafrost is allowed to recover (by reducing temperatures) causing the vulnerable carbon to refreeze some of the permafrost carbon loss can be avoided depending on the peak warming and the rate of subsequent cooling. The contribution of permafrost

carbon needs to be included when assessing targets for stabilisation and developing policies designed to avoid dangerous climate change.

P-1116-04

Is Ocean really a source to atmospheric CO2 during cyclones in the Arabian Sea ?

K. Chakraborty (1) ; S. Prakash (2) ; A. Paul (2)
(1) Indian National Centre for Ocean Information Services (INCOIS), Information Services and Ocean Sciences Group (ISG), Hyderabad, India; (2) Indian National Centre for Ocean Information Services (INCOIS), Information services and ocean sciences group, Hyderabad, India

The enhanced biological production, and associated regeneration, leads to higher pCO2 in the sea water compared to atmosphere and ocean becomes a source of atmospheric CO2 (Sarma et al., 2008) during such events. Cyclone induced productivity intensify this source. Byju et al., (2011) reported that Phyan associated net CO2 flux to the atmosphere was 0.123 Tg C. We have employed a coupled 3-D bio-physical model, ocean general circulation model ROMS with an ecosystem model, to study whether Ocean is really a source to atmospheric CO2 during cyclones in the Arabian Sea. It is observed that the storm has a significant effect on the thermocline and mixed layer depth which in-turn enhance sea surface chlorophyll concentration. Model generated sea surface chlorophyll concentration during several extreme events is validated using satellite derived ocean colour data which also shows higher concentrations of chlorophyll in the storm influenced region. The high concentration of chlorophyll appeared as a bloom over an area of approximately 150 km in diameter along the storm passage. It is observed that thermocline shoaled up after the storm passed and this shoaling of the thermocline caused entrainment of nutrients in upper 50 meters which triggers high biological productivity. The 50 meter vertically integrated primary production during three different cyclones (Cyclone 01A, Tropical storm 05A and Tropical Storm PHYAN) was estimated in terms of carbon using the model along the track of the cyclone/storm. The net sequestration of carbon due to the above mentioned cyclones are 0.125 Tg C, 0.16 Tg C and 0.125 Tg C, respectively. Our study, in conjuction with Byju et al., suggest that ocean is not a source of CO2 to the atmosphere during cyclones but more such study is required to ascertain whether the ocean acts as a sink during such events.

P-1116-05

The great climate change and the fuzzy C sink: how irrigation can change soil carbonates dynamics

IS. De Soto (1) ; I. Virto (1) ; P. Barré (2)
(1) Universidad Pública de Navarra. Escuela Superior de Ingenieros Agrónomos, Departamento de Ciencias del Medio Natural, Pamplona, Spain; (2) PSL Research University, Laboratoire de géologie de l'ens, Paris, France

There are two types of carbonates in soils: lithogenic or primary carbonates, and pedogenic or secondary carbonates. The formation of the later depends on the availability of bicarbonates (HCO3-) and cations in the soil solution. When bicarbonates present in the solution are the result of the dissolution of CO2 from soil respiration, the formation of pedogenic carbonates can be considered a net CO2 sink. Carbonates dynamics in soil are however complicated to depict because in addition to the sources of carbonates (which can include pre-existing carbonates, bicarbonates dissolved in incoming water and the soil atmosphere) and cations, the conditions for precipitation and/or dissolution and leaching are continuously changing. From a global perspective, these conditions can be considered at steady state in a given place when relatively long periods of time (f.e. one year) are considered, and local climate and soil conditions do not change.

However, when the annual soil water balance changes, alterations in soil carbonate concentrations can be expected in a short period of time because of the solubility of carbonate minerals. In this context, human-induced changes, such as the implementation of irrigation, can accelerate the dissolution and precipitation cycles of soil carbonates. In addition, irrigation stimulates the soil biological activity and biotic CO2 generation and also irrigation water can be an external source of cations and bicarbonates. For this reason, studying the evolution of carbonates in dryland agricultural soils converted to irrigation can help to understand the extent of this change in terms of carbonates dynamics. The complexity of these biogeochemical interactions makes modelling a useful and interesting tool.

The purpose of this work was to evaluate the variations of carbonate concentrations in the topsoil of a semi-arid Mediterranean agricultural soil after the implementation of irrigation. Two adjacent plots were selected for this study; one under dryland conditions with wheat since at least 50 years and another under irrigation conditions with corn for 7 consecutive years. The plots were located in the same soil unit (Calcic Cambisol) in Funes (Navarra, Spain). Numerical simulations of carbonates concentration, dissolution and precipitation were performed with PHREEQC for the evaluation of the geochemical interactions between the soil, the soil solution and irrigation water, for a simple model based in the monthly water balance and the observed concentrations in the soil solution and irrigation water. In addition, a sensitive analysis was developed in order to investigate the potential impact of the type of crop, salt concentrations in the irrigation water and partial CO2 pressure due to soil respiration. Finally, for the validation of the model, samples of the irrigated and non-irrigated plots were analyzed for their carbonate content and isotopic composition (δ13C).

Simulated values were consistent with the observed values of carbonates concentrations and isotopic signature of the soil samples. The simulation results also suggested that the amount of new precipitated carbonates and the amount of carbonates leached varies with the salt concentration in the irrigation water, the partial CO2 pressure and the type of crop. The most sensitive parameter was the partial CO2 pressure of the soil solution. The modelling results showed annual values of carbonates-C leaching around hundreds of kg/ha in the studied area under irrigation.

This study showed that in a relatively short period of time (seven years) the differences observed in the inorganic C budget of the agricultural soil studied could be significant in relation to the total soil C budged. Irrigation could therefore have an important effect in soil fractions of carbonate-rich soils and this should be taken into consideration in regional-scale studies.

P-1116-06

The long-term effect of short-lived species through the climate-carbon feedback

T. Gasser (1) ; P. Ciais (1)
(1) LSCE, Gif-sur-Yvette, France

This work aims to quantify and discuss the impact of short-lived species on the carbon-cycle and through the climate-carbon feedback. It proceeds in three steps. First, we isolate the climate-carbon feedback and its contribution to the currently observed, human-driven, change in atmospheric carbon dioxide. Second, we attribute this feedback to its various anthropogenic causes following the concentration-based attribution of radiative forcing provided by the IPCC. To do so, we updated the compact Earth system model OSCAR to its version 2.2, and we use it combined with attribution algorithms developed to answer the Brazilian Proposal (Trudinger and Enting, 2005; doi: 10.1007/s10584-005-6012-2).

In the first step, the model is used as a carbon-cycle model in which the sensitivity of the ocean and land modules were calibrated on complex three-dimensional models used in CMIP5 (Arora et al., 2013; doi:10.1175/JCLI-D-12-00494.1). Using three historical drivers: (1) anthropogenic CO2 emissions from fossil-fuel burning, (2) land-use and land-cover changes, and (3) reconstructed climate, the historical change in atmospheric CO2 is shown to be satisfactorily reproduced by the model. This change in atmospheric CO2 is then attributed to the three drivers. As best guesses, we find that the observed 2008 burden increase of 107 ppm is attributed at 56% to fossil-fuel emissions, at 28% to land-use activities, and at 16% to climate change.

In the second step, we expand the model with a climate module whose global and local responses to radiative forcing are also calibrated on CMIP5 outputs (Geoffroy et al., 2013; doi:10.1175/JCLI-D-12-00195.1). Using

the radiative forcing timeseries produced for the fifth IPCC report (Myhre et al., 2013), we repeat the previous experiment, albeit this time the contribution of «climate change» is further broken-down into contributions by the various primary and secondary radiatively active species: CO2, non-CO2 greenhouse gases, ozone or aerosols. Of the 17 ppm (= 16% of 107 ppm) previously attributed to climate change, we estimate 79% are caused by non-CO2 greenhouse gases, -57% by short-lived species (ozone and aerosols), and the complementary 78% by CO2 itself.

The overall negative figure from short-lived species is explained by the dominance (among the various effects of the these species) of the cooling effect of aerosols. Over the historical period, we show that this cooling avoided a reduction in the carbon sinks efficiency that would have been seen if only CO2 and non-CO2 greenhouses gases had been emitted. To complete this analysis, we make a third experiment with a slightly altered model designed to keep track of past changes in the carbon-climate system. This «book-keeping» approach shows that past emissions of short-lived species still have an impact on present-day atmospheric CO2, and thus on present-day climate. For instance, we estimate that sulfur emissions from the 1980s have an impact of about -2 ppm over the 107 ppm observed in 2008.

To conclude, this study quantifies one of the indirect biogeochemical effect of aerosols (and ozone), as first introduced by Mahowald (2011; doi:10.1126/science.1207374). It provides an emission-based analysis of the causes of the change in CO2 atmospheric concentration (and thus of its radiative forcing), similarly to what was done for CH4 or O3 in the last IPCC report (Myhre et al., 2013). The emission-based approach complements the «traditional» concentration-based one, since it has the interest of providing a diagnosis of the anthropogenic drivers of climate change that is one step closer to the political decision, albeit at the cost of an increased uncertainty as we will also show.

P-1116-07

Response of Soil Carbon Storage to Temperature and Carbon Input Variability in Earth System Models

K. Georgiou (1) ; WJ. Riley (2) ; MS. Torn ()

(1) University of California, Berkeley, Chemical and Biomolecular Engineering, Berkeley, CA, United States of America; (2) Lawrence Berkeley National Laboratory, Climate and carbon sciences, Berkeley, CA, United States of America

Soil comprises the largest terrestrial carbon pool, containing more than double the carbon currently in the atmosphere and triple that in vegetation. Soil organic matter (SOM) is particularly vulnerable to environmental change, with potential carbon-climate and carbon-concentration feedbacks resulting from soil warming, CO2 fertilization, nitrogen (N) enrichment, and precipitation. These changes are expected to influence SOM decomposition and stabilization processes, thereby threatening the soil's capacity to serve as a carbon (C) sink. Earth system models (ESMs) currently use linear kinetics to represent soil C dynamics, and therefore lack explicit representation of the non-linear biotic and abiotic mechanisms that govern soil processes. As such, ESMs exhibit high uncertainty in their simulated current and future soil C storage. Recent studies have shown that explicit representation of microbial and mineral interactions improve estimates of current global C stocks and better capture spatial heterogeneity. These microbe-enabled SOM models also better represent non-linear responses to changes in soil temperature and C inputs (e.g., priming of old SOM in response to increased soil C inputs) that have been observed in many field and laboratory experiments.

Although recent work has explored the feasibility of incorporating microbial and mineral mechanisms into SOM models within ESMs, most of these models lack explicit representation of nutrient cycling (nitrogen and phosphorus) and seasonal variability (temperature, C inputs, and moisture). Omitting nitrogen cycling significantly affects simulated global priming responses to elevated CO2 concentrations, as nitrogen availability plays an important role in dictating microbial activity in nutrient-constrained environments. Thus far, microbe-enabled SOM models within ESMs have also largely ignored the effect of temporal forcing on soil C dynamics, representing seasonal and diurnal temperature, C and N inputs, and moisture with annual averages. These simplified model input assumptions, however, omit the seasonal and inter-annual fluctuations that microbial communities undergo in response to environmental conditions, greatly affecting the prediction of soil C equilibria and dynamics in ESMs. For example, a significant amount of soil respiration can occur during winter, while soils sampled in the summer (with different microbial composition) do not show respiration at winter temperatures. Leaf litter (primarily in the fall) and root exudates (throughout the growing season) support different microbial strategies depending on the type and duration of inputs. Global environmental change will affect the seasonality of these processes, which cannot be resolved by annual averages.

In this study we demonstrate that the frequency at which the system is resolved matters, i.e., that the seasonality and magnitude of temperature, and C and N inputs greatly impact the magnitude and sign of model response to climate change. We incorporate a trait-based, microbial-mineral, SOM model into the vertically-resolved Community Land Model (CLM4.5) of the Community Earth System Model (CESM) and present simulated current and future global C stocks that result from including seasonal forcing. We explicitly represent microbial diversity and physiology in our SOM model, allowing microbes with distinct temperature and C input optima to dominate decomposition at different times of the year when forced with seasonal temperature and C inputs from CLM4.5. We show that this temporal variability plays an important role in the diverse responses attained at sites with similar mean annual temperatures, but very different seasonality. The results of our vertically-resolved model also show that surface and deep soils' distinct diurnal and seasonal temperature fluctuations greatly affect their respective C storage capacity and vulnerability to global warming. We compare our model to the conventional SOM model within the CESM and to global observations from the Harmonized World Soil Database, and discuss improvements in estimating global and regional C storage and their response to anthropogenic climate change.

Spatial distribution of atmospheric variability of greenhouse gases measured at the IC3 climatic stations

C. Grossi (1) ; R. Curcoll (1) ; A. ÀGueda, (1) ; O. Batet, (1) ; S. Borràs, (1) ; L. Cañas Ramírez (1) ; M. Nofuentes Ramos (1) ; P. Occhipinti, (1) ; E. Vazquez, (1) ; X. Rodó (1) ; JA. Morgui (1)

(1) Institut Català de Ciències del Clima, Barcelona, Spain

Changes in the atmospheric greenhouse gases (GHGs) content results as a combinationof natural and anthropogenic factors. Understanding the GHGs composition, theiratmospheric variability and its effect on climate change is necessary for mitigation andadaptation strategies. Indeed, GHGs variability is strongly related to the climaticconditions and closely dependent on the latitude.

In the framework of the ClimaDat project funded by Fundació Obra Social "la Caixa".researchers at the Catalan Institute of Climate Sciences (IC3) have established anetwork of eight climatic stations across Spain performing continuous high-precisionobservations of CH4, CO2, N2O concentrations together with meteorological variables.The climatic stations are located in protected and remote areas within Spanish NaturalParks with middle latitudes ranging between 33N and 41N (Ebre River Delta, Xurès, Valderejo, Gredos, Grazalema, Segura, El Estrecho and El Hierro).

Analysis of the atmospheric variability of GHGs concentration is performed at eachstation of the ClimaDat network. The study of the influence of the atmosphericcirculation on GHGs observations is carried out by a source characterization of the airmasses and their pathways using experimental meteorological data, daily backtrajectories and cluster analysis. The observed GHGs concentrations at differentlatitudes and under different climatic conditions are analyzed and presented in thisstudy.

Multidecadal variability of subsurface oxygenation off the Central Peruvian Coast since the nineteenth century

D. Gutierrez Aguilar (1) ; J. Cardich (2) ; C. Almeida, (2) ; R. Salvatteci, (3) ; D. Romero, (4) ; A. Sifeddine (5)
(1) Instituto del Mar del Perú, IMARPE, Dirección General de Investigaciones en Oceanografía y Cambio Climático, Callao, Peru; (2) Universidad Federal Fluminense, Niteroi, Brazil; (3) Kiel University, Institute of geosciences, Kiel, Germany; (4) Universidad Peruana Cayetano Heredia, Maestría en ciencias del mar, Lima, Peru; (5) Institut de Recherche pour le Développement - IRD, Umr locean (ird/upmc/cnrs/mnhn), Paris, France

Subsurface and benthic biogeochemical conditions over the upper Peruvian continental margin are characterized by oxygen deficiency in the bottom waters, strong fluxes of settling organic matter and reducing conditions in the surface sediments. Previous work has shown a multidecadal cooling trend in the surface waters off Central Peru, and an increase of export productivity, particularly since the 1960's to the present, suggesting an intensification of coastal upwelling. The present study aims to reconstruct the coeval variation of subsurface oxygenation and benthic paleo-redox conditions for the last two centuries, based on laminated sedimentary records of benthic foraminiferal assemblages and redox-sensitive metals (Mo, Re, etc.) in the upper margin off Callao (12°S) and Pisco (14°S). The period between the mid to the late nineteenth century, during which there was an enhanced ENSO activity and paleo-temperatures were higher, was characterized by the occurrence of massive diatom-rich sedimentation events and development of bottom anoxia. Afterwards, decadal variations marked the changes of the proxy records since the late nineteenth century to the mid-twentieth century. Finally for the late twentieth century until the early 2000's, redox-sensitive metal records and benthic foraminiferal assemblages exhibited a trend towards less reducing conditions. This period also featured an increase of organic matter sedimentation and a declining trend of siliceous sedimentation. Our findings suggest that pelagic-benthic fluxes, vertical mixing and/or subsurface ventilation are important factors that modulate the subsurface oxygenation and benthic redox conditions in the Peruvian upwelling system.

Contribution of Carbon, Nitrogen and Climate Interactions to Terrestrial Carbon Uptake

A. Jain (1) ; S. Shu (1)
(1) University of Illinois, Urbana-Champaign, Atmospheric Sciences, Urbana, IL, United States of America

There is compelling evidence showing that terrestrial biosphere has acted as a net carbon (C) sink in recent decades. However there is a large uncertainty regarding the magnitude and location of the C sink, predominantly due to large uncertainties associated with C emissions from land use change and our limited understanding of processes affecting plant C sequestration, such as CO2 fertilization effect, impact of changing climate conditions on plant and soil respirations and the interaction of N dynamics with carbon and climate change. This presentation focuses on understanding and assessing the interactions between the C cycle, N cycle and climate and how they might impact terrestrial C sources and sinks in the context of changing global environment (particularly, increasing atmospheric CO2 concentrations ([CO2]), climate change, N deposition and land use change) by using a global terrestrial C-N cycle model in the modeling framework of the Integrated Science Assessment Model (ISAM). The ISAM model to be used here has been calibrated based on in situ data (Ameriflux and LBA field campaign). The model is also evaluated with two sets of global GPP data, MODIS and FLUXNETMTE. Analysis on the results of this study suggests that responses of available N in terrestrial ecosystems to global environmental changes might have not significantly affected the net global amount of terrestrial C uptake over the last three decades, but these N responses have a strong influence on the spatial and temporal distribution of predicted C sequestration as are the influences of global environmental changes.

Are soil organic carbon and its decomposers sensitive to a temperature increase? New insights from long term bare fallows and consequences for the terrestrial carbon biogeochemical cycle

R. Lefevre (1) ; P. Barré (2) ; PA. Maron, (3) ; S. Terrat, (3) ; S. Dequiedt, (3) ; T. Eglin, (4) ; BT. Christensen, (5) ; T. Kätterer, (6) ; S. Houot, (7) ; OF. Van (8) ; C. Chenu (9)
(1) University Pierre et Marie Curie, Ecosys, Grignon, France; (2) ENS/CNRS, Dpt geology, Paris, France; (3) INRA, Umr agroecology, Dijon, France; (4) ADEME, Direction productions et energies durables - service agriculture et forêt, Angers, France; (5) Aarhus university, Department of agroecology - soil fertility, Tjele, Denmark; (6) Swedish University of Agricultural Sciences, Department of ecology, Ultuna, Sweden; (7) INRA, Ecosys, Grignon, France; (8) INRA, Ecosys, Versailles, France; (9) Agroparistech, Ecosys, Grignon, France

The IPCC projects a temperature increase of 0.3-4.8°C at the global scale by the year 2100 as well as longer and more frequent extreme events such as heat waves (IPCC, 2014). The impact of a temperature increase and of extreme events on the dynamics of stable soil organic carbon (SOC) and its decomposers remains a major source of uncertainty in predicting future changes in atmospheric CO2 levels.

Long-term bare fallow experiments in which plants and organic amendments were excluded for at least 25 years represent a unique research platform to examine this issue as with increasing duration of the treatment, the proportion of stable SOC increases. This study employs soils from four experiments situated at Askov (Denmark), Ultuna (Sweden) and Grignon and Versailles (France). We used archived soils sampled at the start of the experiments and after 25, 49, 53 and 79 years of bare fallow, respectively, when the soils had become enriched in stable SOC. The samples were incubated at constant soil moisture and at four different temperatures (4, 12, 20 and 35 °C). The evolution of total CO2 and of 13CO2 from the incubated soils was monitored for more than one year. At the end of the incubation, SOC decomposers were determined thanks to next generation sequencing techniques.

The results indicated a higher temperature sensitivity of SOC in soils enriched in stable carbon. However, we observed no relationship between the duration of the bare-fallow treatment and the temperature sensitivity of SOC. Interestingly, the quality (as determined by 13CO2) of the mineralized SOC depended on the incubation temperature. Our results provided strong evidence for a general relationship between temperature sensitivity and SOC stability upon which significant improvements in predictive models could be based.

This study also showed that soil microbial richness and equitability were both enhanced in organic resource depleted soils. We observed a shift from copiotrophic to oligotrophic microorganisms, indicating a radical change of ecological niches with carbon depletion and temperature increase. Surprisingly, the more diverse soil microbial communities linked to stable soil organic carbon were more sensitive to a temperature increase than less diverse communities linked to more labile organic carbon compounds. It provided evidence that biodiversity is not the only factor of functional stability and that functional stability might be a combination of biotic and abiotic soil characteristics.

Seasonal and inter-annual variability in wetland methane emissions simulated by CLM4Me□ and CAM-Chem and comparisons to observations of concentrations

L. Meng (1) ; R. Paudel, (2) ; PGM. Hess, (3) ; NM. Mahowald, (3)
(1) Western Michigan University, Kalamazoo, MI, United States of America; (2) Cornell University, Earth and atmospheric sciences, Ithaca, NY, United States of America; (3) Cornell University, Ithaca, NY, United States of America

Understanding the temporal and spatial variation of

wetland methane emissions is essential to the estimation of the global methane budget. We examine the seasonal and inter-annual variability in wetland methane emissions simulated in the Community Land Model (CLM4Me¢). Methane emissions from both the Carbon-Nitrogen (CN, i.e. CLM4.0) and the Biogeochemistry (BGC, i.e. CLM4.5) versions of the CLM are evaluated. We further conduct simulations of the transport and removal of methane using the Community Atmosphere Model (CAM-chem) model using CLM4Me¢ methane emissions from both CN and BGC along with other methane sources and compare model simulated atmospheric methane concentration with observations. In addition, we simulate the atmospheric concentrations based on the TransCom wetland and rice paddy emissions from a different terrestrial ecosystem model VISIT. Our analysis suggests CN wetland methane emissions are higher in tropics and lower in high latitudes than BGC. In CN, methane emissions decrease from 1993 to 2004 while this trend does not appear in the BGC version. In the CN versions, methane emission variations follow satellite-derived inundation wetlands closely. However, they are dissimilar in BGC due to its different carbon cycle. CAM-chem model simulations with CLM4Me¢ methane emissions suggest that both prescribed anthropogenic and predicted wetlands methane emissions contribute substantially to seasonal and inter-annual variability in atmospheric methane concentration. It also suggests that different spatial patterns of wetland emissions can have significant impacts on N-S atmospheric CH4 concentration gradients and growth rates. This study suggests that large uncertainties still exist in terms of spatial patterns and magnitude of global wetland methane budgets, and that substantial uncertainty comes from the carbon model underlying the methane flux modules.

Effects of multiple global environmental changes and fire on soil greenhouse gas emissions: feedbacks to climate change

A. Niboyet (1) ; B. Hungate (2) ; J. Brown (2) ; P. Dijkstra (2) ; J. Blankinship (3) ; KJ. Van Groenigen (2) ; X. Le Roux (4) ; P. Leadley (5) ; L. Barthes (5) ; R. Barnard (6) ; C. Field (7)

(1) AgroParisTech, Institute of ecology and environmental sciences - paris, Thiverval-Grignon, France; (2) Northern Arizona University, Biological sciences, Flagstaff, United States of America; (3) Earth Research Institute, Eemb, Santa Barbara, United States of America; (4) INRA, Laboratoire d'ecologie microbienne, Villeurbanne, France; (5) Université Paris-Sud, Laboratoire ecologie, systématique et evolution, Orsay, France; (6) INRA, Umr agroécologie, Dijon, France; (7) Carnegie Institution for Science / IPCC WGII, Stanford, CA, United States of America

Global environmental changes are expected to alter ecosystem carbon and nitrogen cycling, but the combined effects of multiple simultaneous environmental changes are poorly understood. Furthermore, little is known about the combined effects of chronic global environmental changes and ecological disturbances on ecosystem functioning. In particular, these combined effects on soil emissions of greenhouse gases might be critical as they could accelerate climate change.

We assessed the responses of soil nitrous oxide (N2O) production, an important greenhouse gas, to elevated CO2, warming, increased precipitation, and enhanced nitrogen deposition, as well as their interactions, in an annual grassland as part of the Jasper Ridge Global Change Experiment (CA, USA). In addition, we took advantage of an accidental, low-severity wildfire that burned part of this long-term global change experiment to investigate the interactive effects of a fire disturbance and chronic global environmental changes on soil N2O emissions. We examined the responses of soil N2O emissions, as well as the responses of the two main microbial processes contributing to soil N2O production - nitrification and denitrification - and of their main drivers.

We found that elevated precipitation increased soil N2O emissions, especially in combination with added nitrogen and warming. Furthermore, we show that the fire disturbance greatly increased soil N2O emissions over a three-year period, and that elevated CO2 and enhanced nitrogen supply amplified fire effects on soil N2O emissions: emissions increased by a factor of two with fire alone and by a factor of six under the combined influence of fire, elevated CO2 and nitrogen. We then provide evidence that these responses were caused by increased microbial denitrification, resulting from increased soil moisture and soil carbon and nitrogen availability.

Our results indicate that the combined effects of multiple simultaneous environmental changes and fire can exceed their effects in isolation, thereby creating unexpected feedbacks to soil greenhouse gas emissions. In our data and across the literature, single-factor responses tended to overestimate interactive responses, except when global change was combined with disturbance by fire, in which case interactive effects were large. Thus, for chronic global environmental changes, higher order interactions dampened responses of N2O emissions to multiple global environmental changes, but interactions were strongly positive when global change was combined with disturbance.

These findings highlight the need to further explore the impacts of ecological disturbances on ecosystem functioning in the context of global change to see how much these combined impacts might play critical roles in shaping ecosystem processes that in turn feed back to climate change.

As the global climate warms the Arctic is experiencing rapid increases in temperature causing permafrost (perennially frozen ground) to thaw and thereby exposing large quantities of previously frozen organic matter to microbial decomposition. High latitude ecosystems store almost twice as much carbon in soils and permafrost than what is currently contained in the atmosphere. Warmer temperatures in the Arctic will not only increase carbon emissions from previously frozen organic matter in the permafrost zone but also indirectly affect the carbon cycle through changes in regional and local hydrology. As permafrost degrades due to warming, soil drying will occur in upland ecosystems as a result of increased natural drainage as the water table moves further down. On the contrary, low lying areas can turn into anoxic environments as the topography and the underlying permafrost layer prevent runoff. These changes in soil surface hydrology and oxygen availability in permafrost ecosystems have broad impacts on the amount and form (carbon dioxide or methane) of carbon release from newly thawed permafrost and have the potential to further increase the permafrost carbon feedback. In order to successfully include the permafrost carbon feedback into models relevant to IPCC reports it is important to provide data sets that serve as constraints for complex models assessing the carbon-climate feedback from high latitude soils.

We have compiled a database of 26 incubation studies with soils from active layer and permafrost from across the entire permafrost zone to quantify a) the effect size of

increasing temperatures and b) the changes from aerobic to anaerobic environmental soil conditions on carbon release from permafrost. Results from two different meta-analyses show that a 10°C increase in temperature increased carbon release by a factor of two in the three most important permafrost ecosystems (boreal forest, peatland and tundra). Under aerobic incubation conditions, soils released on average 3.4 times more carbon than under anaerobic conditions which was consistent for all three ecosystems as well as for soils with different organic carbon concentrations. While the lack of oxygen in anaerobic incubations reduced the amount of total carbon release it increased the amount of the more potent greenhouse gas methane. Even if accounting for the higher global warming potential of methane one unit of soil released more than twice as much carbon under aerobic incubation conditions than under anaerobic conditions.

This pan-arctic synthesis shows that carbon release from newly thawed organic matter in high latitude ecosystems is highly affected by increasing temperatures but that changes in soil moisture and oxygen availability have an even larger impact on carbon release. The permafrost carbon feedback is stronger in an aerobic environment as the faster decomposition offsets the higher heat trapping capacity of methane occurring under anaerobic conditions over a 100-year timescale.

P-1116-15

Topography and geochemistry influence methane response to permafrost thaw

L. Smith (1) ; M. Conrad, (2) ; MS. Torn (3) ; J. Curtis, (2) ; O. Chafe, (2) ; B. Markus (2)

(1) University of California Berkeley, Energy and Resources Group, Berkeley, CA, United States of America; (2) Lawrence Berkeley National Laboratory, Berkeley, CA, United States of America; (3) Lawrence Berkeley National Laboratory, Earth Sciences Division, Berkeley, CA, United States of America

Arctic wetlands are currently net sources of atmospheric CH4. CH4 emissions in Arctic tundra vary widely in space and time, with proximate controls—substrate availability, competition for substrate among decomposition processes, CH4 oxidation, and CH4 transport—dependent on local climate, soil, hydrology, and biology. These complex controls and high spatial and temporal variability make it difficult to characterize current CH4 processes and predict their responses to climate change. We investigated these processes in Arctic polygon tundra, across a permafrost thaw gradient from low-centered (intact) polygons to flat- and high-centered (degraded) polygons. We asked: (1) how do CH4 production and consumption vary with permafrost thaw and microtopographic feature, and (2) how do subsurface CH4 processes relate to surface CH4 and CO2 fluxes? We made measurements in 3 microtopographic features (polygon centers, rims, and troughs) across the permafrost thaw gradient. Measurements included surface CH4 and CO2 fluxes, concentrations and stable isotope compositions of CH4 and DIC at 3 depths in the soil profile, and soil moisture and temperature. We found clear patterns in CH4 processes with permafrost degradation, as well as polygon feature and month. More degraded sites had lower CH4 emissions, a different primary methanogenic pathway, and greater CH4 oxidation than intact permafrost sites, to a greater degree than soil moisture or temperature could explain. Surface CH4 flux decreased from 190 nmol m-2 s-1 in intact polygons to 9 nmol m-2 s-1 in degraded polygons. Stable isotope signatures of CH4 and DIC showed that acetate cleavage dominated CH4 production in low-centered polygons, while CO2 reduction was the primary pathway in degraded polygons. We see evidence that distinct patterns of water flow and geochemistry between intact and degraded polygons contribute to these observations, through transport of redox-active species among high-centered polygon features. These findings suggest that future Arctic tundra CH4 emissions will depend not only on profile-scale changes in soil moisture and inundation, but also on the effect of warming on larger-scale geomorphic, geochemical, and hydrologic factors. Wetland drainage due to ice wedge degradation may reduce CH4 emissions across the landscape, even in inundated inter-polygon troughs.

P-1116-16

Feedbacks between climate change and the terrestrial biosphere

BD. Stocker (1) ; S. Williams, (2) ; IC. Prentice (1)

(1) Imperial College London, Department of Life Sciences, Ascot, United Kingdom; (2) Imperial College, Physics department, London, United Kingdom

Land ecosystems are absorbing ~25% of anthropogenic CO2 emissions but emit a range of other greenhouse-gases and indirectly regulate their concentrations in the atmosphere through the emission of chemically active compounds. Terrestrial greenhouse-gas emission rates and the energy exchange between the land surface and the atmosphere are sensitive to climate and atmospheric CO2 and thus represent a feedback to anthropogenic climate change. Recent research using coupled Earth System Models has demonstrated that land-based feedbacks may amplify climate change through positive feedbacks that have previously not been accounted for. Here, we present a comprehensive compilation of feedback strength estimates from individual land-mediated forcing agents (CO2, CH4, N2O, albedo, etc.) and their interactions based on observational data and Earth system modeling. Today, the dominant negative feedback arising from the CO2-stimulated land C sink compensates smaller positive feedbacks from non-CO2 forcing agents. Under a future business-as-usual scenario, these positive feedbacks exert an increasingly strong additional warming. Anthropogenic land use change and inputs of reactive nitrogen by atmospheric deposition and fertilizers act to further shift the balance of feedbacks towards more positive values. This may be mitigated by protection of forest ecosystems and a more efficient use of mineral fertilizers in agriculture.

Frozen organic carbon stored in northern permafrost soils may become vulnerable due to the rapid warming of the Arctic. The loss of carbon through the emissions of CO2 and CH4 may imply a critical warming potential, resulting in positive feedbacks to global climate change. However, positive and negative feedback dynamics associated with thawing permafrost and ecosystem biogeochemistry on a landscape scale is still unclear. Here, we combine two contrasting modeling techniques to model the high-Arctic ecosystems in Northeast Greenland. Firstly, the Coup (Coupled Heat and Mass Transfer Model for soil-plant-atmosphere system) model is validated with three years' measurements of active layer depth and soil carbon content. Secondly, to account for the transient impacts of climate change to potential vegetation dynamics, we employ the leaf area index, projective cover fraction and climatic forcing produced by a regional Earth system model (RCA-GUESS), which simulates climate as well as vegetation dynamics, as the driving data to the Coup model to project future active layer depth and greenhouse gas exchange. Comparing to the Coup model driven with static vegetation properties of the validation period, we are able to quantify the effects of vegetation dynamics on the magnitude and timing of active layer depth, and ecosystem greenhouse gas exchange in the high-Arctic subject to the scenarios in different representative concentration pathways (RCP2.6, 4.5 and 8.5) as simulated with the regional Earth system model.

Effects of nitrogen deposition on photosynthesis of an alpine meadow ecosystem in Eastern Qinghai-Tibetan Plateau

L. Zhang (1) ; S. Yan (1)
(1) Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Key Laboratory of Ecosystem Network Observation and Modeling, Beijing, China

Responses of leaf and canopy photosynthesis to global change play an important role in global carbon cycling. Due to human activities, especially the burning of fossil fuels, the extensive use of farmland ecosystem nitrogen and continuous development of animal husbandry, the nitrogen input level into ecosystem increases significantly. However, the effects of increasing atmospheric nitrogen deposition on leaf and canopy photosynthesis of grassland ecosystems in Qinghai-Tibetan Plateau are unclear. In this study, we measured leaf nitrogen content, photosynthesis, and leaf area index in an alpine meadow ecosystem in Eastern Qinghai-Tibetan Plateau, based on a multi-form N addition experiment. Maximum rates of carboxylation (Vcmax) and electron transport (Jmax) were calculated from A-Ci curves measured with an LI-6400 portable photosynthesis system. The results showed that leaf nitrogen content in Stipa aliena growing with a high-level nitrogen input (40 kg N ha−1 yr−1) increased by 6.2% and 9.7 % in 2012 and 2013. Vcmax and Jmax at 25oC increased by 46.5% and 39.8% in 2012, 37.9% and 25.4% in 2013, respectively. Meanwhile, leaf area index of the alpine meadow ecosystem also had an increase of 45.0% in 2012 and 21.9% in 2013. Positive effects of nitrogen addition on leaf nitrogen content, leaf photosynthetic capacity, and canopy leaf area undoubtedly resulted in an increase in gross primary production of the alpine meadow ecosystem.

P-1116-19

Carbon Cycle Response to Artificial Atmospheric Carbon Dioxide Removal

K. Zickfeld (1)
(1) Simon Fraser University, Vancouver, BC, Canada

Artificial removal of carbon dioxide from the atmosphere (CDR) is increasingly discussed as a complementary approach to CO2 emission reductions, particularly in the context of stringent climate targets. The efficiency of CDR is determined by the interplay between the natural carbon sinks on land and in the ocean and atmospheric CO2 levels. Only a few studies have explored the response of the global carbon cycle to CDR. Here, we use an Earth System model of intermediate complexity – the University of Victoria Earth System Climate Model (UVic ESCM) – to explore the response of the carbon cycle to atmospheric CO2 removal under a range of idealized scenarios, which differ in the total amount and rate of negative emissions, and the initial state of the system. We perform two sets of model simulations: one where a drop in atmospheric CO2 to a target level and maintenance at that level is prescribed (P), and one where an equivalent amount of negative CO2 emissions is prescribed over a given period of time, with atmospheric CO2 left to evolve freely thereafter (E).

Results indicate that for both simulation sets, CO2 outgasses from the terrestrial biosphere and the ocean during the atmospheric CO2 removal phase. The amount of outgassing is sensitive to the experimental setup (P versus E simulations) and the rate and amount of CO2 removal. For P simulations we find that the lower the target atmospheric CO2 level, the larger the outgassing from natural sinks, and the larger the negative emissions required to maintain the target level. The efficiency of CDR – defined for P simulations as the cumulative negative emissions required to achieve a unit decrease in atmospheric CO2 – is independent of the rate of removal in the long-term, but increases significantly for scenarios with larger amounts of CDR.

1117 - Understanding decadal variations in the climate system and implications for the future

Global and regional climate variability: a pause for thought

E. Hawkins (1)
(1) University of Reading, Dept. of meteorology, Reading, United Kingdom

Our experience of how climate changes depends on the interaction between externally driven changes, such as those due to greenhouse gases, aerosols and volcanic eruptions, and internal climate variations, both globally and locally. The recent slowdown in global temperature rise has dramatically highlighted these interactions and challenged the climate community to understand, explain and communicate the complex issues involved.

This talk will focus on some of the history of our understanding of climate variability, the links between changes in global temperature and regional climate, and the limits on the precision with which we can make climate projections. The concept of 'climate emergence' will also be discussed as a useful framework to help understand the role of climate variability and to help communicate the many plausible possibilities for how regional climate may change over the coming decades.

K-1117-02

Past and future European climate trends: uncertainty due to internal variability

L. Terray (1) ; C. Deser (2)
(1) CERFACS/CNRS, Sciences de l'Univers au CERFACS, URA1875, Toulouse, France; (2) National Center for Atmospheric Research, Climate analysis section, Boulder, United States of America

This talk will highlight the relative importance of internally generated versus externally forced climate trends over the past and next fifty years at local and regional scales over Europe. The assessment is based on a large ensemble of climate simulations performed with the CESM1 NCAR model that cover the 1920-2100 period. The ensemble contains a large number of integrations (30), each of which is subject to identical natural and anthropogenic radiative forcing but initialized from a slightly different atmospheric state. The large ensemble shows that natural climate variability superimposed upon forced climate change results in a large range of possible trends for surface air temperature and precipitation over the past and next fifty years. A variant of the flow-analogue approach is used to partition the temperature and precipitation changes due to internal variability into dynamical and thermodynamical components. Internal thermodynamical changes are shown to be more important in summer while dynamical ones are the dominant contributors in winter. Removing the unpredictable dynamical contribution results in a significant increase of the signal to noise ratio, particularly in winter. The thermodynamical changes are shown to be linked with the ocean, sea-ice and land surface conditions. While large ensembles are needed to fully characterize the forced response at global and regional scales, they also provide a robust estimation of the uncertainties due to internal variability that is needed to better characterize model structural differences. This is important for a wide range of stakeholders as the partial masking of human-induced climate change by internal multidecadal variability is an important consideration for policy and planning efforts.

The Pacific decadal oscillation, revisited

M. Newman (1) ; M. Alexander (2) ; T. Ault, (3) ; K. Cobb (4) ; C. Deser (5) ; E. Dilorenzo (4) ; N. Mantua (6) ; A. Miller (7) ; S. Minobe (8) ; H. Nakamura (9) ; N. Schneider (10) ; D. Vimont (11)

(1) University of Colorado/CIRES and NOAA/ESRL/PSD, Boulder, CO, United States of America; (2) NOAA/ESRL/PSD, Boulder, United States of America; (3) Cornell University, Ithaca, United States of America; (4) Georgia Tech, Atlanta, United States of America; (5) National Center for Atmospheric Research, Climate analysis section, Boulder, United States of America; (6) NOAA/NMFS Southwest Fisheries Science Center, Santa Cruz, United States of America; (7) Scripps Institute of Oceanography, La Jolla, United States of America; (8) Hokkaido University, Sapporo, Japan; (9) University of Tokyo, Tokyo, Japan; (10) University of Hawaii, International Pacific Research Center, Honolulu, United States of America; (11) University of Wisconsin, Madison, United States of America

Since its identification in the late 1990's as the dominant pattern of North Pacific sea surface temperature (SST) variability, the Pacific decadal oscillation (PDO) has been connected both to other parts of the climate system and to impacts on natural resources and marine and terrestrial ecosystems. Variability associated with the PDO has often been confused iwth externally forced climate change including anthropogenic effects. Subsequent research, however, has found that the PDO is not a single physical mode of climate variability but instead largely represents the combination of three groups of processes: (1) changes in ocean surface heat fluxes and Ekman (wind-driven) transport related to the Aleutian low, due to both local, rapidly decorrelating, unpredictable weather "noise" and to remote forcing from interannual to decadal tropical variability (largely El Nino) via the "atmospheric bridge"; (2) ocean memory, or processes determining oceanic thermal inertia including "re-emergence" and oceanic Rossby waves, that act to integrate this forcing and thus generate added PDO variability on decadal time scales; and (3) decadal changes in the Kuroshio-Oyashio current system forced by the multi-year history of basin-wide Ekman pumping, manifested as SST anomalies along the subarctic front at about 40°N in the western Pacific ocean. Thus, the PDO represents the effects of different processes operating on different timescales, with few of its apparent impacts due to extratropical SST anomalies. This talk presents a synthesis of this current view of the PDO, and discusses corresponding implications for climate diagnosis, including of PDO climate impacts and predictability (both oceanographic and atmospheric); potential decadal «regime»-like behavior; simulations of the PDO in climate models; the interpretation of paleoclimate multicentennial reconstructions of the PDO; and its impacts on marine ecosystems. We conclude with some suggested "best practices" for future PDO diagnosis and forecasts including investigating the potential role of the PDO in the global temperature hiatus.

O-1117-02

Importance of Atlantic decadal variability for near-term assessment and predictability of western Amazon dry-season dry and wet events

K. Fernandes (1) ; W. Baethgen, (2) ; L. Verchot (3) ; A. Giannini (1) ; M. Pinedo-Vasquez, (3)

(1) Columbia University, International Research Institute for Climate and Society (IRI), Palisades, NY, United States of America; (2) Columbia University, International institute for climate and society (iri), Palisades, NY, United States of America; (3) CIFOR, Bogor, Indonesia

The drought of 2005 was a "1 in 100 years" event in western Amazon resulting in fire damage to over 300,000 hectares of rainforest in the Brazilian state of Acre and 22,000 hectares in the province of Coronel Portillo in Peru. In 2010 another severe drought resulted in the isolation of entire communities as the Negro River, a major northwestern Amazon tributary, registered its lowest water lever in over 100 years. The Amazon ecosystem is sensitive to repeated occurrence of droughts, which interferes with the forest's natural ability to recover from stress and undermine climate change mitigation efforts to reduce CO2 emissions from deforestation and forest degradation. Whether this apparent increase in drought severity and frequency is related to natural low-frequency modes of climate variability, to anthropogenic influence on climate, or to a combination of both is explored here.

A modest negative trend in dry-season precipitation is observed in western Amazon over the period 1935-2012, which along with a multi-decadal pattern of reduced moisture transport from the tropical Atlantic worked to enhance the severity of the recent droughts. Most of the western Amazon dry-season precipitation decadal variability is attributable to decadal fluctuations of the north-south gradient (NSG) in Atlantic sea surface temperature (SST). The observed western Amazon and NSG decadal co-variability is well reproduced in Global Climate Models (GCMs) pre-industrial control (PIC) and historical (HIST) experiments that were part of the Intergovernmental Panel on Climate Change fifth assessment report (IPCC-AR5). This suggests that unforced or natural climate variability, characteristic of the PIC simulations, determines the nature of this coupling, as the results from HIST simulations (forced with greenhouse gases (GHG) and natural and anthropogenic aerosols) are comparable in magnitude and spatial distribution. Decadal fluctuation in the NSG also determines shifts in the probability of repeated dry and wet events in western Amazon, as there is a 66% chance of 3 or more years of dry events per decade when NSG>0 compared to 19% when NSG<0. The HIST and PIC model simulations also reproduce the observed shifts in probability distribution of dry and wet events as a function of the NSG decadal phase, suggesting there is great potential for decadal predictability based on GCMs. Persistence of the current NSG positive phase may lead to continuing above normal frequencies of western Amazon dry-season droughts.

Stochastic low-frequency variability in the eddying ocean: mid-latitude imprints, possible atmospheric impacts

T. Penduff (1) ; L. Terray (2) ; S. Leroux (1) ; G. Sérazin (1) ; B. Barnier (1) ; JM. Molines (1) ; L. Bessières (2)

(1) LGGE, MEOM, Grenoble Cedex 9, France; (2) CERFACS/CNRS, Sciences de l'Univers au CERFACS, URA1875, Toulouse, France

Laminar Ocean General Circulation Models (2° to 1° resolution) used in recent climate projections are being progressively replaced by turbulent ocean models (about 1/4° resolution) in the perspective of the next CMIP exercise. Atmospherically-forced ocean experiments show that this resolution increase improves the physical consistency of simulations, but also allows the ocean to spontaneously generate a substantial variability up to interannual-to-multidecadal timescales. Consistently with idealized studies, this low-frequency intrinsic variability (LFIV) is negligeable when mesoscale oceanic eddies are not explicitly resolved, and spontaneously emerges in the turbulent regime.

This non-linearly driven oceanic LFIV has a stochastic character, and a marked signature on the upper ocean temperatures in mid-latitude regions where air-sea fluxes are maximum in Nature. Seasonally-driven global eddying ocean simulations exhibit the strong, large-scale imprints of this stochastic LFIV on several climate-relevant oceanic indices: sea-surface height (SSH) and temperature (SST) in western boundary current systems and the Antarctic Circumpolar Current, Meridional Overturning Circulation (AMOC) throughout the Atlantic Ocean, etc.

How these low-frequency intrinsic variability modes are impacted, and may or not be paced, by the interannually-varying atmosphere is an important question about climate uncertainty. The ongoing OCCIPUT project aims at investigating these questions probabilistically through a 50-member ensemble of 1/4° global ocean/sea-ice 57-year hindcasts, driven by the same 1958-present atmospheric forcing. Present results demonstrate that initial state perturbations spontaneously grow, cascade toward long space and time scales and non-linearly saturate. The resulting ensemble spread describes the atmospherically-paced stochastic LFIV (uncertainty), with marked imprints on oceanic variables at large space and time scales both at the surface (SST, SSH) and below (AMOC, mode/intermediate/deep water mass properties and depths, etc).

This ensemble experiment will provide the first probabilistic description of the global ocean state and evolution over the last decades, and a measure of the actual constraint exerted by the atmosphere on low-frequency ocean variability. The imprint of this stochastic LFIV on the upper-ocean thermal fields and AMOC will then provide insights into how this eddy-driven low-frequency oceanic "noise" might ultimately impact the atmosphere and climate predictability in future coupled climate projections.

O-1117-04

Contribution of sulfate anthropogenic aerosols to the Euro-Mediterranean climate trends since 1980 using a regional coupled modelling approach

P. Nabat (1) ; S. Somot (1) ; M. Mallet (2) ; A. Sanchez-Lorenzo (3) ; M. Wild (4)

(1) Météo-France / CNRM-GAME, Toulouse, France; (2) Laboratoire d'Aerologie, Toulouse, France; (3) University of Girona, Department of physics, Girona, Spain; (4) ETH, Zurich, Institute for atmospheric and climate science, Zurich, Switzerland

Since the 1980s, sulfur emissions have considerably been reduced in industrialized countries, notably in Europe, thus leading to a decrease of sulfate aerosol concentration over the Euro-Mediterranean region. Meanwhile, an increase of incoming solar radiation reaching the surface, known as the brightening effect, has been observed over the same period but global and regional climate models still have trouble in reproducing the all-sky surface solar radiation trends and their consequences on climate.

In order to investigate the consequences of this aerosol trend on regional climate and its role in the observed changes during the last three decades, the present study introduces an original approach, through the use of a fully coupled regional climate system model (CNRM-RCSM). The latter includes the different components of the regional climate system, namely the atmosphere (with ALADIN-Climate), the ocean (with NEMOMED8), the land surface (with ISBA) and the rivers (with TRIP). This approach enables us to take into account the high-frequency feedback of the sea surface temperature (SST) on the atmosphere, as well as the river-ocean-atmosphere feedback. Aerosols are included in ALADIN-Climate through monthly interannual climatologies, coming from a combination of satellite-derived and model-simulated products, and considered as the best possible relevant estimation of the atmospheric aerosol content for the five most relevant species (sea salt, desert dust, sulfates, black and organic carbon aerosols). Simulations using the lateral boundary forcing of the ERA-INTERIM reanalysis have been carried out over the period 1980-2012 with and without the trend in sulfate aerosols.The scattering of the incoming solar radiation by sulfate aerosols leads to important changes in the Euro-Mediterranean climate. Comparisons between both simulations and homogenized surface observations reveal that our model is able to reproduce the all-sky surface shortwave radiation trends only when the aerosol trend is included. This improvement is particularly visible in regions where aerosols have been strongly reduced (i.e., Central Europe, Po Valley). Aerosol changes explain 81 ± 16 per cent of the simulated brightening over the 1980-2012 period, while the direct effect has been found to be the main cause of the simulated brightening.

As a result of this brightening effect, when including the aerosol decrease, the surface temperature trend is higher and closer to homogenized surface observations, indicating that aerosols explain 23 ± 5 per cent of the observed warming between 1980 and 2012. The use of an atmosphere-ocean coupled model enables us to show that Mediterranean sea surface temperature changes are also better reproduced using the aerosol trend. Air-sea fluxes have consequently been modified by this evolution in the sulfate aerosol content, as well as river flow.

Overall, our results demonstrate the importance of changes in aerosol loads for the understanding of regional climate variability.

O-1117-05

Volcanic Forcing: new initiatives to establish its impacts on climates of the Southern Hemisphere

P. Harvey (1) ; S. Grab (1) ; F. Engelbrecht, (2)

(1) University of Witwatersrand, Geography, archaeology and environmental studies, Johannesburg, South Africa; (2) Centre for Scientific and Industrial Research, Natural resources and the environment, Pretoria, South Africa

In the northern hemisphere (NH), 1816 is well known as 'the year without a summer'. But what happened in the southern hemisphere (SH) in 1816, or for that matter following other major tropical or SH volcanic eruptions? Whilst recent work has taken on an increasingly global focus on volcanic forcing as a driving mechanism influencing climate, the emphasis has largely been on the NH where most of the world's landmass and people have been impacted by large scale volcanic eruptions. To this end, the SH continues to remain in the shadows; hence our initiative to investigate: a) past impacts of major volcanic eruptions on SH climate and environment/society, and b) to model the climatic impacts of such eruptions on specific SH landmasses such as southern Africa, South America, Australia and New Zealand.

Several numerically based studies and experiments have confirmed global mean temperature declines during years immediately following major volcanic eruptions, and in particular, this correlation seems to be driven by considerably cooler than normal summers which more than compensate for warm winter anomalies over the NH (e.g. Briffa et al., 1998; Fischer et al., 2007; Miller et al., 2012). Such work has additionally been supported with longer-term tree ring density and frost ring data for North America and Europe, demonstrating a clear environmental response and signature to such events (e.g. D'Arrigo and Jacoby, 1999; Breitenmoser et al., 2012). Recent modeling approaches have demonstrated the association between high northern latitude volcanic eruptions and the dispersion of aerosols, which remain mostly confined north of 30°N (Oman et al., 2006), and the connection to Arctic/sub-Arctic ice growth development and consequent sea-ice/ocean feedbacks causing hemispheric cooling (Miller et al., 2012). Thus, much is known and much has been learnt from volcanic forcing events on NH climates and environments, but to what extent are these patterns mirrored in the SH?

Given the scarcity of SH instrumental records covering the Tambora and other major historical period volcanic events, little is known about their impact in southerly latitudes. Here we triangulate evidence from a variety of proxies including historical documentary sources, and tree ring and speleothem data, to demonstrate that major tropical or SH volcanic eruptions are usually followed by extreme climate events across much of the SH. For instance, in southern Africa, such events may be followed by exceptionally hot summers and severe winters (with unusually early and/or late frosts and heavy snowfall events) (Grab and Nash, 2010). Whilst this temporally mirrors austral winters and summers in the NH (which are warmer and cooler respectively), the cooling anomalies are seasonally reversed between the hemispheres. In addition, data thus far suggest that one to two years following such a major eruption has [have] a very high probability of experiencing very wet [floods] or very dry [drought] conditions, but that the relationship is not linear owing to other climate drivers such as ENSO cycles. This work is ongoing and seeks further evidence to substantiate these new findings.

Finally, we present our current and future aims to model the climatic impacts (all major climate parameters) of major volcanic eruptions across various spatial and temporal scales in the SH using the Variable-Resolution Earth System Model (VRESM) and its atmospheric component the Conformal Cubic Atmospheric Model (CCAM) (see Engelbrecht et al., 2011). The models will be integrated to simulate volcanic events ranging in size from Toba to Pinatubo (or smaller), and will test the associations between geographic location (longitude/latitude) and event magnitude to establish spatial, temporal and type/magnitude of climatic impacts in the SH.

P-1117-01

Calibration and Validation of Summer Monsoon Rainfall over Bangladesh Using PRECIS Model

MN. Ahasan (1)
(1) SAARC Meteorological Research Centre (SMRC), Synoptic Division, Dhaka, Bangladesh

A regional climate model named PRECIS is employed in generating rainfall scenarios for SAARC region. PRECIS generated rainfall scenario is calibrated with ground-based observed rainfall during 1961-1990 in Bangladesh. Through calibration regression coefficients such as slope and constant are obtained at 27 observational sites over Bangladesh. The regression coefficients are utilized in validation of PRECIS generated rainfall during 2000 to 2006. Better performance of PRECIS through validation encourages employing it in rainfall forecasting for Bangladesh. In this work rainfall forecast for Bangladesh is performed experimentally for 2009. The monsoon rainfall is projected surplus 0.29 mm/day or 2.03% in 2009 and it will be surplus 0.44 mm/day or 14.02% in post-monsoon. It will deficit 0.11 mm/day (2.08%) and 0.01 mm/day (1.44%) in pre-monsoon and dry season respectively. Through the analysis of monsoon rainfall in Bangladesh this work discloses that PRECIS simulated rainfall is not directly useful in application purposes. Without calibration with ground-truth data model outputs are very risky in providing long-term rainfall prediction. However, after performing calibration excellent result is obtained in estimating rainfall in Bangladesh with R2 is 0.94 and correlation is 0.97. The encouraging results of this work can be taken as the starting point of SMRC to do more realistic research on long-term rainfall forecasting. The monsoon rainfall forecasting approach using down scaling of regional climate model outputs is very new in Bangladesh and also in SMRC. This persuades result suggests extending the work for other SAARC countries in a consecutive research project. Model run with other ensembles and with high horizontal resolution are also under consideration with the improvement of computational facilities in the Centre. After completion of the calibration and validation of PRECIS for SAARC region, the projected rainfall is supposed to be posted through SMRC website (www.saarc-smrc.org) which is now available only for Bangladesh. Completion of such type of job is really necessary for SAARC region where SMRC can play important role as a regional meteorological research centre.

P-1117-02

Crops response to climate variability and societal implications on rural dwellers of Nigeria

S. Ayanlade (1)
(1) Obafemi Awolowo University, Ile-Ife, Nigeria, Dept. of Geography,, Ile-Ife, Osun, France

This study examines impacts of climate variability on the yield of eight major crops in the guinea ecological of Nigeria, using both quantitative and qualitative methods. The Guinea ecological zone represents a rich agricultural area for Nigeria, sometime call "the food basket zone of the country". Several studies have been show that variability of rainfall has significant implication not only on the differences in the types of crops cultivated but also the rate of yield of such crops. Majority of these studies were based on assessment of two to four crops. Thus, the present study apply GIS techniques to examine the climate variability and its implications on the eight crops (Cassava, yam, Maize, sorghum, Groundnut, Cowpea, Cocoyam and Melon), majorly cultivated in the area. Rainfall, temperature and the crops yield dataset from 1982 to 2012 were used in the analysis. A year is divided into two growing seasons. These seasons are: early growing season (April-June) and late growing season (July- October) with regard to seasonal differences and the crops yields. The results show that during the past decades the yields of these crops were associated with climate variability, which vary differently in the year with high rainfall than the year with low rainfall. The study found out that the crops yield have been dominated by reduction in the number of rain days during the middle of the rainy season and there is evidence of a significant change in the crop yield as climate varied. The study concluded by recommending the need to encourage rain fed agriculture and agricultural research to improve crop yields.

P-1117-03

Diatoms evidence for past two centuries major changes in seasonal sea surface conditions prior the instrumental period in the southern Gulf of California

L. Barbara (1) ; S. Schmidt (2) ; J. Urrutia Fucugauchi (1) ; L. Perez Cruz (1)
(1) Universidad Nacional Autónoma de Mexico, Instituto de geofisica, Mexico D.f, Mexico; (2) CNRS, UMR 5805 EPOC, Université Bordeaux , Pessac, France

Studies on laminated marine sediments have enabled to exploit annual to subseasonal information of oceanic and climatic conditions of the past, and particularly in the Gulf of California where there are excellent laminated records, underlying anoxic basins. These studies, however, are based on resin-embedded thin sections and present only qualitative snapshots of the past environments. Any of them have compared high resolution records with instrumental data, in order to reconstruct the environmental conditions and document the variability on interannual to decadal timescales beyond the instrumental period.

Here, we describe environmental conditions in the eastern part of Carmen Basin in the southern Gulf of California, over the past two centuries using diatom census counts in the DIPALV-C33 marine sediment box core. Diatom census counts show progressive changes since AD 1850, marked by persistent warm stratified and nutrient limited water conditions on the Gulf eastern sector. In parallel, inferred environmental conditions provide evidence for reduced seasonal upwelling during the last century and limiting primary productivity, concurrent with increase of storm/hurricane frequency. We propose that these multi-decadal sea surface variations are mainly governed by synoptic and regional wind fields in relation to the position and intensity of the atmospheric low and high-pressure trough around the Gulf of California. However, both ENSO and PDO variability patterns in the last century cannot explain the regional trend observed in this study, probably due to the effect of local processes on the response of our biological proxies.

P-1117-04

Mechanisms relating the MJO to intraseasonal variability of the surface climate in the Americas

EH. Berbery (1) ; M. Natoli (2)
(1) University of Maryland, Earth System Science Interdisciplinary Center/CICS-MD, College Park, Maryland, United States of America; (2) University of Maryland, Earth system science interdisciplinary center, College Park, Maryland, United States of America

This study uses the NCEP's Climate Forecast System Reanalysis (CFSR) to revisit the dynamical mechanisms associated with the Madden-Julian Oscillation (MJO) that affect the surface climate over the Americas. During the boreal cold season, North America sees a notable eastward propagation in temperature anomalies through the MJO evolution. Despite the smaller land area, temperature effects in South America during the austral cold season appear clearer than in North America and more appropriately connected to MJO convection. This is especially true over subtropical portions of the continent. These structures are related to the MJO enhanced tropical convection that can induce anomalous upper-tropospheric cyclonic circulation on the leading edge of the MJO enhanced convection and anomalous anti-cyclonic circulations trailing the convection. During each hemisphere's winter season, and connected with these patterns, enhanced direct circulations favor changes in the subtropical and polar jet streams. Intra-seasonal changes in the divergent circulation in upper levels modulate the Rossby Wave Source centers around 30-45° latitude and the propagation of Rossby waves, as noted in the wave activity fluxes, into the extratropics inducing near-surface

temperature and precipitation anomalies.

During the corresponding summer seasons, the diagnostics show that precipitation patterns are more directly connected to the convection anomalies rather than the circulation anomalies. The Americas see enhanced precipitation in the monsoon regions when the large scale upper tropospheric divergence associated with the MJO convection passes over the western hemisphere. Similarly, suppressed precipitation in these regions is observed when the large scale upper tropospheric convergence passes over the continents.

P-1117-05

Climate Change Studies over Western-ghat Region using Remote Sensing & GIS Modelling

N. Bhat (1) ; KC. Gouda (2)
(1) Shri Madhwa Vadiraja Institute of Technology and Management, computer sc & engg, Udupi, Karnataka, France; (2) CSIR CMMACS, CEMP, BANGALORE KARNATAKA, India

Western ghat region is one of the major mountain system in the Indian sdunbcontinent, extending in the western part of Indian from Kerala in South till Maharastra in north and the total area is about 160,000 Sq. km. The western ghat is of important from different point of view starting from the flora and fauna to medicin al plant to the rich region of river systems and the orography is most important for its role in the Rainfall during Monsoon and other seasons. In the study the remote sensing data from different soiurces like MODIS, TRMM, IRS and the multi-source observations from reanalysis products like NCEP, ERA-40, JMA and the high resolution observations like IMD are being used to study the climate change and quantified in terms of the different climate parameters mainly temperature, rainfall, humidity etc. The IRS and Landsat data are being analtysed in the GIS Modelling frame work to see the signature in the Land Use and Land Cover Change detaection at high resolution over the mountain region. Finally the spatio-temporal analysis of the climate change are presented. Various algorithm and visualisation to understand the climate change over the mountain region are developed and presented in a very user friendly way which can be easily used by the users of different sectors for the better understanding of the climate change.

P-1117-06

Temperature impact on Non-Communicatble Diseases in Africa – a Blind Spot in Research

A. Bunker (1) ; E. Diboulo, (2) ; A. Sié, (3) ; R. Sauerborn (4)
(1) University of Heidelberg, Network Ageing Research and Institute of Public Health, Heidelberg, Germany; (2) Swiss Tropical and Public Health Institute, Epidemiology and Biostatistics, Basel, Switzerland; (3) Centre de Recherche en Santé de Nouna, Nouna, Burkina Faso; (4) Heidelberg University, Institute of public health, Heidelberg, Germany

The mean temperature in northwest rural Burkina Faso, in the Nouna Health and Demographic Surveillance System (HDSS) region, is projected to increase under different climate change scenarios by the end of the 21st Century[1]. The Nouna HDSS consists of approximately 100,000 people, and is one of several International Network for the Demographic Evaluation of Populations and Their Health (INDEPTH) sites that collect health and demographic data across populations in low-and-middle income countries. As life expectancy increases in Burkina Faso and people live for longer with chronic and degenerative diseases, non-communicable disease will play a greater role in contributing to the burden of disease. This study assesses the impact of 18 years of temperature exposure on non-communicable disease years of life lost, an indicator of premature mortality, in the Nouna HDSS population.

Preliminary analysis used all-cause mortality data from the Nouna HDSS, to conduct a survival analysis and calculate the outcome variable, years of life lost, for 12,769 deaths between 1993-2000. A time-series regression analysis using the generalized additive model, adjusted for time-trends and seasonality was used to study the impact of mean temperature on all-cause mortality. Results indicate that a 1°C increase in temperature was associated with a 1.024 relative risk increase (p value=0.029) in all-cause mortality per 1°C increase in mean temperature above 30°C (1 day lag). We will present an extended 18-year cause-specific time-series analysis on the impact of mean, maximum and minimum temperature on non-communicable disease years of life lost, including the lagged effects.

As life expectancy at the Nouna HDSS increases, the burden on non-communicable disease is likely to increase with higher temperatures. Targeted preventive measures are required to alleviate this burden.

Farmers' perceptions of climatic trend in Allada plateau in southern Benin

A. Cayossi Ulrich (1) ; A. Abel (2) ; G. Hervé, (3) ; EK. Agbossou (4) ; V. Pierre, (1) ; C. Baron (3)
(1) université d'Abomey-Calavi, COTONOU, Benin; (2) Universite d'Abomey-Calavi, Graduate research program on climate change and water resources, Abomey-Calavi, Benin; (3) CIRAD, Montpellier, France; (4) UNIVERSITY OF ABOMEY-CALAVI, Faculty of agronomic sciences, Abomey-Calavi, Benin

Although several studies show an increase in agricultural production in West Africa in connection with the improvement in rainfall, farmers perceive otherwise. This study highlights the differences between farmers' perceptions of changes in precipitation and their impacts on agricultural production and scientific observations in the Guinea region where two rainy seasons coexist. For this purpose, it compared precipitation data (from 1951 to 2010) and potential yields of corn (from 1970 to 2010), simulated by SARRA-H model, to farmers' perceptions of changes in precipitation collected from 201 farm managers spread over 67 villages in Southern Benin. The study clearly shows that farmers do not make any distinctions between the long rainy season and short rainy season in terms of changes in rainfall and agronomic impacts. On the contrary, climate analysis results, and agronomic simulations reveal that the long rainy season and short one are not affected in the same way by atmospheric forcing. Consequently, these two rainy seasons have opposite agronomic trends. Since 1970, the long rainy season has a rainfall deficit coupled with a poor temporal distribution of rainfall and a shortening in its duration which led to a sharp drop in potential crop yields. Conversely, since the late 1980s, the short rainy season rainfall recorded a surge which causes a sharp increase in agricultural yields. This pessimistic perceptions of farmers on the evolution of rainfall in both rainy seasons influences their choice of management of the farming calendar of the short rainy season, worsening food insecurity in the study area.

P-1117-08

On the characteristics of climate change in Scandinavia and its association with the Northern Atlantic Oscillation (NAO) and sea ice

Y. Chen (1) ; S. Stefan (1)
(1) Uni Research Climate, Bjerknes Centre for Climate Research, Climate Data Service, Bergen, Norway

We analyzed some characteristics of climate change over Scandinavia using CRU data (1901- 2012), and both temperature and precipitation exhibit well-documented positive trends. However, the spatial variability of the trends is large with some areas showing high significance (northern Norway and Sweden) and others none at all (central Finland). The scenarios simulated by NorESM and ECHAM6 models exhibit continued warming and increased rainfall in the 21st century over Scandinavia. Given the

well-known zero-lag relationships between the NAO and both temperature and precipitation, responses of sea ice to external forcing and its potential influence on the NAO are of interest. The summer sea ice, fall-early winter NAO relationship suggests that in a warming climate, and under continued decreasing sea ice conditions, the tendency will be towards more positive NAO conditions leading to a wetter, warmer Scandinavia and potentially drier conditions in central-southern Europe. Initial modeling experiments appear to support such speculation (e.g., Folland et al., 2009) but more research is needed.

P-1117-09

Dengue, Weather and Urbanization in Brazil

I. Dallmann (1)
(1) Université Paris Sud, Economics, Sceaux, France

Since two decades, the population affected by dengue disease is exponentially increasing and dengue is now affecting more than 100 million people in the world. It ranks behind malaria as the second most important vector-borne disease in the world and the first one in Latin America. Despite the important economic and social cost of the uncontrollable growth of the disease, little economic analysis has been devoted to it. In addition to weather, socio-economic factors such as urbanization and sanitary systems play an important role in the proliferationof dengue. In this paper, I measure the impact of weather and urbanization factors on dengue incidence in Brazilian states durin gthe 1992-2012 period, since Brazil is the most affected country in Latin America. I find a positive and statistically significant effect of different weather factors (temperature, vapour pressure, temperature anomalies) and urbanization factors (population density and urbanization rate). I find also statistically significant support for a negative impact of education and wealth on dengue proliferation.

Evaluation of Climate Change Effects on the Growing Season in Butana Region and North Kordofan, Sudan

F. El-Hag, (1)
(1) Agricultural Research Corporation, Dry lands research center, Khartoum, Sudan

This study applied remote sensing to evaluate the effects of climate changes on growing season in different agro-ecological zones, in North Kordofan and Butana region, Sudan, for the period 2001-2011. NDVI data were used for the NDVI time series and phenological analysis. Within the semidesert zone in Butana region, the trend for the starting date of the growing season was stable, while that for the end of the season indicated a shift to an earlier date, resulting in shorter growing season (av. 80 days). Minimum NDVI value was 0.13 in 2011 and maximum value was 0.16 in 2010, indicating an increasing trend. In North Kordofan, however, the average length of the growing season was 69 days and the minimum and maximum NDVI (production) value was 0.12 in 2011 and 0.32 in 2009, respectively, indicating a decreasing trend. Within the arid zone in Butana region, the trend for the end of the growing season indicated a shift towards a later date, resulting in more number of days (av. 81 days). Minimum and maximum NDVI (production) value was 0.27 in 2009 and 0.45 in 2003, respectively, indicating a decreasing trend. In North Kordofan, the shortest length of the season was 59 days in 2005 and the longest was 116 days in 2009, reflecting a considerable increase in the length of the growing season. The minimum and maximum NDVI value was 0.23 in 2011 and 0.39 in 2002, respectively, with an average of 0.31, indicating a decreasing trend. Within the semiarid zone in Butana region, the length of the growing season and the NDVI value showed a trend of increase, whereas in North Kordofan, they showed a decreasing trend.

P-1117-11

Climatic trend in Nepal Himalaya since early 17th century as reconstructed from the ring-width chronologies of multiple tree species

NP. Gaire (1) ; DR. Bhuju, (2) ; UK. Thapa, (3) ; M. Carrer, (4) ; SK. Shah, (5) ; M. Koirala, (2) ; S. Bhandari, (2) ; R. Timileina, (6)
(1) Nepal Academy of Science and Technology, Faculty of Science, Lalitpur, Nepal; (2) Central Department of Environmental Science, Tribhuvan university, Kathmandu, Nepal; (3) Department of Geography, Environment and Society, University of minnesota, Minneapolis, United States of America; (4) Department of Land and Agro-forest Environments, University of padova, Padova, Italy; (5) Birbal Sahni Institute of Paleobotany, Lucknow, India; (6) College of Applied Sciences, Kathmandu, Nepal

Climate change in Nepal is more pronounced compared to other countries or regions. Centrally located in the Himalayan range, its average annual increase in temperature is 0.06 °C since late 1970s while the precipitation pattern is much erratic. Even within the country, the warming trend is double in the high mountains than that in its foothills or lowland Tarai conjoint to Gangetc plain. The future projection of the trend is deemed necessary; however, available meteorological data is too short for this purpose. Taking advantage of Nepal's rich tree diversity distributed in diverse topography of varied aspect and high elevation range, we carried out dendro-climatological study in 15 different sites of Nepal Himalaya from east to west that included eight protected areas of the high mountains. The objective of the study was to reconstruct the past climate of Nepal Himalaya. For the purpose, over 1400 tree core samples collected from major tree species, viz. Abies spectabilis, Abies pindrow, Betula utilis, Juniperus recurva, Larix grifithiana, Picea smithiana, Tsuga dumosa were analyzed following standard dendrochronological techniques. A positive correlation was observed among the chronologies of different species within and between different sites indicating some common climatic factors limiting the growth of these trees, and this gave us the basis for climate reconstruction.

Response function analysis revealed that pre-monsoon temperature (March-May) had an indirect relationship with growth of most of the species while such positive relation with precipitation of pre-monsoon to monsoon (March-July) depended also on the site condition. In some treeline sites, winter climate had significant influence for the growth in subsequent growing period of the some of these species. The seasonal correlation analysis with climate data for 1899-2012 revealed a significant indirect relationship between the ring width and spring temperature ($r = -0.56$) and positive correlation with spring precipitation ($r > 0.50$). The temporal stability of correlation model was tested by dividing the annual time series data into two equal halves as early and late period and found significant with correlation of $r = -0.51$ and -0.62, respectively. The stability of the models led to the reconstruction of March-May average temperature for the past 373 years (AD 1640 to 2012).

We used a simple linear regression model for temperature reconstruction. The validation of the reconstruction model was assessed with validation statistics such as reduction of error (RE) and coefficient of efficiency (CE) using split sample procedure i.e., by dividing the calibration period into two equal sub-periods. The model was further validated through spatial correlation with gridded temperature data. This temperature reconstruction identified several periods of warming and cooling, however, it did not show the significant pattern of cooling during the Little Ice Age except few cold episodes. Similarly the reconstructed precipitation for 311 years (AD 1702-2013) showed several high events and low events of precipitation. High precipitation events were seen in AD 1721-1740, 1751-1765, 1819-1830, 1882-1888 and 1912-1922. On the other hand low precipitation event was in AD 1741-1720, 1741-1750, 1780-1788, 1800-1818 and 1922-1975.

The correlation of spring temperature with Sea Surface Temperature (SST) index of different region of the equatorial Pacific viz., NINO1.2, NINO3, NINO3.4 and NINO4 and extended multivariate ENSO Index (MEI) was carried out. It presented a significant negative correlations with monsoon and post monsoons seasons. These negative relationships suggest that warm (cool) spring season over the western Nepal Himalaya region are associated with cool (warm) SSTs in the following seasons. Furthermore spatial correlation of spring temperature with Sea Surface Temperature showed similar negative correlation in the equatorial belt of the Pacific Ocean. The relationship showed the climate of western Nepal has linkages with spatio-temporal climatic variability at a global scale.

P-1117-12

Temperature effects of the large volcanic eruption events during the past 100 years over China

Z. Hao (1) ; D. Sun (1) ; J. Zheng (1)
(1) institute of Geographic Sciences and Natural Resources Research Chinese Academy of Sciences, Beijing, China

Based on the meteorological temperature data and the records of volcano events, the temporal and spatial temperature characteristics after the different types of large volcanoes which were classified by the geographic latitudes were identified in China five climatic regions, and the effects of the large volcanic events on regional temperature were analyzed. The results showed that there were significant differences between the temperature variation during winter years and the summer years after different large volcanic eruptions, northeast region was warmer in winter year after the large volcanic eruptions at the middle and high latitudes, other regions mainly appeared temperature decrease, northeast and northwest regions which were sensitive to climatic change was cooler. In addition, there was an obvious secondary cooling process during the summer year and in some regions during the winter year, the change of cooling even more obvious than the first cooling process. At the same time, the impact of large volcanic eruptions was different in five climate regions, regional temperature variation related to latitude after large volcanic eruptions at equatorial and high latitudes, but this variation related to longitude after volcanic eruptions at low and middle latitudes.

P-1117-13

A Study of Multi-decadal Global Sea Surface Temperature Variability Based on CMIP5 and Reanalysis Data

S. Henson, (1) ; C. Beaulieu, (1) ; L. Zhang, (1)
(1) University of Southampton, Ocean and earth science, Southampton, United Kingdom

The analysis of long-term changes in the distribution (mean, variance and extremes) of climate variables is essential for a full understanding of climate change and its impacts. The majority of climate change studies have focused on changes in the mean climate, therefore underestimating how changes in climate variability may impact biological and food systems. Observed and projected long-term changes in climate variability still lacks investigation.

Noticing this, we explore the patterns of sea surface temperature variability by looking at the observed sea surface temperature data record from 1854 to 2014. We investigate the global yearly and monthly sea surface temperature variability changes. For example, annual mean sea surface temperature and intra-annual variability (measured by the standard deviation and range). We also investigate the global and regional decadal changes in sea surface temperature variability, for example, using normalized probability density functions for different periods of anomalies in the data set.

In addition to the analysis of observational data, we assess how sea surface temperature variability may change in the future using model projections. We analyse the model projections by targeting the RCP8.5 (business-as-usual emission scenario) and the RCP4.5 (mitigation scenario) from the Coupled Model Intercomparison Project Phase 5 (CMIP5). This allows us to verify whether mitigation has an impact on projected changes in climate variability.

Comprehending the changes in climate variability is important for our society. Revealing the potential patterns of sea surface temperature variability can help us better understand the climate variability.

P-1117-14

Correlation between Polar motion and climate variables during 1962-2013

M. Huang (1)
(1) Institute of Geographical Sciences and Nature Resources Research, Chinese Academy of Sciences, Beijing, China

Polar motion is a significant Earth orientation parameter, but our understanding of its relation to climate forcing remains highly uncertain. In this study, the relationships between the polar motion excitation and climate variatbles are examined. High correlations are found between the excitation and annual mean climate variables, such as air temperature, atmospheric pressure, zonal wind at various atmospheric pressure levels, especially at 1000 hPa level. High correlation coefficients between the excitation and climate variables are found for the regions of the Arctic, Antarctic and Indian Ocean, with the center values exceeding 0.72. Two abrupt changes in polar motion excitation time series are detected and the accompanied changes of climate variables are also studied. Since the polar motion can be accurately measured by satellite, the accurately determined polar motion can be used as an indicator for monitoring and understanding the global climate change.

P-1117-15

Climate change vulnerability of fishery-dependant coastal communities in Bangladesh

N. Islam (1) ; MM. Islam (1)
(1) Sylhet Agricultural University, Department of Coastal and Marine Fisheries, Sylhet, Bangladesh

Being situated in a deltaic geographic setting, Bangladesh is considered as one of the most climate-vulnerable countries on earth. The country frequently faces different climate change related events such cyclones, rising tidal floods, erosion and inundation, saline water intrusion which are further compounded by degraded natural resources base. In contrast to other climate vulnerable communities, very few research have conducted in Bangladesh on vulnerability of fishery-based livelihoods to climate change impacts. Based on a fieldwork with four fishing communities in Patuakhali region of south-west coastal Bangladesh, the present study assessed vulnerability of fishery-based livelihoods to climatic change and variability. Bottom - up research approach was adopted in the study and participants' information was collected through 70 individual interviews and 5 focus group discussions. The result revealed multi-faceted vulnerabilities across different scales that impinge on the livelihoods of already resources-poor fishers' community in coastal Bangladesh. In line with global evidences, the level of vulnerabilities differs among the communities and across households within a community. Being dependent on climate sensitive fisheries resources, fishers' vulnerability further depend on their level of exposure, and adaptive capacity. For instance, fishers' level of exposure varied depending on areas of their fishing. Fishers with limited asset base usually do fishing in rivers and estuaries thus less exposed to extreme events, however when disaster stuck in their living places they are more vulnerable due to limited adaptive capacity. The case is reverse in case of better off fishers. They go for sea fishing thus more exposed to extreme events; however has better adaptive capacity due to strong financial capabilities. In both cases, fishers reported an increase of climate change-induced extreme events such as storm surge, strong wind, higher wave and stronger current during fishing operation that often cause loss in physical capitals and subsequent financial hardship. Loss of fishers' lives is also common as a deadly consequence during fishing in sea. A number of internal and external factors regulate adaptive capacity of fishing communities in the study areas. Adaptive capacity of fishers often undermine by different internal factors such inappropriate fishing vessels, lack of modern fishing appliances, inadequate and poor infrastructure of cyclone shelter, complexities and non-availability of scheduled credit during crises period, exploiting relationship between fishers and fish entrepreneur (money lender) lack of alternatives livelihood opportunity etc. To illustrate, with absence of state loan facility, fishers often have to take loan from moneylender at higher interest rate that create long term debt bondage with fish entrepreneur that weaken fishers' adaptive capacity. A number of external factors such as lack of security during deep sea fishing, also make fishers' lives more vulnerable by influencing their financial and social capabilities. For instance, increased risk of piracy in the bay causes financial loss of fishers in the form of ransom pay, bodily harm including death as well as loss of fishing gears and craft. In the above-mentioned, the present study submits

that to make climate resilient fishing communities in Bangladesh, it is important to address no-climate related external factors, along with climate change related factors for a more holistic adaptation policy.

P-1117-16

Assessment of Regional Climate Models over Côte d'Ivoire and Analysis of Future Projec-tions over West Africa

K. Kouadio (1) ; A. Konare (2) ; A. Diawara (3) ; K. Dje (4) ; VO. Ajayi (5) ; A. Diedhiou (6)

(1) LAPA-MF, Université Felix Hou-phouët-Boigny; WASCAL,Federal University of Technology Akure, Abidjan, Ivory Coast; (2) Universite Felix Houphouet Boigny, Cocody, Ufr ssmt, Abidjan, Ivory Coast; (3) University Felix Houphouet Boigny - Cocody Abidjan, Physic, Abidjan, Ivory Coast; (4) Société d'exploitation et développement Aéroportuaire et Météorologique, Abidjan, Ivory Coast; (5) WASCAL,GRP-WACS, Federal University of Technology Akure, Akure, Nigeria, Federal Republic of; (6) Institute of Research for Development (IRD), LTHE - University Grenoble Alpes, Grenoble Cedex 9, France

The ability of six Regional Climate Models (RCMs) used in AMMA-ENSEMBLES project is assessed over six meteorological stations in Côte d'Ivoire. The ensemble mean of the models is also used for the prediction of climate change over West Africa. The study focused on two periods: the period 1995-2005, the present-day simulations, is used to evaluate the skills of the models over the country and the years 2010-2013, for assessment of the future climate change scenario used. The results show that the skills of the models vary from one station to another and from one season to another. None of the models considered, presents an excellent performance over the entire country and in all the seasons. Generally, the ensemble mean of all the models presents better results when compared with the observation. These results suggest that the choice of any model for study over the country may depend on the focus of interest: intensity or variability of the rain and also on area of interest. The projection for 2020-2040, future climate change over West Africa shows that the Sahel exhibits a tendency to be drier while wetter Guinean coast is observed.

P-1117-17

Recent Observations and Experiences of Glaciers response to Intrinsic Climatic Variability: the Himalayan Inquest

P. Kumar (1) ; M. Sharma (2)

(1) Jawaharlal Nehru University, Centre for the Study of Regional Development, Delhi, India; (2) Jawaharlal Nehru University, Centre of the study of regional development, Delhi, India

The earth's climate has undergone a many phases of both long and short term fluctuations in the past; more so during the late Quaternary period. However, the recent climatic fluctuation has become a bone of contention among scientist for as to what causes these changes; to be precise, through the human actions. Therefore, the understanding the varying role of natural and human actions needs to be precisely quantified for a better understating and impact thereof. The Himalayan environ, with one of the sensitive parameters in the form of ice and glaciers, provides an indispensable laboratory for evaluating and understanding climate variability through these fluctuations in space over a longer temporal scale. Many climate scientists agree on the warming trend of climate past few decades. There are no concrete studies on regional climatic variability especially at the higher altitudes. As a layman we understand that climate changes regionally, based on latitude, altitude, aspect, and land-cover and so on. Lack of climatic data in the Himalayan region limits us to assess just this sensitive key in the form of glaciers on a longer time scale, given the understating that response time is very large. Now the question arises, how much do we know about the changing climate in the Himalayas? We present here the land surface temperature (LST, MODIS) data of the higher altitudes and behavior of glaciers for past one decade in the Himalaya and an assessment among the point source data and grid based data analyzed. Point source data of Bhojbhas has taken from the Automatic Weather Station (AWS), Snow and Avalanche Study Establishment (SASE). The grid source data are satellite based Land Surface Temperature (LST) temperature data obtained from Moderate Resolution Imaging Spectroradiometer (MODIS).A strong relationship emerges between satellite based and ground based data, a useful indicator if considered, especially in case of high altitude and a complex climate system like the Himalaya. The analysis of data are provides a very strong and positive correlation (0.887), which means 89 percent of SASE data, is explained by the MODIS data, which is very encouraging. The coefficient of determination is 0.7870; therefore, about 78.7% of the variation in the SASE data is explained by MODIS data. The root mean square error (standard deviation of regression) is 2.4569, which is very close also provides a better fit. All the stations values are represented on the simple line; and a simple linear trend lines have been drawn on temporal framework. The daily data trend of all the station does not show significant results in a simple regress line (2000-2013). But the yearly trend line data shows variability as; Harsil (0.241); Bhaironghati (0.157); Bhojbhas (0.158); Kalapani (0.208), Rudugaira (0.104), Raktavarn (0.0103) and Chaturangi (0.134) which is highly significant. There is a high variability in the elements but is not reflected as such in the study area during the last thirteen years. Trend lines show downward dip, meaning that there has been, without any doubt, temperature has dropped during 2000-2013. It is but true that temperature is a highly variable component in the high altitudes and may vary on the hourly and daily basis. But the thirteen years of data for five different stations portray a declining trend. Behavior of minimum and maximum temperature variability is not similar, each at varied nature in different stations. Given that we have not been able to assess precipitation characteristics for the same duration for these stations, it is highly speculative to assume that declining trend line may, on a longer temporal scale, would uphold the Himalayan glacier beyond the limit of imagination. Indeed the last 100 years glacier responses with differential rate due to their different geomorphological, geographical, climatic conditions and especially the response time. Same types of results are observed in Western Himalaya, particularly in case of Gangotri glacier, which is retreating with an alarming rate until. Although since 2001 rate of retreat has been slow down and particularly 2007 onwards there are no significant changes in glacier snout. Interestingly terrestrial records are showing that two of its tributary glaciers as Rakatavarn and Chaturangi glacier are showing positive change in their mass and terminus position since 1994. It propounds the complexity of glacier responses even within same geographical and climatic conditions, which means behavior of glacier is identical in nature, with self strength of mind.

P-1117-18

Simulations of Future Climatological Conditions in Central Asia CORDEX Region 8 by Using RegCM4.3.5

L. Kurnaz (1) ; MT. Turp (2) ; T. Ozturk, (3) ; M. Turkes (4)

(1) Bogazici, Center for climate change and policy studies and department of physics, Istanbul, Turkey; (2) Bogazici, Institute of environmental sciences, Istanbul, Turkey; (3) Isik University, Physics department, Istanbul, Turkey; (4) Bogazici, Center for climate change and policy studies, Istanbul, Turkey

In this work, projected future changes in mean surface air temperature and precipitation climatology, inter-annual and seasonal variability and climatic aridity/humidity conditions for the period 2010-2100 over the large Central Asia region with respect to present climate (from 1970 to 2000) were simulated based on the RCP4.5 and RCP8.5 emission scenarios. Regional Climate Model (RegCM4.3.5) of the International Centre for Theoretical Physics (ICTP) was used for projections of future and present climate conditions. HadGEM2 global climate model of the Met Office Hadley Centre and MPI-ESM-MR global climate model of the Max Planck Institute for Meteorology were downscaled to 50 km for the CORDEX Region 8. We investigated the seasonal time-scale performance of RegCM4.3.5 in reproducing observed climatology over the domain of Central Asia by using 2 different global climate model outputs. For the future climatology of the domain, the regional model predicts relatively high warming in the warm season and northern part of the domain at cold season with a decrease in precipitation almost all part of the domain. The results of our study show that surface temperatures in the region will increase from 1 ◦C up to

more than 7 ◦C on average according to the emission scenarios during the period 2010–2100 with respect to past period 1970–2000. Therefore, the projected warming and decrease in precipitation and also resultant or associated increased aridity and more frequent and severe drought events very likely adversely affect the ecological and socio-economic systems of this region, which is already characterised with mostly arid and semi-arid climate and ecosystems.

P-1117-19

Spring temperatures in the far-western Nepal Himalaya since AD 1640 reconstructed from Picea smithiana tree-ring widths

U. Kuwar Thapa (1) ; SK. Shah, (2) ; DR. Bhuju, (3) ; NP. Gaire (4) ; S. St. George (1)

(1) University of Minnesota, Geography, Environment and Society, Minneapolis, Minnesota, United States of America; (2) Birbal Sahni Institute of Paleobotany, Lucknow, India; (3) Central Department of Environmental Science, Tribhuvan university, Kathmandu, Nepal; (4) Nepal Academy of Science and Technology, Faculty of Science, Lalitpur, Nepal

The Nepal Himalaya has heated rapidly over the last four decades (more than twice the mean global rate), with this warming being even more pronounced in higher elevations. Unfortunately, because climate records in most of the country does not go extend prior to AD 1980, these short records make it more difficult to gauge the rate and (potential causes) of recent changes or enact long-term plans for resource management in the Nepal Himalaya under changing climate.

We conducted dendroclimatic study in order to extend the temperature record in western Nepal Himalaya beyond the instrumental period. For this, we developed a new, 422-year long tree-ring width chronology (spanning AD 1591–2012) from Picea smithiana (Wall.) Boiss in Khaptad National Park, which is located in the far-western Nepalese Himalaya. Seasonal correlation analysis revealed significant indirect relationship with spring temperature (March–May) and lead to the reconstruction of March–May average temperature for the past 373 years (AD 1640–2012). The reconstruction was found significant based on validation statistics commonly used in tree-ring based climate reconstruction. Furthermore, it was validated through spatial correlation with gridded temperature data. This temperature reconstruction identified several periods of warming and cooling. The reconstruction did not show the significant pattern of cooling during the Little Ice Age but there were few cold episodes recorded. However, the reconstructed temperature revealed the recent warming for last three decades as recorded in the stations. Wavelet analysis revealed high frequency variability (2–7 years) of spring temperature in western Nepal Himalaya for last four centuries, which can be linked to global climate system, El-Nino Southern Oscillation (ENSO). Significant negative correlations were found between the spring temperature in western Nepal and temperatures of monsoon and post monsoon seasons over the equatorial Pacific Ocean. This showed western Nepal Himalaya has linkages with climatic variability in a global scale.

This multi-centennial reconstruction of temperature in western Nepal Himalaya would serve as a basis for Ministry of Environment, Science and Technology to develop climate change adaptation strategies, including the National Adaptation Program of Actions and Local Adaptation Plans of Action. Future climate modeling shall also possible with this long available estimated temperature record for west Nepal.

P-1117-20

Drought monitoring with root zone soil moisture derived from ASCAT satellite data over the East Asian region

JH. Lee (1) ; J. Im (1)

(1) UNIST, Urban and env engineering, Ulsan, Republic of Korea

Several studies showed that semi-arid regions of Asia are vulnerable to climate change induced drought (Alimullah Miyan , 2014). While drought has often occurred over the East Asia, we have little understanding of drought at a large scale in that region. Accordingly, there is a need to establish an appropriate drought monitoring and prediction system. There are different types of drought such as agricultural drought or hydrological drought (Rhee et al., 2010). The factors that influence drought are interconnected through land-atmosphere interactions. One of the major factors is soil moisture, which can be effectively used to monitor agricultural drought. The surface soil moisture information from ASCAT satellite data is employed to provide root zone soil moisture for drought monitoring. This approach suggests several merits, when compared to the MODIS Vegetation Index-based indicators or precipitation-based indices often applied to drought monitoring. First, it is difficult to characterize the dynamics of soil dryness with the vegetation indices such as leaf-area-index (LAI) or normalized difference vegetation index (NDVI), as some vegetation species well grow up in dry soils. Secondly, it is difficult to monitor the deep soil that is actually important for predicting the agricultural productivity solely with the precipitation indices, because it is still unknown whether precipitation will infiltrate into the soils, evapotranspirate, or run off.

For these reasons, root zone soil moisture is considered a key indicator for agricultural drought monitoring due to its direct relationship with agricultural productivity and its climatic implication over the land (Lee, 2014). In this study, we use an exponential filter to infer root zone soil moisture from the satellite-retrieved surface soil moisture dynamics. The spatial distribution of soil moisture profiles over this region is evaluated with other datasets such as SMOS and ECMWF data. The 1D soil moisture profile is validated with newly obtained in-situ observations (e.g. precipitation, soil moisture) from the Monsoon Asian Hydro-Atmosphere Scientific Research and Prediction Initiative (MAHASRI) research program under the frame of The Global Energy and Water Cycle Experiment (GEWEX). The role of soil moisture on the East Asian monsoon circulation is also assessed.

Global warming and cause-and-effect relations in solar cycles 20–23

B. Lilia (1)

(1) Institute of terrestrial magnetism, ionosphere and radiowave propagation of RAS, Solar terrestrial, Moscow, Troitsk, Russia

Since the early works by Bernard Vonnegut and Edward Ney that related cosmic radiation to the weather a lot of controversial results were discussed. Thereby we have studied solar activity and interplanetary space conditions, which can have an influence on galactic cosmic ray (CR) and on global temperature. In this connection the solar wind and interplanetary magnetic field parameters and cosmic ray variations have been compared with geomagnetic activity represented by the equatorial Dst index from the beginning 1965 to the end of 2012. The important drivers in interplanetary medium which have effect on cosmic rays as CMEs (coronal mass ejections) and CIRs (corotating interaction regions) undergo very strong changes during their propagation to the Earth. Because of this CMEs, coronal holes and the solar spot numbers (SSN) do not adequately reflect peculiarities concerned with the solar wind arrival to 1 AU. Therefore, the geomagnetic indices have some inestimable advantage as continuous series other the irregular solar wind measurements. We have compared the yearly average variations of Dst index and the solar wind parameters with cosmic ray data from Moscow, Climax, and Haleakala neutron monitors during the solar cycles 20–23. The descending phases of these

solar cycles (CSs) had the long-lasting solar wind high speed streams occurred frequently and were the primary contributors to the recurrent Dst variations. They also had effects on cosmic rays variations. We show that during the 11-year solar cycles 20-23, the IMF B, global temperature and Dst variations were correlated with the cosmic ray count rate. We demonstrate that the detrended annual means of global surface air temperature in 1965-2012 show the maxima during CRs and Dst index minima. It proves that CRs play essential role in climate change and main part of climate variations can be explained by mechanism of action CRs modulated by the solar activity on the state of lower atmosphere and meteorological parameters. Following this we have to seek for another ways of looking for global warming reason, first of all, as a man impact on climate.

P-1117-22

Solar wind effects on climate change

B. Lilia (1)
(1) Institute of terrestrial magnetism, ionosphere and radiowave propagation of RAS, Solar terrestrial, Moscow, Troitsk, Russia

Climate change in connection with evolution of Dst index and cosmic rays (CR) variations is analyzed. We considered Dst index evolution from the point of view of solar variability, cosmic rays and climate during SCs 20-23. It is shown that together with other solar and interplanetary parameters the long-term variations of the Dst-index can be used for studies of this kind of solar-terrestrial relationship. During the descending phases of these solar cycles the long-lasting solar wind high speed streams occurred frequently and were the primary contributors to the recurrent Dst variations and had effects on cosmic rays variations. We have studied conditions in interplanetary space, which can have an influence on galactic cosmic rays (CRs) and climate change. We show that long-term cosmic ray count rate variations in SCs 20-23 were modulated by solar activity and by the B of IMF which are correlated with Dst variations. On the long-term scale, the correlation CRs count rate in term of the B of IMF and Dst index is much higher than the correlation between solar spot numbers.

P-1117-23

Local climate assessments in data scarce mountain areas; for example Kullu district, Himachal Pradesh, India

A. Linsbauer (1) ; N. Salzmann (1) ; M. Rohrer (2)
(1) University of Fribourg, Department of Geosciences, Fribourg, Switzerland; (2) Meteodat GmbH, Zurich, Switzerland

High-mountain regions like the Himalayas and their adjacent downstream areas are often highly affected by climatic changes, climate variability and/or related extremes. As a result of cascading effects of rising air temperatures, melting glaciers, thawing permafrost - as well as anthropogenic water usage or changes in forest and agro-biodiversity - vulnerability of people's livelihood has broaden and increased. However, climate impacts assessments on physical and societal systems are often limited due to the scarcity of reliable long-term observations, particularly in remote high mountain regions, which additionally also hampers robustness of future projections. Since livelihoods in remote high-mountain regions are particularly vulnerable to climate related impacts, and have typically only low adaptive capacities, studies assessing climate variability pattern of the past and for the future are an important basis for sound impact assessments, and as such for preparing and planning adequate adaptation measures. Key for such studies and measures are climatic baselines.

Within the Indian Himalayas Climate Adaptation Programme (IHCAP) integrated vulnerability and hazard and risk assessments are on the way for the Kullu district in Himachal Pradesh, India, for the sake of supporting adaptation planning there. Related to these studies, the present work aims to provide an approach and according results for climatological baseline generation for regions without respective observations available or accessible. Here, we use observational gridded data sets (CRU, GPCP, TRMM, IMD, Berkeley) and Reanalyses (ERA-i, MERRA, NCEP/NCAR-R1, CR20) to provide spatially and temporally continuous data. For the grid boxes covering the area of interest, the time series for temperature and precipitation are analysed and possible trends and variations are assessed for the time window 1981-2010, as well as the entire time line of the respective gridded dataset. Preliminary analyses reveal that the 2m air temperatures have slightly increased over time, whereas the 500 hPa temperatures do not portray this trend clearly. Seasonal analysis for the same time window for the 500 hPa temperatures show a clear positive linear trend for winter (DJF), whereas there is no clear linear trend visible for spring (MAM), summer (JJA) and autumn (SON) temperatures. Precipitation amounts seem to have significantly decreased in MAM and JJA for the period 1981-2010.

As gridded datasets are prone to inhomogeneities, an 'ensemble' of observational and reanalysis datasets are analysed and possible uncertainties are discussed. In conclusion it is important to state that global observational datasets and reanalysis are not a surrogate for ground and upper air in-situ measurements and allow only a very coarse estimation of air temperature and precipitation trends. Nevertheless, it often remains the only option for local studies.

P-1117-24

Spatial pattern of recent rainfall trends in Serbia (1961-2009)

J. Lukovic (1) ; B. Bajat (2) ; D. Blagojevic (2) ; M. Kilibarda (2)
(1) University of Belgrade, Department of Geography, Belgrade, Serbia; (2) University of Belgrade, Deaprtment of civil engineering, Belgrade, Serbia

This study examines a spatial pattern of annual, seasonal and monthly rainfall trends in Serbia. The study used data from 63 weather stations between the period of 1961-2009. The rainfall series was examined by applying the nonparametric method of the Mann-Kendall test and Sen's method to determine the significance and magnitude of the trends. Significant trends have not been detected for the whole country at an annual scale. Seasonal trends at the confidence level of 97.5 %, however, indicate a slight decrease in winter (5 stations out of 63) and spring (7 stations out of 63) precipitation and an increase in autumn precipitation (10 stations out of 63). Results for monthly rainfall trends also generally showed a nonsignificant trend with the exception of a negative trend in May (6 stations out of 63) and positive trend for October (9 stations out of 63). Calculated global autocorrelation statistics (Moran's I) indicate a random spatial pattern of rainfall trends on annual, seasonal and monthly timescales with exceptions for March, June and November. Overall, results suggest that only weak, mostly nonsignificant trends are present in Serbia in the period 1961-2009. To obtain spatial pattern of rainfall trends web mapping techniques are used applying recently developed package plotGoogleMaps.

Evaluation of regional climate models in the context of AGRHYMET

M. Ly (1)
(1) AGRHYMET Regional Centre, Training and Research, Niamey, Niger, Republic of

The AGRHYMET regional Center is a specialized institution of the Permanent Interstates Committee Drought Control in the Sahel (CILSS) composed presently of thirteen member states. It has the objective to contribute to achieve food security for agroclimatological and hydrological applications with emphasis on rural and natural resource management. It contributes to achieve food security for increasing agricultural production in the CILSS member states by providing training and information to stakeholders and partners. For these missions some innovative projects have been initiated in the recent years to help countries to achieve the Millennium Development Goals (MDG) throughout their ability to analyse the climate change impacts. In this regard AGRHYMET has just initiated a climate modelling activities to examine the present and future climate for identifying the climate related risks in the main sectors and provide information for decision-makers. In the Sahel, food security is highly reliant on rainfed agriculture, and thus the intra-seasonal variability of rainfall including the onset dates, the cessation dates, the length of the rainy season remain an

important factors to investigate. The aim of this work is to provide improved knowledge and evidence on current and probable future climate conditions, for use by decision makers in the region. It will also enhance the capabilities of the above mentioned characteristics of the rainy from regional climate simulations. Some approaches are then used in the region through the regional seasonal outlook forum (PRESAO) to determine a suitable planting date aiming to minimize the water stress in the growing period and then optimizing the staple crop yields in the Sahelian and the guinean cost countries The exercise is focusing to analyse the divergence of regional climate models in the CORDEX experiment on intra-seasonal variability of daily rainfall as well as the likely occurrence of long dry and/or wet spells during the critical growth of the dominant crop varieties sown by West African farmers.. The project outputs will contribute to significantly lower uncertainties by developing better and more tailored climate change knowledge to inform the user communities on climate related risks, as well as enhance their resilience to food insecurity and other climate related disasters.

P-1117-26

Effects of Drastic climatic variability in Pakistan

U. Mehmood (1) ; U. Aslam (2)
(1) University of Management and Technology, Department of political science, Lahore, Pakistan; (2) university of the punjab, Lahore, Pakistan

Weather and climate have very important socio-economic impacts. Climate of Pakistan have become unpredictable. This study describes the effects of intense flooding during 2010 and severe drought since December 2013 in Pakistan. Because of rapidly growing population and industrialization in Pakistan, the waste material is getting into the atmosphere and contaminating it and producing greenhouse gases. In late July 2010, heavy monsoon rains in Pakistan increased the water level in Indus River which caused heavy flooding in southern Pakistan. During the wet spel from 27 to 30 July Risalpur, Islamabad, Peshawar, Lahore, and Rawalpindi received rainfal of 415 mm, 394 mm, 333 mm, 288 mm, and 219 mm respectively. More than one fifth of Pakistan land was under water and 20 milion people were affected and there was a large-scale destruction of property, livelihood, and infrastructure. On the contrary, currently most of the areas of southern Pakistan (i.e. Tharparkar district) are facing a severe drought since December 2013. More than 120 malnourished children have died and about 175,000 families have been affected and some of them have been forced to leave their homes and move to barrage areas. There is a need to explore the causes of climatic variability and sophisticated methods of weather forecasting so that damages can be minimized to a greater extent.

P-1117-27

Climate Variability and Waterborne Diseases: Case of Typhoid Fever and Enteric Viral Hepatitis in Meknes city, Morocco

O. Mouhaddach (1) ; A. El Yaacoubi (1) ; I. Boularab (1) ; M. Bend-Daoud (1) ; MP. Kestemont (2) ; S. El Jaafari (1)
(1) Moulay Ismail University, Faculty of science, Meknes, Morocco; (2) Catholic University of Louvain, Lsm, Louvain-la-Neuve, Belgium

Background: In spite of all efforts deployed by health officers to control the waterborne diseases, Meknes stills the most severely affected province in Morocco. Various factors may explain this trend, including climatological and environmental ones.

Therefore, this study was carried in Meknes province and aims to understand the impact of climatological factors on typhoid fever and enteric viral hepatitis temporal variability, and to highlight the relation between climatological and environmental factors in this case, over the period 2004-2013.

Methods: Due to non-normal distribution of our input data, Spearman correlation was used. In order to point out the relevant periods of the year where the infection by Salmonella typhi and hepatitis viruses A & E, was strongly correlated to climate conditions, namely air temperature and rainfall, a new statistical approach was used, Partial Least Squares.

Results: The results reveal a temporal periodicity of typhoid and enteric viral hepatitis recorded cases, and the presence of significant positive correlation between the studied factors and the cases.

Partial Least Squares regression showed two relevant periods where the number of typhoid and viral hepatitis recorded cases increased, in coincidence with rise of air temperature and decrease of rainfall. The first period started from the end of March to the beginning of June, while the second one extended from the beginning of August to the end of October.

In fact, need of water for irrigation is more required during these two periods which are characterized by water scarcity. The wastewater reuse in irrigation is a common practice during the hot season, what may explain this typhoid and enteric viral hepatitis temporal variability.

Conclusion: This study identified some of climatological and environmental determinants of waterborne diseases in Meknes Province which currently exhibits the highest incidence in Morocco. This knowledge can be used to design intervention measures to reduce and control the said diseases in this area.

Evaluation of model simulation of the Southeast Asia climate under the Southeast Asia Regional Climate Downscaling (SEACLID)/CORDEX Southeast Asia project

G. Narisma (1) ; F. Cruz (2) ; J. Dado (3) ; F. Tangang (4) ; L. Juneng (4) ; T. Phan Van (5) ; T. Ngo-Duc (5) ; L. Trinh-Tuan (5) ; T. Nguyen-Xuan (5) ; J. Santisirisomboon (6) ; P. Singhruck (7) ; D. Gunawan (8) ; E. Aldrian (8) ; JX. Chung (4) ; ST. Ngai (4) ; TW. Teh (4)
(1) Ateneo de Manila University, Physics Department, Quezon City, Philippines; (2) Manila Observatory, Quezon City, Philippines; (3) Tokyo Metropolitan University, Department of geography, Hachioji, Japan; (4) National University of Malaysia, School of environmental and natural resource sciences, Bangi, Selangor, Malaysia; (5) VNU Hanoi University of Science, Hanoi, Vietnam; (6) Ramkhamhaeng University, Bangkok, Thailand; (7) Chulalongkorn University, Bangkok, Thailand; (8) Agency for Meteorology, Climatology and Geophysics, Jakarta, Indonesia

In the face of future climate change impacts, high-resolution climate projections are essential in developing appropriate adaptation measures. The Southeast Asia Regional Climate Downscaling/CORDEX Southeast Asia (SEACLID/CORDEX-SEA) project aims to generate these projections through a collaborative effort in regional climate downscaling. However, before downscaling global climate projections, a regional climate model is first evaluated to determine its performance in simulating the climate over the SEA region. In this study, simulations using the 4th version of the International Centre for Theoretical Physics (ICTP) Regional Climate Model system (RegCM4) have been conducted over the SEA domain (80°E-145°E; 15°S-40°N) at 36 km spatial resolution for the period of 1989-2008 using the ECMWF ERA Interim data as boundary condition. Comparisons of model temperature and rainfall with observed data show areas where the regional model tends to enhance (or reduce) biases from the boundary forcing. For example, there is a consistent cold bias over the Tibetan plateau and Indochina, especially during the boreal winter. However, the seasonal cycles are generally well-represented in the model. The correlation between model and observed data also tends to be high over the mainland Asia continent but low over the Maritime continent, which may either be due to the model or to uncertainties in the observation data used. Results also indicate relatively higher similarities for both seasonal and inter-annual variabilities in the temperature and rainfall extremes among the different model experiments performed over mainland Asia compared to the Maritime continent. These results emphasize the need to evaluate and appropriately configure the regional climate model, particularly for the SEA region.

P-1117-29

Atmospheric Systems and Thermical Comfort Index in Presidente Prudente (Brazil) in January-March 2014 period

M. Noli Da Fonseca (1) ; MC. Silva, (2) ; PRD. Alves, (1)
(1) UFPR, Curitiba, Paraná, Brazil; (2) UFPR, Curitiba, Brazil

Since humanity's beginnings man has a concern with the phenomena that originate in the atmosphere. The city of Presidente Prudente is located in the western portion of the state of São Paulo, with a population estimated at 218,960 inhabitants (IBGE, 2013). The city is situated at an average altitude of 472m above sea level and has a great diversity of land use, because the neighborhoods are densely built. With regard to the climate, the city is located in a tropical climate system, a climate transition area, thus hurting the performance of most air systems present in South America. Thus, this research is to identify the performance of weather systems and its relation to the thermal comfort in the city of Presidente Prudente in the quarter January, February and March 2014. For this purpose, we applied initially to Rhythmic Analysis methodology developed by Monteiro (1971) and index calculations Thermal Comfort. Given this, it was found that the feeling of «great discomfort» prevailed during the three-month study, and in the second half of January and the first half of February this feeling was linked to the phenomenon Lock Atmospheric, which caused an increase of up to 5 ° C in temperature and made cities registrassem record highs. Moreover, the action of «atmospheric blocking» and the daytime heating caused the sensation of «maximum discomfort» was set up, which is active mainly in the afternoon.

P-1117-30

Analysis of the Effects of Climate Variability on Crop Yield in Imo State of Nigeria

F. Okorie (1)
(1) Imo State University, Owerri, Geography and Environmental Management, Owerri, Imo State, Nigeria, Federal Republic of

Agriculture is one of the sectors that are strongly affected by climate variability and change especially in developing countries of the world which Nigeria is among. Africa is considered the most vulnerable region in the world in terms of climate variations and change due to its physical and socio-economic characteristics. In Nigeria, it is well known that climate has varied in time and space and it will continue to vary in future. Many variations in rainfall particularly have occurred for the different climatic regions and individual locations in Nigeria. In the Southeast, Imo state for example, droughts have been relatively less persistent, while rainfall is observed to be increasing and temperature increases and reduces moderately over the years compared with other states in the Northern parts of the country. Many parts of Imo state in Southeastern Nigeria experience flood disasters following excessive rainfall which destroy their farmland and wash away their crops. One major issue with respect to climate variability involves its influence on crop yields. Some studies have shown that fluctuations in rainfall and temperature regimes are the atmospheric driving forces that are responsible for the changes in the climate systems of Imo state and other parts of the Southeastern Nigeria. The yield and quality of food crops is central to the wellbeing of humans and is directly affected by changes in climatic systems. Climate variability affects crop cultivation, uncertainties in the onset of the farming season due to changes in rainfall characteristics (early rain may not be sustained and crops planted at that instance may become smothered by heat waves) can lead to an unusual sequence of crop planting which results to poor harvest. Extreme weather events such as thunderstorms, heavy rainfall and extreme temperature also devastate farmlands and leads to poor yield of crops. Pest and crop diseases migrate in response to climatic variations and change. In the study, 15 years (1999-2013) climatic data (rainfall and temperature) generated from the archives of Nigeria Meteorological Agency (NIMET) and crop yield data on selected crops from Agricultural development program (ADP), Owerri, Imo state were examined . After data analysis, the result shows fluctuations in temperature and rainfall pattern in the state with negative effects on crop yield, which also affects humans socioeconomically. Based on this, it is suggested that farmers should adopt good farm management techniques in order to adapt to the prevailing climate variability.

P-1117-31

Climate variability and susceptibility to desertification in Maranhão State, Brazil

S. Oliveira Sa (1) ; CMDA. Eloi (1) ; JR. Lopes (1) ; EP. Araújo (1) ; GA. Reschke (1) ; CWS. Dias (1) ; JA. Nogueira (1) ; C. Gehring (2)
(1) Maranhao State University, Geoenvironmental Center, São Luis, MA, Brazil; (2) Maranhao State University, Post-graduate program in agroecology, São Luis, MA, Brazil

Desertification is a serious global problem. Its impact is greater in developing countries, because it can increase hunger, malnutrition and rural exodus. This paper investigates the susceptibility to desertification in the State of Maranhão, the transition zone between Amazonia, inland Cerrado and the semi-arid Northeast Provinces of Brazil. For this purpose, we spatially interpolate data from 84 climatological stations in operation >20 years throughout the state, provided by the National Hydro-meteorological Network developed by National Water Agency. There is a marked contrast between humid and dry areas reflect the transition-zone between Amazonia and the semi-arid Northeast. Rainfall distribution is very unequal, followed by rapid water-loss via evapotranspiration after the end of the rainy season. Total rainfall varies from about 700.0 to 2784.0 mm/year, with highest rainfall in March (531.3 mm) and April (523.5 mm), whereas August is the driest month (17.1 mm), monthly and annual potential evapotranspiration varies from 20.6 - 302.2 mm/month and 276.0 - 2300.0 mm/year respectively, and annual water deficiency varies from 53.0 to 1421.0 mm/year. In the months of August and September we registered water deficiencies throughout the entire State. The highest rates of annual and monthly water surpluses are 1678.9 mm/year and 424.6 mm/month, respectively. 20.1% (66.854 km2) of the total area of the State of Maranhão, is susceptible to desertification, affecting an estimated 361 thousand inhabitants. Coincidentally, the counties with desertification risk are among the least developed and poorest of Maranhão State and of Brazil. Exposure is especially high in the indigenous population (55.2% of the State´s total indigenous population). Until recently, Maranhão was not included in Brazil´s map of desertification, and public awareness of desertification risks continues almost absent. Our results demand an increased public awareness, and call for the development and implementation of policy and management strategies designed to combat against and adapt to desertification risks, in order to avoid increased rural poverty, food insecurity and further rural exodus.

P-1117-32

Spatial and Temporal Variability of Precipitation over the Gandaki River Basin of Nepal Himalaya

J. Panthi (1)
(1) The Small Earth Nepal (SEN), Research, Kathmandu, Nepal

Landslides, floods, and droughts are recurring natural disasters in Nepal related to too much or too little water. The summer monsoon contributes more than 80% of annual rainfall, and rainfall spatial and inter-annual variation is very high. The Gandaki River, one of the three major rivers of Nepal and one of the major tributaries of the Ganges River, covers all agro-ecological zones in the central part of Nepal. Time series tests were applied for different agro-ecological zones of the Gandaki River Basin (GRB) for rainfall trends of four seasons (pre-monsoon, monsoon, post-monsoon and winter) from 1981 to 2012. The non-parametric Mann-Kendall and Sen's methods were used to determine the trends. Decadal anomalies relative to the long term average were analyzed using the APHRODITE precipitation product. Trends in number of rainy days and timing of the monsoon were also analyzed. We found that the post-monsoon, pre-monsoon and winter rainfalls are decreasing significantly in most of the zones but monsoon rainfall is increasing throughout the basin. In the hill region, the annual rainfall is increasing but the rainy days do not show any trend. There is a tendency of the late departure of monsoon from Nepal, indicating an increase in its duration. These seasonally

and topographically variable trends may have significant impacts for the agriculture and livestock smallholders that form the majority of the population in the GRB.

P-1117-33

Early warning of climate variability and change from seasonal forecasts

KA. Peterson (1) ; A. Scaife (1) ; C. Maclachlan (1) ; A. Arribas (1) ; A. Maidens (1) ; M. Gordon (1) ; A. Brookshaw (1) ; J. Camp (1) ; D. Fereday (1)
(1) Met Office, Hadley Centre, Exeter, United Kingdom

Projections of future climate suggest that extreme events such as drought, floods, storms, cold spells, and heatwaves will all change their regional frequency of occurrence due to long term climate change. However, on planning timescales of months to years in advance, the timing and occurrence of extreme or unprecedented events is determined by climate variability. In particular, it depends on the superposition of climate variability and climate change. In order to advise on the risk of imminent extremes we therefore need climate predictions which accurately take into account current climate variability. This requires initialisation of the current state of the climate in the atmosphere, ocean, sea ice, and land surface as well as the changes in radiatively active greenhouse gases and aerosols.

Here we discuss near term climate predictions from the Met Office Hadley Centre out to seasonal lead times. We show evidence of predictability of the leading modes of climate variability in both the tropics (El Nino Southern Oscillation) and the extratropics (North Atlantic/Arctic Oscillation). We show how this can lead to predictability for regional climate extremes and discuss the prospects for improved warnings and adaptation to imminent extreme events.

P-1117-34

Ability of a high regional climate model to represent key climatic features over West Equatorial Africa

W. Pokam (1)
(1) Department of Physics-Higher Teacher Training College-University of Yaounde 1, Physics, Yaounde, Centre, Cameroon

Climate dynamics over West Equatorial Africa (WEA) is dominated by four prominent features. At lower level, two cells of westerlies (LLW) are discernible, controlled by different mechanisms. At middle level, African easterly jet prevails with a northern component (AEJ-N) discernible year round, and a southern cell discernible from September to February. The upper troposphere is dominated by the Tropical Easterly Jet (TEJ) which drivers over the region vary with season. Surface processes over WEA play a prominent role on the variability of the atmospheric dynamic over the region.

This underlines the complexity of atmospheric features over WEA, and the requirement of fine scale climate model for investigating locally driven atmospheric circulations. High resolution (25 Km) regional climate model HadRM3P was evaluated in its capacity to capture and model key dynamical features over WEA.

Results show the ability of HadAM3P to reproduce features related to the development of the two cells of LLW over WEA. HadAM3P do well in locating the core speed of the two cells of LLW and simulate well their annual variability. HadAM3P does a well job in simulating characteristics of AEJ-N and AEJ-S. The height of the core speed of the two components of AEJ is well simulated, together with their annual latitudinal migration. In upper troposphere, TEJ is well captured by HadRM3P.

However, some biases appear in the simulations. Investigation of the reasons behind these biases leads to highlight some mechanisms over the region. Exploration of the overestimation of the strength of LLW shows that HadRM3P overestimates surface temperature over the coastal region in WEA. This leads to overestimation of local vertical convergence of sensible heat flux from the surface, inducing a warm bias of diabatic heating. This promotes positive bias of vertical motion and in turn overestimation of LLW. This reveals the key role of surface condition over coastal region in WEA for the development of LLW.

Analysis show that during the main rainy season over WEA, from September to November, the prominent feature for the development of uplifts is diabatic heating release by condensation throughout the depth of the troposphere over WEA, rather than jet streak type circulation associated to the development of AEJ-S and AEJ-N.

P-1117-35

Stochastic Dynamical Cascade for Downscaling Precipitation signals over Complex topographies in the High Andes

A. Posadas (1) ; E. Duffaut (2) ; C. Jones (3) ; L. Carvalho (3) ; M. Carbajal (4) ; H. Heidinger (3) ; R. Quiroz (5)
(1) International Potato Center, Production System and Environment/ICRAF, Nairobi,, Kenya; (2) Electrical and computer engineering, Electrical and computer engineering department, George Mason University, Virginia, United States of America; (3) Earth Research Institute, Department of geography, Santa Barbara, California University, United States of America; (4) International Potato Center, Production system and environment, Lima, Peru; (5) International Potato Center, Crops systems intensification and climate change, Lima, Peru

Global Climate Models (GCMs) suggest that rising concentrations of greenhouse gases will have significant implications for climate at global and regional scales. Less certain is the extent to which meteorological processes at individual sites will be affected. Downscaling climate techniques are used to bridge the spatial and temporal resolution gaps between what climate models are currently able to provide and what decision-makers require. Among the most important impacts of regional-scale prediction of climate change is to assess how food production will affect the food security. Regional scale precipitation and temperature simulations are crucial to understand how global warming will affect fresh water storage and the ability to grow agricultural crops. Precipitation and temperature downscaling improve the coarse resolution and poor local representation of global climate models and help decision-makers to assess the likely hydrological impacts of climate change, and it would also help crop modelers to generate more realistic climatic-change scenarios. Thus, a spatial downscaling method was developed based on the multiplicative random cascade disaggregation theory, considering a β-lognormal model describing the rainfall precipitation distribution and using the Mandelbrot-Kahane-Peyriere (MKP) function. The Multifractal downscaling technique, complemented by a heterogeneity filter, was applied to a 15 years (01/11/1998 - 03/31/2013) daily rainfall time series produced by the Weather Research and Forecasting model (WRF- 15 km grid spacing). A downscaled signal of approximately 1 km grid spacing was generated for a 220 km x 220 km region within the high plateau of the Andes. The model parameters were estimated from gauged daily rainfall data registered over 15 years from 18 weather stations. A detailed testing of the model was undertaken by comparing statistical characteristics of the spatial and temporal variability of rainfall between the rainfall fields obtained from the rain gauge network and those generated by the simulation model. The potential advantages of this methodology are discussed.

P-1117-36

Volcanic Eruptions, Carbonaceous Aerosols and ENSO Events

K. Potts (1)
(1) Kyna Keju Pty Ltd, Adelaide, South Australia, Australia

El Niño/Southern Oscillation (ENSO) events are the dominant mode of variability in the global climate responsible for significant variations across the world including drought in Australia and Indonesia, floods in the Americas and a generally increased global temperature. An El Niño commences when the Trade Winds blowing across the Pacific Ocean relax, reduce in strength or even reverse. This is a major perturbation of the Walker Cell, the major zonal atmospheric circulation system over the tropical Pacific Ocean, and, as the literature, IPCC and the USA Climate Change Science Program suggest that

aerosols can affect the large-scale atmospheric circulation and hydrologic cycle I examine the relationship between certain volcanic eruptions and carbonaceous aerosol plumes and ENSO events and demonstrate a causal link exists between the eruptions, aerosols and ENSO which logically must be that the volcanic eruptions and aerosols trigger and then sustain ENSO events until the eruptions end and the aerosol plume dissipates enabling the climate system to recover to a non-ENSO state.

P-1117-37

Heating and cooling rate calculations for realistic volcanic ash clouds and applications to climate simulations

A. Prata (1) ; S. Siems (1)
(1) Monash University, School of earth, atmosphere and environment, Melbourne, Victoria, Australia

The radiative effects of long-lived stratospheric volcanic sulphate aerosols have been widely studied, while the impacts of short-lived, but more strongly absorbing volcanic silicate particles have seen less attention. Silicate ash injected into the stratosphere by the 1982 eruptions of El Chichón volcano were estimated to have induced a net radiative heating rate of up to 20 K per day. This research involves the use of satellite measurements to determine important characteristics of dispersing volcanic ash clouds in order to develop new knowledge on the radiative effects of silicate ash on the atmosphere. Ten explosive volcanic eruptions (VEI ≥ 4), occurring over the last decade (2006-present), have been considered in this study. Hyperspectral infrared and satellite-based lidar remote sensing measurement techniques have been used to detect and quantify volcanic cloud heights, thicknesses, mass loadings and microphysical properties. These measurements are well suited to provide this size and compositional information. Finally, the new data has been used to provide some realistic estimates of the radiative impact of silicate ash on the atmosphere using a 1D radiative transfer model. The significance of the results and possible applications to climate simulations are discussed.

P-1117-38

Observed connections between temperature increase and the altitude of snowfall / snow pack in the Swiss Alps

M. Rebetez (1) ; G. Klein, (2) ; C. Marty, (3) ; C. Rixen, (3) ; Y. Vitasse, (3) ; G. Serquet, (2)
(1) WSL Swiss federal research institute, Neuchatel, Switzerland; (2) University of Neuchatel, Institute of geography, Neuchatel, Switzerland; (3) WSL Institute for Snow and Avalanche Research SLF, Davos, Switzerland

The consequences of global warming are particularly visible in mountain areas. The impact of changing temperatures on the snow to rain ratio is highly critical for alpine ecosystems as well as for winter tourism. Knowledge of the decrease in snow amount is still poor, due both to high interannual variability and to the frequent lack of data.

Here, we analyse snowfall and snow pack for up to 100 years at 140 stations, spanning elevations from 200 to 3500 m asl in Switzerland. Our method allows to assess the impact of changing temperatures on snowfall while minimizing the impact of variability in precipitation frequency and intensity.

Our results show the connection between the decrease in snowfall / snow pack and the increase in temperature. This decrease was stronger at locations with temperatures closer to the melting point. These locations depend both on elevation and season. The current frequency of snowfall for December, January and February are similar to those of the 1960s for November and March. These changes also result in a decrease in snowpack and in earlier snowmelt, particularly at higher elevation.

The transfer in altitude of snowfall affects the beginning and end of the ski seasons. Currently approximately every second precipitation day already consists of rain up to 1400 m asl in November and March.

The amount of snow available for water storage and runoff during the spring and summer months is declining, because more and more winter precipitation will directly contribute to runoff. Impacts can also be expected on the alpine vegetation, which will experience a shorter snow season and possibly be more exposed to late spring frost events, irrespective of variability or changes in precipitation.

P-1117-39

First signs of climate change in Lyon (France) according to Köppen and Hess-Brezowsky classifications

F. Renard (1) ; W. Langlois De Septenville (1) ; B. Lédée (1)
(1) University Jean Moulin Lyon 3 - UMR 5600 EVS, Department of Geography, Lyon, France

The Greater Lyon (France) gathers human and environmental issues that can be affected by climate change by heat waves and intense precipitation. The objective of this study is to identify recent trends of climate change using the annual climate types from the Köppen-Geiger classification and the catalog situations of Hess-Brezowsky, to assess the dynamics and evolution of heat waves and heavy precipitation.

1. Annual climate types in Lyon since 1922

The Köppen-Geiger climate classification is the most used method to categorize the earth's climates. The methodology used is the one detailed in Kottek et al. (2006) and Rubel and Kottek (2010). Rainfall and temperature data are from the weather station of Lyon-Bron (Météo-France). The annual climate types is calculated, for each year (1922 - 2013), and analyzed by decades. All years are placed in the category of warm temperate climate, with the exception of 1940, 1945, 1956 and 1963 which have a snow climate. Regarding temperatures, two types are identified in Lyon since 1922: warm and hot summer. There has, since 1965, a strong increase of the years with hot summer at the expense of warm summer. Indeed, absent for the decade 1965-1975, the hot summers represent 30%, 40%, 80% and 70% for the following decades. Thus, the hot summer type is the majority since the 1995-2005 decade. An additional study on heat waves shows also an increase of the latter.

Concerning rainfall, the proportion of dry winters is constant with about 20% of the years of this type by decades. Fully humid and dry summer years have high variability for the decades before 1995, where they are since observed in the same proportions (40% each). This first study on rainfall is complemented by studying the evolution of the weather types causing rainfalls, using the Hess-Brezowsky classification.

2. Rainfall atmospheric patterns evolution since 1881

Greater Lyon floods are caused by rainfalls with different characteristics. Their natures (intensity, water height, duration) are known since 1988 thanks to the Lyon 30 rain gauges network. In addition, rain is measured daily, since 1881, using Lyon-Bron station. The second part of this study relates the different types of rainfall to atmospheric circulation, and highlights trends related to climate change.

A comparison of many atmospheric circulation type catalogs has been made, and the method of Hess-Brezowsky (Gestengarbe and Werner 1999, 2005) was chosen to identify the types of rainy weather and its evolution. Since 1881, most of the rainfalls occur with southerly (22%) and westerly (31%) circulations. However, most of extreme rainfalls in terms of intensity, water height or duration are due to southerly regimes, with 57 %; 47 % and 34 % respectively. Concerning the evolution of synoptic circulations since 1881, it is noticed a sharp and steady decrease of north-west and north regime, as well as north-east and north regimes, whereas southerly regimes have strongly increased, going from 20% of rainy weather in 1881 to about 45% in 2013. Regarding intense precipitation and focusing on the sub-types of circulation (Großwetterlagen GWL), it is noticed that the GWL «zonal Ridge across Central Europe» is the most frequent, with a strong increase since 1881, according to the Mann-Kendall trend test. This is the same results for the «cyclonic south-westerly» and «trough over western europe» GWLs that have strongly increased since 1881. According to these results, it can be expected an increase in hot summer and

an intensification of rainfall in the Greater Lyon.

Average Bias of Diurnal Precipitation Over Maritime-Continent

F. Royan (1)

(1) Indonesian Agency for Meteorology Climatology and Geophysics, Research and Development Center, Jakarta, Indonesia

Numerical simulation of diurnal precipitation over maritime-continent were inverstigated using WRFV3.5.1. The numerical model use input data from GFS and from GFS+RTGSST data then the average bias from both input data shows that the precipitation is bigger in the afternoon untill morning from 12 UTC until 00 UTC. In March, Most of the diurnal precipitation are on southern part of Indonesia, In June, most of the diurnal precipitation are almost around Indonesia, in September, most of the diurnal precipitation are on northern part of Indonesia and in December, most of the diurnal precipitation are around Indonesia, except south of Java. It's also revealed, that the diurnal precipitation over ocean is strongest in June rather than Land.

P-1117-41

Spatio-temporal characteristics of the recent rainfall recovery in West Africa

S. Sanogo (1) ; A. Ba (1) ; AH. Fink (2) ; JA. Omotosho (3) ; R. Redl (4) ; V. Ermert (4)

(1) Université des Sciences des Techniques et des Technologies de Bamako (USTT-B), Faculty of science and technique (fst, der-physics), Bamako, Mali; (2) Karlsruhe Institute of Technology (KIT), Institute of meteorology and climate research, Karlsruhe, Germany; (3) Federal University of Technology, Akure, Wascal graduate research programme in west african climate system, Akure, Nigeria, Federal Republic of; (4) University of Cologne, Institute of geophysics and meteorology, Cologne, Germany

Using daily (monthly) rainfall data from 167 (254) stations across West Africa with at least 80% data availabilityfor the 31-year period 1980-2010 and the gridded African Rainfall Climatology Version 2 (ARC2) for the period 1983-2010,linear trends in yearly and monthly rainfall totals were investigated. Measures of the Expert Team on Climate Change Detectionand Indices (ETCCDI) and two rainy season onset and retreat definitions were employed to assess the corresponding trendsin frequency and intensity of daily rainfall and changes to monsoon season length. A rotated Empirical Orthogonal Functionanalysis yielded two homogeneous rainfall regions, the Sahel and Guinea Coast, in terms of interannual to decadal rainfallvariability, and this led to analysis of station data and Standardised Precipitation Index for the two regions. Results showthat the majority of stations in the Sahel between the West Coast and 15◦ E shows a statistically significant positive rainfalltrend for annual totals. The August-October period exhibits the largest rainfall recovery in the Sahel and the date of theretreat of the rainy season significantly moved later into the year by 2 days per decade. The recovery is reflected both in morerainy days associated with longer wet spell duration and more extreme rainfall events. Trends along the Guinea Coast are weak and non-significant except for extreme rainfall related indices. This missing significance is partly related to the hiatusin rainfall increase in the 1990s, but also to the larger interannual rainfall variability. However, the tendency towards a moreintense second rainy season suggests a later withdrawal of rains from the West African subcontinent. ARC2 trends are broadlyconsistent where ground calibration was undertaken, but are dubious for Nigeria and Ghana, and especially for the Guinea, Jos and Cameroon Line highlands due to missing gauge data.

P-1117-42

Characteristics of Hydro-Climatic variables In Nigeria during episodes Of Sea Surface Temperature Anomalies in the Gulf of Guinea

M. Sholademi (1)

(1) Nigerian Meteorological Agency, Applied Meteorological Services, Lagos, Nigeria, Federal Republic of

This study examined the characteristics of hydro-climatic variables in Nigeria at various Agro-ecological zones (Forest, Southern-Guinea-Savanna, Northern-Guinea-Savanna and Sudan-Savanna) during different episodes of sea surface temperature anomaly (SSTA) in the Gulf of Guinea (GOG) region. The study utilizes SSTA and continental climatic data spanning 40 years; and with the aid of advance statistical analysis to determine onset of rain, cessation of rain, duration of rain and frequency of occurrence of rain day using rainfall-potential-evapo-transpiration model. Results showed that SST is critical to climate monitoring at the local, regional and hemispheric scales. The result further display how to enhance optimal schedule of farm operations, proper adaptation and mitigation practices against extreme weather events arising from observed warming trends in both the SST and the near air surface temperature. Further recommendation is made for SSTA as a forecasting tool in the prediction of hydro-climatic variables that is essential for optimal agricultural practices.

P-1117-43

Studies on Climatic parameter influencing milk production in Cattle in South West Nigeria

M. Sholademi (1) ; A. Sholademi (1)

(1) Nigerian Meteorological Agency, Applied Meteorological Services, Lagos, Nigeria, Federal Republic of

This study further advance the knowledge of climatic indices applicable to the mitigation strategies aimed at reducing the vulnerability of cattle milk production in south west Nigeria. It shows that milk production in the tropics is affected by environmental factors of which climate appears to be most critical. We adopted Cocheme and Franqiun (1967)'s model of 0.1PE<P<0.5PE lactation method. The experiment was a 2x2x3 factorial arrangement of two cattle breed, two locations and three seasons. Analysis of variance (ANOVA), correlation and regression was used to test the strength of relationship

between climatic parameters and milk yield. The result shows that sunshine duration and evaporation are the dominant climatic parameters affecting milk production irrespective of breed and location. Furthermore, milk production in the study area was highest during the dry season with mean value as (approximately 331 litres/cow/day). However, no significant interactive effect of cattle, breed, location and season on the lactation yield of cattle is observed in the study.

P-1117-44

Influences of climatic variability on coastal oceanography of benin

Z. Sohou (1) ; TC. Guidi (2) ; CL. Hinvi (3) ; R. Djiman (4) ; DE. Fiogbe (5)

(1) Benin Fisheries and Oceanographic Research Institute (IRHOB), Biological Oceanography, Godomey, Benin; (2) Institute of Technology Lokossa, University of Abomey-Calavi (Benin), Industrial engineering and maintenance chair of mechanical and energy, Lokossa, Benin; (3) Faculty of Agronomic Sciences, University of Abomey-Calavi, Faculty of Agronomic Sciences,, Abomey-Calavi, Benin; (4) Fisheries and Oceanological Research Institute of Benin (IRHOB), Physical oceanography, Cotonou, Benin; (5) Science and Technic Faculty of Abomey-Calavi University, Zoology departement, Abomey-Calavi, Benin

In article are analyzed temporary ranks for average monthly air temperature at Cotonou station Kazhekhun(06 ° Nord, 002 ° 23 East) during 10 years (from 1975 to 1984) with every fifteen days discretization ofcounting in. For same the period are used average monthly temperatures of the ocean surfaces near the capital ofthe Republic of Benin, Cotonou. Authors calculated correlation coefficients for humidity of air; air temperature;sea surface water temperature. Research of interrelations between sea surface water temperature variations andsalinity changes on depth, allow to identify a mesolimnion zone; gives the chance to understand distinctionswithin a year, concerning lifting of deep waters (upwelling). Also authors carried out calculations of correlationcoefficients between monthly bioproduction of a pelagic species of fish (Sardinellamaderensis), as «the upwellingindicator», with air temperature. In addition in article are represented fields of sea water temperatures andthe salinity, received with use of SURFER program.

Rectification of El Nino–Southern Oscillation into Climate Anomalies of Decadal and Longer Time Scales: Results from Forced Ocean GCM Experiments

DZ. Sun (1) ; T. Zhang, (1) ; Y. Sun, (2) ; Y. Yu, (3)

(1) National Oceanic and Atmospheric Administration, ESRL/PSD, Boulder, United States of America; (2) Chinese Academy of Sciences, Institute of oceanology, Qingdao, China; (3) Chinese Academy of Sciences, Institute of atmospheric physics,, Beijing, China

To better understand the causes of climate change in the tropical Pacific on the decadal and longer time scales, the rectification effect of ENSO events is delineated by contrasting the time-mean state of two forced ocean GCM experiments. In one of them, the long-term mean surface wind stress of 1950–2011 is applied, while in the other, the surface wind stress used is the long-term mean surface wind stress of 1950–2011 plus the interannual monthly anomalies over the period. Thus, the long-term means of the surface wind stress in the two runs are identical. The two experiments also use the same relaxation boundary conditions, that is, the SST is restored to the same prescribed values. The two runs, however, are found to yield significantly different mean climate for the tropical Pacific. The mean state of the run with interannual fluctuations in the surface winds is found to have a cooler warm pool, warmer thermocline water, and warmer eastern surface Pacific than the run without interannual fluctuations in the surface winds. The warming of the eastern Pacific has a pattern that resembles the observed decadal warming. In particular, the pattern features an off-equator maximum as the observed decadal warming. The spatial pattern of the time-mean upper-ocean temperature differences between the two experiments is shown to resemble that of the differences in the nonlinear dynamic heating, underscoring the role of the nonlinear ocean dynamics in the rectification. The study strengthens the suggestion that rectification of ENSO can be a viable mechanism for climate change of decadal and longer time scales.

Sub-Saharan Africa Climate in CMIP5

W. Thiaw (1)

(1) 5. National Centers for Environmental Prediction, NOAA, College Park, United States of America

This paper examines the Sub-Saharan Africa climate in CMIP5. First we evaluate the historical simulations of continental and regional climatology with a focus on a core set of thirteen models. Second, we compare the CMIP5 climate projections with the historical simulations. We use both RCP 4.5 and RCP 8.5 model simulations. We evaluate the historical runs for a set of basic surface climate and hydrological variables and their extremes for the continent for the period 1979 - 2005. In addition, we conducted evaluations for selected regional climate processes relevant to the African climate, including the West African monsoon, the Greater Horn of Africa spring and fall bimodal rains, and the southern Africa warm season. For temperature and climate variables, we use ERA-I and NCEP reanalysis as proxy for observations. For precipitation, we use GPCP and CMAP. Models are able to reproduce the observed spatial patterns of basic climate and hydrological variables but with considerable differences across models and regions in the magnitude and sign of errors. The variability in surface air temperature compares reasonably well with observations. For West Africa precipitation, the north-south migration of the ITCZ is fairly well captured in 10 of the 13 models. However, while CMAP and GPCP place the area of maximum precipitation in August around 10°N, only a few of the models (3 out of 13) captured this feature. Results from a similar analysis for the Greater of Africa and for southern Africa are presented. The ability of the models to capture extreme events such as drought or flood events has also been investigated and the results presented.

Examining the projected changes in precipitation and temperature trends, we present the differences from the seasonal mean between the last 27 years of the 21st century (2073 - 2099) and the period spanning 1979 - 2005. For DJF southern Africa rainfall season, precipitation changes are significant for only four of the models. Two of these models exhibit a drying trend over southern Africa, one exhibit a wet trend, and one model shows dryness in the northeastern part of southern Africa and wetness in the south. For the MAM season, only the CSIRO and HADGEM2 show a reduction in rainfall across south central Africa. For the JAS season, MIROC exhibits a wet trend in West Africa, while CSIRO reduces precipitation there. Precipitation changes in all other models are not significant. For the OND season, CanESM2, CSIRO and HadGEM2 exhibit a wet trend over East Africa, though there are some differences in the location of the changes in intensity. None of the models depicts a significant dry trend over this region. For temperature, however, all the models project positive temperature changes across Africa. Finally, the dynamic patterns associated with the changes in precipitation and air temperature are presented.

P-1117-47

Changes induced by dust on West African Monsoon features

NE. Toure (1) ; A. Konare (2) ; KO. Ogunjobi (3) ; S. Silue (4) ; I. Diallo (5) ; A. Diedhiou (6)

(1) Universite Felix Houphouet Boigny, Cocody Abidjan / Federal University of Technology Akure, UFR SSMT, Abidjan, Ivory Coast; (2) Universite Felix Houphouet Boigny, Cocody, Ufr sst, Abidjan, Ivory Coast; (3) Federal University of Technology Akure, Meteorology and climate science, Akure, Nigeria, Federal Republic of; (4) Universite Peleforo Gon Coulibaly de Korhogo, Physics, Korhogo, Ivory Coast; (5) Université Cheikh Anta Diop, Ecole superieure polytechnique, Dakar, Senegal; (6) Institute of Research for Development (IRD), LTHE - University Grenoble Alpes, Grenoble Cedex 9, France

The generation and transportation of dust from North Africa are thought to modulate the West African Monsoon (WAM) features. In this study we investigated the relationship between the Saharan Air Layer located above Atlantic Ocean (OSAL) and WAM features, including Monsoon flow, African Easterly Jet (AEJ), and Tropical Easterly Jet (TEJ) over West Africa using the RegCM4 regional model. Toward this purpose, we performed two sets of experiments from 2000–2010, one including dust and one without dust effect over the West African domain, encompassing the whole West Africa and a large part of the adjacent Atlantic Ocean. An Intercomparison of the two simulations show that dust load into the atmosphere has an effect on both the wind and temperature structure at different levels, inducing observed changes in WAM system during JJAS seasons. These changes lead to (1) a westward shift and slight strength of AEJ core over tropical Atlantic which is associated to (2) a weak TEJ and (3) lastly to West Africa monsoon penetration over land. Moreover despite the prescribed Sea Surface Temperature, correlations have been found between Aerosol Optical Depths in OSAL and wind, suggesting that mechanism relationship between dust and WAM features is well reproduced by RegCM4.

P-1117-48

Perceived Effects of Climate Change on Nomadic Practice of the Gujjar and Bakarwal Tribe in Kashmir Valley, India: A Socio-Demographic Analysis

J. Tufail (1)

(1) JAWAHARLAL NEHRU UNIVERSITY, CENTRE FOR THE STUDY OF REGIONAL DEVELOPMENT, SCHOOL OF SOCIAL SCIENCES, DELHI, India

Despite the effects of climate change being evident at a global scale, its negative impact will severely affect those communities highly dependent on natural resources. Significant discussion has been focused on the possibility that climate change will displace large numbers of nomads from their nomadic way of life in the developing world, but few multivariate studies have addressed this issue. High Mountain areas in the arid environment are extremely sensitive indicators of sometimes only slight changes of precipitation and temperatures. Himalayas as the most vulnerable mountains for climate change has already been affected by climate change impacts. Climate change, however, is not the only consequence. Climate and environmental changes have deep impacts on the traditionally nomadic population, their economy and lifestyle. Thus it is justified to speak of both cultural and socio-economic vulnerabilities that characterise the present day development of India's mountain regions. Regional focus of this study is the Jammu and Kashmir mountain area in the north of India and its forelands. Although however, temperature and rainfall trends suggest an increase exposure of the Jammu and Kashmir Nomads to the environmental stresses. Thus, their adaptation strategies show a clear trend towards different forms of agro-pastoralism as a reaction to the climatic change and changing political and socio-economic pressures. This holds true especially for the so far under-researched mountain regions of Kashmir in the Himalayas.

The study examined perceived effects of climate change on grazing land, livestock performance and examined the coping strategies of the nomadic to climate change. Multistage sampling technique was used to select 140 respondents for the study. Data were analysed using percentages, frequencies, tables and Chi square statistical tools. The result of the study showed that 37.5% of the respondents were between the ages of 51-60 years with an average age of 49.8 years. The results revealed that 67.5% of the pastoralists strongly agreed that the pattern of rainfall in recent time affects pasture availability. Consequently 47.5% and 52.5% of them reported a decrease in milk production and increase in livestock's mortality rate respectively due to the effect of climate change. A significance relationship was established between factors of climate change and milk production of the herd (calculated $x2 = 52.00$, tabulated $x2=7.8147$. $p \leq 0.05$). It is therefore recommended that the pastoralists be trained in forage conservation techniques. They should also be encouraged to pool their resources to enjoy economics of scale by the extension workers. Grazing reserves should be developed by the government to fast track the disposition of the pastoralists to sedentary life. It was recommended that animal production/veterinary services should be stepped up, diversify their production to include crops and other sources of income generation and establish more gazing reserves.

P-1117-49

Summer precipitation in Ukraine - observations, modeling and controlling factors

V. Tymofeyev (1) ; V. Martazinova (2)
(1) Ukrainian Hydrometeorological, Kiev, Ukraine; (2) Ukrainian Hydrometeorological, Climatre and long-range forecast, Kiev, Ukraine

Summer atmospheric precipitation in Ukraine is studied via climatology, atmospheric circulation and simulation in operative and climate models. Climatology of summer precipitation in Ukraine is studied with special attention to recent decades' with growing number of extreme events contributed greatly to the present-day climate variability. Trends in total precipitation amounts and other indexes were obtained; showing difference between early and late season; trends in extreme parameters in threshold values are found statistically significant; they are used for regionalization of spatial changes.

Spatial inhomogeneity is found in precipitation indexes across Ukraine, greatest growth in the daily intensity of extreme precipitation occurred between 1990s and 2000s. Precipitation changes are analyzed against near-surface air temperatures (SAT) variability, showing great intraseasonal contrast, on the background of general seasonal warming. Early summer became much wetter in 2000s with numerous extreme events, and period from August till mid-Autumn is much drier causing greater frequency of droughts or heat waves in the last decades. In contrast, early period of global warming in 1970s-mid-1980s has been characterized by much drier climate in the early summer.

It is shown that it is convection intensification that resulted in significant growth in extreme precipitation and attendant events in 2000s and is contributed greatly to the present-day climate variability. In turn increased frequency of summer extreme events are attributed to larger-scale atmospheric circulation change that responsible for significant spatial in broader scale (also across Europe) and intraseasonal contrasts. Growth in extreme precipitation is detected in the latest decade due to deeper European trough with frequent cut-off lows, and its interaction with blocking high over the East Europe, and their greater time residence. The latter became strengthened in the late July-August, providing great weather contrast across Europe, causing rains and floods in the West and greater frequency of droughts in the East.

Ability of WRF ARW and NMM models to reproduce different scales' convection is assessed. Types of mesoscale fields responsible for extreme rainfall events due to the strong convection development are recognized within the larger-scale synoptic systems, threat potential is assessed to increase during the last decade. Transition between atmospheric scales can be used to assessing general threat of extreme precipitation.

Many uncertainties in climate models outputs are detected, not reproducing well observed growth in extreme precipitation in the recent decade as well as spatial variability. One of the main challenges facing the recent climate change is intensification of convective potential and summer showers on the background of further warming; many uncertainties exist in future climate projections. Our own model of the atmospheric circulation change is developed, and scenarios are built, on the basis smaller rate of near-surface warming and variable precipitation. Recommendations for sustainable development for national economy, mainly for agriculture are given.

P-1117-50

Instability intraseasonal of rainfall and its implications on agricultural activities in the middle of Benin Republic (West Africa)

I. Yabi (1) ; S. Zakari (2) ; PAB. Chabi (2) ; F. Afouda (2)
(1) University of Abomey-Calavi, Departmnt of Geography, Abomey-Calavi, Benin; (2) University of Abomey-Calavi, Department of geography, Abomey-Calavi, Benin

Until now rainfed agriculture is the main occupation of the people and is the basis of socio-economic development of rural areas of Benin (food security, monetary income). Furthermore inter-annual variability (which has already been the subject of several studies), it is necessary to understand the intra-seasonal rainfall perturbations which depend mainly cropping calendars in this region known for its agricultural potentials.

Daily rainfall amounts of 4 stations (Dassa-Zoumé, Savalou Savè and Bantè) for the period 1941 to 2010, obtained the National Direction of Meteorology (DNM) were used. Determining the beginning of the end and the length of the dry season was done according to the criteria Gueye and Sivakumar (1992) used by Sane et al. (2008). Similarly, the frequency analysis of the beginning, the end and the length of the seasons was made at the frequencies 8 years out of 10, 5 years out of 10 and 2 years out of 10 by calculating the cumulative frequency to better appreciate the risks. Moreover, years of rupture (in season length) were verified by Pettitt test at significance level $\alpha = 5\ \%$. Moreover, the frequency and magnitude of dry sequences (false start of the rains, drought pockets at the heart of seasons) and wet sequences (risk of flooding and water profusion) were analyzed (Zakari et al. 2012) to better characterize the qualities of the seasons.

On average, the first (large) rainy season lasts 120 days (3rd decade of March in the second decade of July-while the second (small) rainy season is longer than 70 days (3rd decade of August to October). this distribution allows two crop seasons per year (farmers cropping calendars are modeled on that distribution), although the

second is short and uncertain. But in reality, the region is characterized by a high occurrence of late start of the rains (between 15 and 30% for the great season, between 10 and 25 % for early season) and ends early (20 and 35% for the great season and 10 and 20 % for early season). It follows a significant trend towards shorter lengths of the seasons, making the crop seasons uncertain. in these episodes add the appearance of dry spells especially at the beginning at the end of the seasons that negatively affect agricultural activities. The degradation of the quality of rainy season has increased since the 1970s in keeping with the decline in seasonal and annual rainfall totals. It should be noted that the relative improvement of annual rainfall totals recorded since the 1990s has not induced an improvement in the quality of agricultural seasons in the region. So the years considered normal (average) or even surplus concerned with intra-seasonal volatility rain. In this context of quality degradation rainy seasons, the region has per moment of high rainfall sequences in the heart of the seasons, causing disastrous floods for crops and / or harvests.

It is therefore appropriate that agricultural promotion policies and strategies integrate these intra-seasonal rainfall fluctuations while taking into account the knowledge and logical farmers in order to define strategies for adapting agriculture to climate change in this region.

Analysis of the West African Heat Waves and their Associated Dynamics Factors using Regional Climate Models Outputs

F. Yoroba (1) ; K. Benjamin (1) ; A. Diawara (2) ; A. Diedhiou (3) ; Y. Kouadio (1)

(1) University Felix Houphouet Boigny – Cocody – Abidjan, Physic, Abidjan, Ivory Coast; (2) University Felix Houphouet Boigny – Cocody Abidjan, Physic, Abidjan, Ivory Coast; (3) Institute of Research for Development (IRD), LTHE – University Grenoble Alpes, Grenoble Cedex 9, France

Diagnostics combining Regional Climate Models Outputs and Station-based temperature Data from 1962 to 2013 indicate characteristics signals of heat waves over the West Africa. These heat waves can be associated with the occurrence of the record warm days during December, January and February (DJF) and the specific atmospheric circulation like Saharan heat low. Heat waves for various continental locations are shown to occur as isolated spatial and temporal events, and not as part of larger-scale systems over continental-size domains. An examination of the physical processes associated with heat waves showed mutually consistent climatic relationships, such that heat waves were associated with reduced rainfall and consequently reduced soil moisture content, evaporation, and increased insolation at the surface. These combined changes created the surface temperature increase intrinsic to the heat waves.

Are humans exacerbating climate and weather extremes?

F. Zwiers (1)

(1) Univesity of Victoria, Vancouver, Canada

This talk will review some of the recent research on extremes, pointing to aspects of changes in extremes in which we have higher and lower levels of confidence. The body of evidence indicating a human contribution to observed climate change has continued to strengthen as indicated by the 5th Assessment Report of the Intergovernmental Panel on Climate Change (IPCC). This continued development includes an accumulating body of evidence suggesting that temperature and precipitation extremes have both changed in response to human influences on the climate. The research on temperature extremes is well established, with recent work indicating that temperature extremes have continued to warm over land despite the recent global warming "hiatus", and that anthropogenic forcing has substantially increased the odds of extreme warm years and summers, both globally and regionally. The evidence on precipitation extremes is less well established, although there is increasingly strong evidence that human influence is detectable in observations at the largest scales that are resolvable in available international compilations of daily precipitation records. In contrast, assessments of historical and projected changes in droughts and storminess remain cautious, due to both data limitations and uncertainty in process understanding and modelling. Despite uncertainties and limitations in knowledge, observed and projected changes in the simple temperature and precipitation indicators in which we have greatest confidence provide ample evidence that adaptation is required now, and that further adaptation will be required in the future under all RCP forcing scenarios.

K-1118a-02

Detecting and attributing impacts of recent climate change on multiple systems worldwide – certainties, uncertainties and new research questions

W. Cramer (1) ; G. Hansen, (2) ; M. Auffhammer (3) ; C. Huggel (4) ; D. Stone (5)

(1) IMBE, Cnrs, aix marseille university, ird, avignon university, Aix-en-Provence, France; (2) Potsdam Institute for Climate Impact Research, Potsdam, Germany; (3) University of California, Berkeley CA, United States of America; (4) University of Zürich, Department of geography, Zürich, Switzerland; (5) Berkeley Lab, Berkeley CA, United States of America

Due to rapidly growing scientific evidence, based on growing stocks of observations as well as on improved methodologies, it is widely accepted that recent climate change has triggered changes in numerous systems worldwide. Most cited examples concern hydrological systems, the cryosphere, and many biological systems in the ocean and on all continents. The recent IPCC assessment, which was based on an unprecedented trans-disciplinary community effort, found more widespread impacts than previous reports, covered a greater range of impacted system types but also identified regions and systems with insufficient research and monitoring effort. Updating the report, three key questions will be addressed: a) To which extent have human systems been impacted, either directly or through cascading impacts through natural systems? b) How much is known about impacts in poorly observed regions? c) To which extent can the impacts of anthropogenic climate change be distinguished from those of natural climate variability?

K-1118a-03

Attribution of extreme events : Taking attribution science to the limits

P. Stott (1)

(1) UK Meteorological Office, Hadley Centre, Exeter, United Kingdom

Around the World recent heatwaves, floods and droughts have demonstrated the vulnerability of citizens to such extreme weather. However, scientifically robust information about the extent to which recent extreme weather events can be linked to climate variability and change is often lacking. There is therefore a clear need to develop better information on weather and climate risks as part of the development of climate services to enable citizens to better deal with the effects of climate change.

This paper describes recent progress in developing the

science needed to deliver such much needed reliable and timely information about weather and climate risks. It focuses on two important developments in particular.

An annual report published each September in the Bulletin of the American Meteorological Society seeks to explain extreme events of the previous year from a climate perspective. This report has demonstrated the capability to deliver assessments relatively quickly while also showing how the scientific capabilities to carry out such studies is developing rapidly with an increasing number of types of event being considered with larger geographical coverage.

One of the main international groups working to further the development of this science is the EUCLEIA project, a European funded project with eleven partners. EUCLEIA (European CLimate and weather Events: Interpretation and Attribution) is developing an attribution system to deliver reliable and user-relevant attribution assessments on a range of timescales; on a fast track basis in the immediate aftermath of extreme events, on a seasonal basis to stakeholder groups and annually to the annual attribution reports in the Bulletin of the American Meteorological Society.

We will illustrate the presentation with some of the main scientific highlights of this work while also exploring how such scientific information can be best developed and applied in future.

Attribution of record high daily temperatures in Australia in 2013

D. Karoly (1) ; M. Black (1) ; A. King (2) ; M. Allen (3) ; F. Otto (4) ; S. Rosier, (5) ; S. Lewis, (6)

(1) University of Melbourne, School of Earth Sciences, University of Melbourne, VIC, Australia; (2) University of Melbourne, School of Earth Sciences, Melbourne, Victoria, Australia; (3) University of Oxford, School of Geography and Environment and Dept of Physics, Oxford, United Kingdom; (4) University of Oxford, Oxford, United Kingdom; (5) NIWA, Wellington, New Zealand; (6) Australian National University, School of earth sciences, Canberra, Australia

There has been increasing scientific interest in understanding the climate factors associated with extreme weather and climate events. This has led to the series of special supplements in the Bulletin of the American Meteorological Society over the last three years on "Explaining Extreme Events from a Climate Perspective". A wide range of extreme events has been considered in the studies included in these supplements, ranging from heavy rainfall and drought events to record hot and cold seasons. However, there have been no studies so far on the attribution of record high daily temperatures at single sites.

The Australian summer of 2012-13 was the hottest summer averaged across Australia since reliable records began in 1910. Lewis and Karoly (2013) showed that human influences on climate have very likely increased the likelihood of extreme summer average temperature across Australia such as in 2012-13 by at least a factor of five. Here we present an analysis of the contribution of human-caused climate change to the frequency of events such as the record high daily temperatures that occurred across Australia on 7 January 2013 and in Sydney on 18 January 2013.

The recently launched citizen science distributed computing project weather@home ANZ (http://www.climateprediction.net/weatherathome/australia-new-zealand-heat-waves/) has generated very large ensembles of simulated regional daily weather data needed for the attribution of extreme events. By comparing the frequency of extreme daily temperatures in the model simulations for 2013 and for a counter-factual world without any human influences on the regional climate, we assess the role of human influences on the likelihood of these two cases of record high daily temperatures in Australia in 2013.

Lewis, S.C., and D. J. Karoly (2013) Anthropogenic contributions to Australia's record summer temperature of 2013. Geophys. Res. Lett., 40, 3705-3709. DOI: 10.1002/grl.50673

Human influence on climate in the 2014 Southern England winter floods and their impacts

N. Schaller (1) ; A. Kay (2) ; R. Lamb (3) ; N. Massey (1) ; GJ. Van Oldenborgh (4) ; F. Otto (1) ; S. Sparrow (1) ; R. Vautard (5) ; P. Yiou (5) ; A. Bowery (1) ; S. Crooks (2) ; C. Huntingford (2) ; W. Ingram (1) ; R. Jones (6) ; T. Legg (6) ; J. Miller (1) ; D. Wallom (1) ; A. Weisheimer (1) ; P. Stott (7) ; M. Allen (1)

(1) University of Oxford, Oxford, United Kingdom; (2) CEH, Wallingford, United Kingdom; (3) JBA, Skipton, United Kingdom; (4) KMNI, De Bilt, Netherlands; (5) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France; (6) Met Office, Exeter, United Kingdom; (7) UK Meteorological Office, Hadley Centre, Exeter, United Kingdom

The whole winter of 2013/2014 was characterized by a near-continuous succession of westerly storms. Accumulated rainfall during January 2014 was the largest ever recorded for that month across much of southern England, including the Radcliffe Observatory record in Oxford that begins in 1767. Severe floods resulted, causing major disruption.

So far, quantifying any contribution from human influence on climate to such weather events and resulting floods has been difficult due to the large natural variability of winter precipitation in the North Atlantic and European regions. The emerging science of probabilistic event attribution however increasingly allows us to evaluate the extent to which human-induced climate change is affecting localised weather events. Under the project "EUropean CLimate and weather Events: Interpretation and Attribution" (EUCLEIA), an end-to-end attribution study is performed for the first time. An ensemble of 134,354 general circulation model simulations is run using the citizen science project weather@home. We find that the frequency of days in January in zonal flows increases jointly with increases in precipitation as a result of anthropogenic climate change. The best estimate of the change in risk of extreme (1-in-100-year in pre-industrial conditions) precipitation for January in southern England is an increase by 42%, but the uncertainty range includes no change or an increase by over 150% due to uncertainty in the pattern of anthropogenic warming. Further, we partition the impact of greenhouse gases to dynamic changes in atmospheric circulation and to thermodynamic increasing water loading, demonstrating that both mechanisms played a role. A hydrological model driven by the model-simulated precipitation gives similar increases in risk compared to precipitation for 30-day peak river flows for the Thames at Kingston. Given these river flows we estimate that anthropogenic climate change has placed an additional 3,500 properties in the Thames catchment (upstream of the tidal reach through London) at risk of flooding from rivers over a broad range of return-times. Our study provides for the first time an estimate of the scale of precipitation-related damages in a specific region due to the effects of anthropogenic changes in the composition of the atmosphere on climate.

O-1118a-03

Role of soil moisture vs. recent climate change for heat waves in western Russia

M. Hauser (1) ; R. Orth (1) ; S. Seneviratne (1)

(1) ETH, Zurich, Institute for atmospheric and climate science, Zurich, Switzerland

Using the framework of event attribution, anthropogenic climate change was found to have a discernible influenceon the occurence-probability of heat waves, such as the one in Russia in 2010. Soil moisture, on the other hand, is an important physical driver for heat waves as its availability has a large influence on the partitioning of the available surface net radiation into latent and sensible heat flux. The presented study investigates the relative importance of both controls, soil moisture and increasing greenhouse gas concentrations, on heat waves in the region of the 2010 Russian heat wave. This is done with a large number of ensemble members from climate simulations with and without interactive soil moisture for both, the 2000s and the 1960s. The simualtions allow to determine the occurence-probability of heat waves with and without the soil moisture-temperature feedback and to compare

it to the warming caused by climate change. Thereby, we expect to see the largest effect on daytime maximum temperatures (TXx) and a smaller influence of soil moisture on the mean temperatures and cold extremes.

Framing Extreme Event Attribution from the Bottom up – an Enquiry into the Social Representations of key stakeholders, of the Press and of Climate Scientists

JP. Vanderlinden (1) ; I. Meinke, (2) ; M. Schwab, (2) ; N. Capellini, (1) ; SH. Von (2) ; C. Winter, (2) ; C. Pacteau (3) ; Y. Remvikos, (1)

(1) University of Versailles-Saint-Quentin-en-Yvelines, Observatory of versailles-saint-quentin-en-yvelines/cearc, Guyancourt, France; (2) Helmholtz- Zentrum Geesthacht, Zentrum für material- und küstenforschung, Geesthacht, Germany; (3) CNRS, Gis climat environnement sociétés, Paris, France

Attribution of extreme weather events has recently generated a lot of interest simultaneously within the general public, the scientific community, and stakeholders affected by meteorological extremes. This interest calls for the need to explore the potential convergence of the current atttribution science with the desire and needs of stakeholders. Such an euiry contributes to the development of climate services aiming at quantifying the human responsibility for particular events.

Through interviews with climate scientists (internationally and within Germany), through the analysis of the press coverage of extreme meteorological events (heat wave in the Paris area, storm surges in the baltic sea), and through stakeholder (private sector, covernment services and local and regional government) focus groups, we analyze how social representations of the concepts associated with extreme event attribution are theorized. From the corpuses generated in the course of this enquiry, we build up a grounded, bottom-up, theorization of extreme weather event attribution. This bottom-up theorization allows for a framing of the potential climate services in a way that is attuned to the needs and expectations of the stakeholders.

From apparently simple formulations: "what is an extreme event?", "what makes it extreme?", "what is meant by attribution of extreme weather events?", "what do we want to attribute?", "what is a climate service?", we demonstrate the polysemy of these terms and propose ways to address the challenges associated with the juxtaposition of four highly loaded concepts: extreme - event - attribution - climate services.

O-1118b-01

Attribution of extreme climate events in coupled and uncoupled GCM experiments

B. Dong (1) ; R. Sutton (1) ; S. Len (1)

(1) NCAS-Climate, Department of Meteorology, Reading, United Kingdom

Extremes of weather and climate events at global and regional scales can have devastating effects on human society and the environment, and there is overwhelming evidence that these extreme events are changing. Interest in attributing the risk of these extreme events to anthropogenic climate change is increasing and understanding these past changes is critical for reliable projections of future changes. However, there is still no consensus about the best methodology for event attribution. A common approach relies on experiments in which the time periods of interest are simulated using an atmospheric general circulation model (AGCM) forced by prescribed sea surface temperatures (SSTs), with and without anthropogenic influences. A potential limitation of these experiments is the lack of explicit atmosphere-ocean coupling, and therefore a key question is whether the attribution statements derived from such studies are in fact robust. In this research, we have carried out climate model experiments to test attribution conclusions in a situation where the answer is known - a so called "perfect model" approach. The study involves comparing attribution conclusions derived from experiments with a coupled climate model (specifically an AGCM coupled to an ocean mixed layer model) with conclusions derived from parallel experiments with the same atmosphere model forced by SSTs taken from the coupled model experiments. We analyse and compare the changes in surface air temperature and precipitation in response to anthropogenic forcing in the coupled and uncoupled experiments, assessing both seasonal mean changes and extreme events. Our experimental design also allows comparison with observed changes. Our results demonstrate that whilst the AGCM method has some strengths, it also has significant limitations and may lead to erroneous attribution conclusions in some situations.

Unreliable climate predictions overestimate attributable risk of extreme climate events

O. Bellprat (1) ; F. Doblas-Reyes (2)

(1) Catalan Institute for Climate Science (IC3), Climate Forecasting Unit, Barcelona, France; (2) IC3, Barcelona, Spain

Climate predictions are increasingly being used to attribute single extreme climate events to anthropogenic factors by retrospective predictions. The reliability of the systems to predict extreme events might be an important aspect in such an assessment, yet limited hindcast periods which cover only a small number of extreme events in the past inhibit a robust evaluation. Using an idealized framework based on a synthetic forecast model this limitation is here circumvented. The framework allows to perform large number of predictions and to compute the fraction of attributable risk (FAR) on extreme events. Varying the forecast reliability shows that unreliable climate predictions are prone to overestimate the FAR due to ensemble overconfidence, which leads to unrealistically small probabilities for the event to occur without climate change. We show under which conditions forecast reliability becomes important an factor and give an outlook for future event attribution systems using climate predictions.

O-1118b-03

Investigating human influence on Southern France heavy precipitation events

A. Ribes (1) ; S. Thao, (1)

(1) CNRM-GAME, Météo France - CNRS, Toulouse, France

In spite of a relatively dry mean climate, the Mediterranean regions in Southern France use to experience heavy rainfalls over short durations - typically a few minutes to one day. If compared to the rest of mainland France, 10-yr return values of maximum daily precipitation are two to four times larger over this area. The 2014 fall season was particularly severe, with 11 events exceeding the 190mm/day threshold, flash floods and several fatalities.

The possible link between such events and anthropogenic climate change has not been specifically addressed so far. Several approaches might be proposed to deal with this issue, including the realisation of specific climate model experiments. Unlike many other studies, we only focus on past observations and investigate the significance of recent trends in such events. Trends are investigated in terms of magnitude, frequency, and extent of events. Some statistical challenges arise to properly account for spatial depencies among locations. While previous studies looked at trends locally or over a small neiborhood, here

we propose an aggregated diagnosis for the whole region (about 100 stations). The consistency of these trends with the change simulated by state of the art climate models is also discussed. Main results suggest that observationnally based estimates of the human influence on heavy precipitation events are still weakly constrained over such a limited area.

O-1118b-04

Attribution of the June-July 2013 heat wave in the southwestern United States

H. Shiogama (1) ; M. Watanabe (2) ; Y. Imada (3) ; M. Mori (2) ; Y. Kamae (1) ; M. Ishii (3) ; M. Kimoto (2)
(1) National Institute for Environmental Studies, Tuskuba, Japan; (2) the University of Tokyo, Kashiwa, Japan; (3) Meteorological Research Institute, Tsukuba, Japan

A severe heat wave occurred in the southwestern United States (US) during June and July 2013. To investigate the effects of natural variability and anthropogenic climate change on this event, we generated large ensemble simulations of possible weather using the MIROC5A climate model forced by "historical external forcing agents, sea surface temperature (SST) observations and sea ice (SIC) observations" both with and without human influence. It was suggested that both the anthropogenic warming and an atmospheric circulation regime related to the natural variability of SST and SIC made the heat wave event more likely. On the other hand, no significant human influence was found in atmospheric circulation patterns. These results were robust for two different estimates of anthropogenic signals on SST and SIC.

O-1118b-05

Attributing regional effects of the 2014 Jordanian drought to external climate drivers

D. Mitchell (1) ; R. Zaaboul, (2) ; K. Bergaoui, (2) ; F. Otto (1) ; R. Mcdonnell, (2) ; S. Dadson, (1) ; M. Allen (1)
(1) University of Oxford, Oxford, United Kingdom; (2) ICBA, Dubai, United Arab Emirates

Throughout 2014, the regions of Jordan, Israel, Lebanon and Syria have experienced a persistent draught with clear impacts on the local populations. In this study we look at how the probability of such a draught has changed under climate change, with a specific focus on the flow rate of the Litani river and the water level of Lake Tiberious (AKA the Sea of Galilee). Both of which hold major societal, political and religious importance. To perform the analysis we make use of distributed computing power to run thousands of modelled years of 2014 with slightly different initial conditions. We use an atmosphere only model (HadAM3p) with a nested 50 km regional model covering Africa and the Middle East. These data are downscaled to 1 km. Two separate experiments and simulations, 1. For all known climate forcings that are present in 2014, and 2. For a naturalised 2014 scenario where we assume humans never impacted the climate. For observations, we use station data obtained from the Jordanian Ministry of Water. Using a combination of these local station observations and model data we are able to make clear statements on the attribution of a 2014-like draught event to human causal factors.

O-1118b-06

Distinguishing natural and anthropogenic influences on extreme fire danger in Australia

M. Black (1) ; D. Karoly (1) ; T. Lane, (1) ; L. Alexander (2)
(1) University of Melbourne, School of earth sciences, Melbourne, Australia; (2) University of New South Wales, Climate change research centre, Sydney, Australia

In the aftermath of the 2013 Blue Mountains wildfires in New South Wales, Australia, the scientific community was faced with the challenge of quantifying the event's link to different causal factors, including human-induced climate change. While there are a number of recorded attribution studies for temperature and precipitation-related events, no such study exists for fire weather.

This study investigates how the likelihood of extreme fire weather in south-east Australia has been changed due to the competing influences of human-induced climate change and modes of inter-annual climate variability. Our analysis benefits from the use of the recently launched weather@home Australia-New Zealand distributed computing citizen science project to generate very large ensembles of regional climate model simulations over Australia. The likelihood of extreme fire weather is examined for different phases of the El Niño Southern Oscillation under present climate conditions and climate conditions with no human influences.

P-1118-01

Contribution of soil initial conditions for the occurrence of the 2003 and 2010 heat waves

O. Bellprat (1) ; C. Prodhomme (2) ; F. Doblas-Reyes (2)
(1) IC3, Climate Forecasting Unit, Barcelona, France; (2) IC3, Barcelona, Spain

Dry soil moisture condition before both 2003 and 2010 heat wave over western Europe and Russia, respectively have been suggested to play an essential role on the occurrence of the event. In order estimated the impact of soil initial conditions on those two heat waves, we run two sets of seasonal hindcasts with the general circulation model EC-Earth2.3. The initialization of those hindcasts is done either using climatological or realistic land surface initialization in May, June, July and August using the ERA-Land re-analysis. Results show that the 2003 heat wave is predictable either with climatological or realistic land-surface initial condition and for all considered start dates. This feature clearly shows that the 2003 heat waves was predictable. Conversely, the 2010 heat wave is reproduced in May only if the land is realistically initialized, while in June the event is not predicted by none of the hindcasts. The present study will investigate the processes behind the occurrence of the two heat waves.

P-1118-02

Evaluation of Mechanisms of Extreme Temperatures over Europe and North America

I. Colfescu (1) ; S. Tett (1) ; G. Hegerl (1)
(1) University of Edinburgh, School of GeoSciences, Edinburgh, United Kingdom

The 20th century reanalysis is used to investigate changes in the monthly frequency, location and intensity of temperature extreme events during the first half of the 20th century for North America and Europe. Using composite analysis the main synoptic weather patterns associated to the events are identified in the 20th Century Reanalysis and compared to those associated with events in the latter 20th century. An assessment of the capability of CMIP5 models to simulate these extreme events and their mechanisms is also performed by comparing the model patterns with those obtained from the 20C reanalysis.

P-1118-03

Attribution of Extreme Summers in Northern Europe

B. Dong (1) ; S. Len (1) ; R. Sutton (1)
(1) NCAS-Climate, Department of Meteorology, Reading, United Kingdom

The summer climate of northern Europe exhibits large variability from year to year and on longer timescales. In extreme summers the region experiences heat waves, droughts, or floods. This presentation will discuss the characteristics and drivers of variability in northern European summers with a particular focus on the summer of 2012, which was a record wet summer in northern Europe and was associated with widespread flooding, and the contrasting warm dry summer of 2013. The wet summer of 2012 was not an isolated event but rather one in a cluster of wet summers that have occurred more

frequently in the 21st century than in the last decades of the 20th century. Wet summers are associated with a southward position of the North Atlantic storm track and a negative phase of the Summer North Atlantic Oscillation, with the opposite pattern for dry summers. The magnitude of decadal variability in these features suggests a role for forcing from outside the dynamical atmosphere. Climate model experiments have been carried out to identify the drivers of variability and to attribute the factors that influenced the summers of 2012 and 2013 in particular. The results indicate that anthropogenic forcing, both through its direct impact, and through its impact on warming sea surface temperatures, has substantially increased the likelihood of hot summers in northern Europe. Establishing the impact on the likelihood of wet or dry summers is more complex. Evidence suggests that changes in North Atlantic Sea Surface Temperatures were an important factor in explaining the striking contrast between the summers of 2012 and 2013. The implications of these findings for future summers in northern Europe will be discussed.

P-1118-04

The extreme wet 2013/2014 winter season in Western Europe in a changing climate

N. Hempelmann (1) ; P. Yiou (1) ; R. Vautard (1)
(1) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France

Southern UK and North Western France witnessed records of precipitation amounts during the winter of 2013/2014. How this specific extreme seasonal event is linked to climate change remains a difficult issue, due to the large inter-annual variability of precipitation amounts. Using observational records and the new EURO-CORDEX regional climate projections ensemble, we find that over the regions hit by the 2013/2014 event, recent trends in winter precipitation have increased. The estimates from observations are consistent with those from climate simulations. The non-significant change of the return period of the seasonal precipitation is found to be reduced.

We also address the issue whether precipitation amounts would have changed across past decades as a result from external changes than those of the regional atmospheric flow, we used the methodology of circulation analogues, computed from anomalies of sea level pressure over the North Atlantic region. Seasonal precipitations in the regions under study are well reproduced by flow analogues. We find that Southern U.K. precipitations occurring with analogue flows taken in the early part of the century are on average weaker than those taken from analogue flows from analogue flows in the past few decades.

P-1118-05

Climate change induced temporal variability of droughts in Ukraine – the role of North Atlantic Oscillation

V. Khokhlov (1) ; N. Yermolenko (1)
(1) Odessa State Environmental University, Hydrometeorological Institute, Odessa, Ukraine

We used the multiscalar drought index – standardized precipitation evapotranspiration index – to investigate spatiotemporal droughts variability caused by the climate change. The index was calculated using the 0.5 degree grid data on the temperature and precipitation for Ukraine. The two periods with different trends of global temperature – 1951-1980 and 1981-2010 – were used to reveal a climate change impact.

The analysis revealed the periods with moistest and driest conditions. The moistest years were registered in the end of 1970s – start of 1980s. Moreover, both the number and intensity of droughts increase significantly since 1980, especially for the Southern Ukraine. During the 2006-2009, the most extreme and long drought was observed in the Odessa region. The analysis also showed that hydrological droughts begin with some delay from the meteorological ones, and have maximal duration.

We used CUSUM method in order to detect specific years, when the significant change points occurred in the time series of droughts. This method also detected the start of 1980s as the years of transition from the moist to the dry conditions.

The cross-wavelet transform was applied to reveal a connection between the droughts in Ukraine and teleconnection patterns in the North Atlantics. The analysis showed that the North Atlantic Oscillation (NAO) has a maximal effect on the droughts in Ukraine. The anti-phase relation is registered for the joint fluctuations with the periods 2-3 years and is most prominent in the Southern Ukraine. On the contrary, the NAO has a small impact on the Northern Ukraine. This fact can be explained by the orientation of main storm tracks for positive and negative phases of the NAO.

P-1118-06

Understanding the role of anthropogenic climate change behind changes in regional heatwaves

S. Perkins, (1) ; E. Fischer, (2)
(1) University of New South Wales, Climate change research centre, NSW, Sydney, Australia; (2) ETH Zurich, Zurich, Switzerland

Since 1950, heatwaves have been increasing in their intensity, frequency and duration over many global regions. This period of time includes the temperature "hiatus", where global average temperature did not significantly increase since 1998. This study makes use of a 21-member of a single GCM to determine whether changes in heatwaves over various global regions are a result of anthropogenic, and whether observed changes and discrete heatwave events could have occurred without human influence on the climate.

The 21-member ensemble of the Community Earth System (CESM) global climate model is a novel tool, in that it provides a considerable estimate of internal climate variability that is not readily obtainable from most other model ensembles. Each of the historical and future simulations has identical prescribed external forcings, the former of which is based on observations. However, they differ only slightly in their atmospheric initial conditions, commencing on 1st January 1950. The resulting simulations provide a unique sample of a large range of "possible" climates that are all equally plausible under the same external conditions and physical mechanisms of the model. This is distinctive from a multi-member model ensemble such as the 5th Phase of the Climate Model Intercomparison Project, where each participating model has a different physical set-up. Moreover, the version CESM employed in this study provides a 980-year control simulation, allowing for substantial research into climate conditions without influence from human activity.

Firstly, this study explores whether a hiatus occurred for regional heatwaves. Results show that for many global regions there is a large range in plausible heatwave trends during the ~15 year hiatus period, thus inhibiting the robustness of any one estimate, including that of observations. Next it is explored whether similar heatwave trends are possible without anthropogenic climate change. Similar to absolute changes heatwave intensity, frequency and duration, we conclude that the rate of change (i.e. trend magnitudes) in heatwaves since 1950 is primarily a result of human influence on the climate system.

Lastly, the fraction of attributable risk methodology (FAR) is employed to determine whether the likelihood of particular heatwave events have increased due to human influence on the climate. For all regions, it is very likely (>90% probability) that there has been a substantial increase in what is now considered the 1-in-20 year heatwave events. Moreover, for some regions, there is little evidence the current 1-in-20 year heatwave event would have occurred at all without anthropogenic activity. Such results highlight that there is already a signal in anthropogenic climate change in the extreme events we observe today.

P-1118-07

Scenarios for extreme climate characteristics

P. Szabo (1)
(1) Hungarian Meteorological Service, Climate modelling group, Budapest, Hungary

State-of-the-art regional climate models (RCMs) are the best tools to provide detailed and quantitative information about future climate change at regional and local scales since it describes physical processes affecting regional climate features in detail. The results obtained from a regional climate model of around 10-25 km horizontal resolution are of good basis for local impact assessments instead of using low resolution global climate model outputs. However, model simulations have different sources and magnitude of uncertainties, the climate modelling community strives to deliver the projection results together with their uncertainties for impact studies. To assess uncertainty in the simplest way, at the Hungarian Meteorological Service two RCMs are run covering Central-Eastern Europe: REMO (25 km) adapted from Max Planck Institute for Meteorology and ALADIN-Climate (10 km) from Météo-France.

Local impact assessments are based mainly on daily minimum and maximum temperature (besides daily mean values). According to observational data, our local climate over Hungary is warming up more rapidly than the global temperature. The main question of our investigation is whether the record highs increase or the record lows decrease faster. Using observations we calculate how many record high daily maximum temperature and record low daily minimum temperature are set in each year over a grid point. Current record high to record low ratio is above one: it is around 3 to 1 in Hungary with an average of 3.6 in the last 5 years and 2.6 in the last 10 years. Relative increase of record highs to record lows is shown for the two locally-run RCMs from 1961 to 2100, however, the increasing ratio could eventuate that record lows could disappear in the whole country around the end of the 21st century.

We give results for the record high daily precipitation, as well. Compared to the theoretical stationary climate conditions, observations show only an intensification in the inter-annual variability of precipitation records in Hungary. The two models also do not expose robust results: only one model shows a clear increase in record high daily precipitation for the end of the 21st century.

Review of Hydrological norms for Climate Change Resilient Hydraulic Infrastructures in Africa (RESIHYST-Africa): towards a regional programme

A. Amani (1)
(1) UNESCO, Hydrololgic international programme, Nairobi, Kenya

In order to address the current and future water needs and to boost the economic growth of African countries, it is crucial to improve substantially the current rate of mobilization of renewable water resources which is less than 5%. Hydraulic infrastructures (Dams) with various sizes are needed to increase substantially the level of water storage. For road construction, urban water drainage and flood protection other types of hydraulic infrastructures are needed. In many African countries, guidelines and hydrological norms currently used by engineers and managers are obsolete.

In West Africa for example, particularly francophone countries, the hydrological norms for the design of hydraulic infrastructures currently used were established during 60-70s. These norms were established based on hydrological data collected from around 200 experimental basins in West and Central African countries for a period of 3 to 5 years during and following the International Hydrological Decade which led to the creation of the UNESCO International Hydrological Porgramme. In regard to the ecological and climate changes recorded within the region and the huge consequence on infrastructures safety and with the future climate change, there is an urgent need to review and adapt these norms for a resilient design of hydraulic infrastructures in the region. Within the framework of its International Hydrological Programme and on the request of countries through a resolution of IHP Africa national committees UNESCO has initiated a regional programme to address the issue of hydrological norms for the design of hydraulic infrastructures within the context of climate change with a focus for the first phase on West and Central Africa. The first phase of the programme will concern 26 countries from ECOWAS and ECCAS. Two experts working meetings have been held in Ouagadougou. Twelve baseline studies have been conducted in the following countries: Senegal, Niger, Ivory Coast, Guinea, Togo, Benin, Chad, Cameroon, Congo, CAR, DRC and Rwanda.

The regional programme will have the following components: i) Data and hydrological monitoring: new basins should be monitored in partnership with hydrological services and universities and all available climate and hydrological data capitalized; ii) Analysis, Methods and Modelling: Based on the available and collected new data, hydrological research will be conducted focusing on techniques, methods and hydrological modelling for a robust and adapted assessment of discharges taking into account non the stationarity; iii) Operational tools: proposition of new adapted hydrological tools (guidelines, softwares,..) and iv) Capacity building and promotion of the new tools: capacity building at various levels including technician, engineer, graduate and a wide dissemination of the new tools will be considered.

There is an urgent need to mobilze key stakeholders and donors for the funding of the programme which has been endorsed by ECCAS and ECOWAS.

Extreme seasonal hydrological events in the Amazon Basin

JC. Espinoza (1) ; J. Ronchail (2) ; N. Filizola (3) ; P. Fraizy (4) ; JL. Guyot (5) ; JM. Martinez (6) ; L. Noriega (7) ; W. Santini (5) ; F. Timouk (8)
(1) Peruvian Geophysical Institute IGP, SCAH, Lima, Peru; (2) LOCEAN and Université Paris Diderot, Paris, France; (3) Federal University of Amazonas, Manaus, Brazil; (4) IRD (Brazil), Manaus, Brazil; (5) IRD, Lima, Peru; (6) IRD, GET Laboratory, Toulouse, France; (7) Servicio Nacional de Meteorología e Hidrología, La Paz, Bolivia; (8) IRD, La Paz, Bolivia

The Amazon basin is the world's major hydrologicalsystem. Its watershed covers about 6,000,000 km2, almost 5% of all continental masses, andits average discharge is the greatest inthe world (±200,000m3/s). During the last decades, an intensification of extreme seasonal hydrological events (droughts and floods) has been reported in the Amazon region, producing strong impacts on humans and natural systems. In this contribution we propose a synthesis of the key aspects of the recent extremes droughts and floods in the Amazon basin from the Andean regions to the lowland rainforest, including their causes and main impacts. Our results are based on large-scale climate data and observed hydrological information coming from the whole Amazonian countries, in the context of the SO-HYBAM observatory. A trend towards an intensification of the hydrological cycle has been reported during the last decades. For instance, in the Peruvian Amazon, a significant discharge diminution trend ($p<0.01$) is noticed during the low-water season; indeed discharge decreased by 30% after the 1990s when comparing to the 1970-1989 period. However, no trend is observed during the high-water season but extreme floods have recently occurred (e.g. 1999, 2012). Extreme hydrological events have been frequently related to sea surface anomalies in the Pacific and Atlantic oceans. For instance, intense rainfall and subsequent floods have been associated with La Niña events (e.g. 1989, 1999, 2011 and

2012) or to warm conditions in the tropical South Atlantic, as observed in 2009. However the 2014 rainfall and flood anomalies have been related to warm conditions in the western Pacific–Indian Ocean and to exceptional positive anomalies in the Subtropical South Atlantic. Rainfall deficits and droughts have been attributed to El Niño events (e.g. 1998), or to warm conditions in the tropical north Atlantic (e.g. 2005) or to a combination of both oceanic features (e.g. 2010).

Evolution rain-vegetation-agricultural yields in the watershed of the Bouregreg (Morocco) from 1980 to 2009

ZA. Tra Bi (1) ; G. Mahe (2) ; T. Brou, (3)

(1) Alassane Ouattara University, Geography Department, Bouaké, Ivory Coast; (2) Institut de Recherche pour le Développement, Milieu et Environnement, Montpellier cedex 5, France; (3) UMR 228 ESPACE–DEV (IRD, UM2, UAG, UR), Saint Denis, France

Bouregreg Watershed (central Northwest of Morocco) belongs to the agricultural area of Morocco. The agricultural area of the country is only 20% of its national territory, where a strong agricultural and pastoral attractiveness for wet areas like Bouregreg watershed. This watershed is subject to a Mediterranean semiarid climate. Precipitations that fall are estimated, on average, 400 mm per year. They are unevenly distributed over the basin. Thus, the altitude is causing a significant rainfall contrast between Northeast parts of the basin where rainfall rising to 760 mm per year and Southwest areas where they drop to less than 350 mm per year. In addition, climate dynamics of this space, since the 1970s, is marked by strong climate variability with a downward trend in rainfall. This is a major concern for the agricultural and pastoral production; especially that agriculture is mainly rainfed. The crop production system (natural or cultivated) is heavily influenced by the soil and climate conditions in Bouregreg watershed.

This study analyzes the interaction between changes in precipitation and dynamics of crop production from 1980 to 2009. It is a component of the SIGMED (project Spatial approach to the impact of agricultural activities in the Maghreb on sediment transport and water resources in large river basins). The study focuses on the impact of droughts and wet periods on crop production. To achieve this goal, a time series of comparative statistical analysis is first performed on Normalized Difference Vegetation Index (NDVI) of NOAA (National Oceanic and Atmospheric Administration) and MODIS (Moderate Resolution Imaging Spectroradiometer), made in space mesh of 8 km x 8 km, and rainfall series. In holding the large spatial variations in rainfall in the basin, the analysis is made by homogeneous climatic unit. Then, a special statistical analysis is performed on the dynamics of agricultural production, frequencies and intensities of agricultural drought. Droughts and their intensity are determined by linear regression of cereal production with a 95% confidence interval.

The analysis of the evolution of vegetation reveals significant interannual variation in plant activity (37% coefficient of variation), with a marked tendency to decline in the summer. A break in the dynamics of plant activity of the basin is observed in 1999: Reductions are 13% and plant activity maxima are before 1995. The largest areas are located downstream, in the center and south of the basin. The analysis of changes in rainfall also highlights an interannual variation of 30 to 40%, with deviations from the average, greater than 120 mm. Paradoxically, there is no annual downward trend in rainfall amounts in downstream, the center and the south of the basin, but in the northeast that is the wettest area of the basin. In addition, the observation of a significant decrease of vegetation in the summer is not correlated to changes in rainfall. For cons, the correlation between precipitation and vegetation change in wet period (growing season) is important. The analysis of the evolution of wheat (soft and hard) and barley agricultural droughts (the three grains representing ¾ of agricultural production of the basin) allows to notice a declining intra seasonal dynamic of rainfall amounts during wet periods. Agricultural drought is particularly great between 1990 and 2002. Analysis of drought frequency for all three cereals allows concluding that the period from 1980 to 2009 was marked by eleven important agricultural droughts. The intensities of droughts between 1990 and 2002 are between 60 and 80% for these cereals. Thus, the high productions of certain grains such as wheat are mainly related to the conquests of new lands. Yield reductions are offset by an extension of cultivation areas at the expense of forests and fallow land. In addition, the overall decline in plant activity in summer is related to increasing grazing pressure and thus to a rapid depletion of crop residues. This further leads to another pressure on forest vegetation and scrub.

Monitoring and seasonal forecasting of droughts in China

X. Yuan (1)

(1) Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing, China

Persistent hydrologic extreme events such as droughts have devastating impacts on the human and natural systems. Their occurrences are associated with anomalous atmospheric moisture transport which may be linked to variations of large-scale climate phenomena (e.g., ENSO), and their severities and durations are also influenced by land–atmosphere coupling that can enhance existing extremes. They may be further exacerbated by anthropogenic climate change and human water consumption. Improving our monitoring and forecasting capability of droughts, and facilitating adaptations through establishing climate service systems at regional to global scales, are among the grand challenges proposed by the WCRP, and are the core themes of the GEWEX/RHP. Focusing on the major river basins in China, I will show the quality of the latest satellite surface soil moisture retrievals produced by the European Space Agency Climate Change Initiative (ESA CCI) for drought monitoring, and the drought predictability and forecast skill based on North American Multi-Model Ensemble (NMME) climate forecast models.

As compared with in-situ observations at 312 stations in China and global reanalysis, the ESA CCI soil moisture products provide independent drought information over sparsely observed regions such as northwestern China, and the active microwave product with better vegetation penetration works the best in southern China. Although remote sensing products can only detect less than 60% of drought months over most in-situ stations, they capture the responses of inter-annual drought variations to ENSO at river basin scales quite well.

For drought forecasting using NMME models, the drought predictability is quantified by using a perfect model assumption. Drought predictability and forecast skill are positively correlated, but they vary depending on seasons, regions and forecast leads. Higher drought predictability is found over regimes where ENSO has more significant impact. For the ENSO-affected regimes, both drought predictability and forecast skill in ENSO years are higher than that in neutral years.

The outputs from NMME climate forecast models are bias corrected and downscaled to drive a hydrologic model to produce hydrologic drought (in terms of soil moisture or runoff anomaly) forecasts over river basins in China. Hydrologic hindcasts will be performed and evaluated against in-situ station observations and satellite products for a comprehensive analysis.

Trends in Precipitation Extremes over Mississippi and Yangtze River Basins in CMIP5 Models

Z. Pan (1)

(1) Saint Louis University, Earth and Atmospheric Sciences, St. Louis, Missouri, United States of America

Both central-eastern portions of U.S. and China are prone to increasing flooding from Mississippi River and Yangtze River Basin respectively. This presentation contrasts historical and projected spatial-temporal distribution of extreme precipitation in these two large river basins using 31 CMIP5 models' historical and RCP8.5 experiments. Results show that 1) over both river basins, the heaviest rainfall events have increased in recent decades while the lightest precipitation reduced in frequency. Over Mississippi River Basin, both the lightest precipitation (<2.5

mm/day) and heaviest (>50 mm/day) would decrease in frequency notably after mid-2020s while intermediate events occur more frequently in future; whereas over the Yangtze River Basin, all categories of precipitation are projected to increase in frequency over the coming decades. 2) Although the consensus of CMIP5 models was able to reproduce well domain-time mean and even time-averaged spatial distribution of precipitation, they failed to simulate precipitation trends both in spatial distribution and time means. In a similar fashion, models captured well statistics of precipitation but they had difficulty in representing temporal variations of different precipitation intensity categories. 3) The well-documented 2nd half of the 20th century surface summer cooling over the two river basins showed different associations with precipitation trends with higher anti-correlation between them over the U.S. region, implying different processes contributing to the cooling mechanisms of the two river basins.

Attribution of Hydrological Extreme Events and the Need for National Inventories of Loss and Damage

M. Allen (1)
(1) University of Oxford, School of geography and the environment, Oxford, United Kingdom

The Report of Working Group I (Physical Science Basis) of the IPCC assessed the evidence for trends in hydro-meteorological extremes and the growing literature on the attribution of extreme weather events, in a probabilistic sense, to anthropogenic drivers. In a very small number of cases, these event attribution studies have been carried through to hydrological impacts, but this remains a new and emerging science.

The Report of Working Group II (Impacts of Climate Change) of the IPCC reported on numerous studies of the hydrological impacts of observed climate change, but because of the paucity of the literature on «end-to-end» attribution, stepped back from making strong statements attributing these impacts to anthropogenic influence. Owing to the multiple uses of the phrase «Climate Change» in the IPCC and UNFCCC, there is considerable scope for confusion on this point, so I will review these issues carefully. The central question is the attribution of harm: how strong is the evidence that past greenhouse gas emissions and other forms of anthropogenic influence on climate have caused actual harm through their impact on hydrological extreme events?

I will argue, perhaps controversially, that these specific issues have evolved in such a way that the IPCC, or any global review process, is no longer the appropriate venue for their assessment: quantifying harm involves value judgments and region-specific contextualising and confounding factors such that it is often impossible to make any useful generalisations. Instead, the role of bodies such as the IPCC should become the assessment and recommendation of methods and standards of evidence, while actual assessments are carried out at a regional or national level.

I will provide a general, non-specialist over-view of the science of Probabilistic Event Attribution, specifically focussing on its application to recent flood and drought events. I will explain how different ways of framing the attribution question can yield different-seeming conclusions even if confronted with the same evidence, requiring the broader community to engage with these issues and not simply rely upon «attribution specialists».

In the context of extreme hydrological events, I will then ask what kind of extreme event is likely to be most important in determining the overall level of climate change harm: is it those very extreme events that would have been «effectively impossible» (or, more accurately, just very, very unlikely) in the absence of climate change, or is is the much broader range of events that have simply been made somewhat more (or less) likely by climate change. I will argue it is often the second category that is overlooked in national climate impact assessments because the role of climate change is relatively subtle, yet because there are simply so many more of these events, their cumulative impact could be quite profound.

All this builds up to the conclusion that, if countries are to get serious about quantifying Loss and Damage from climate change -- and it remains very much a matter of debate whether they will -- then they have no option but to work towards national or shared regional attribution services to allow them to quantify the role of anthropogenic climate change in regional hydrology, accounting for location-specific factors. I will discuss what this might involve, and present some ideas on how to go forward.

Future changes in extreme streamflow over the Amazonian sub-basins

M. Guimberteau (1) ; J. Ronchail (2) ; JC. Espinoza (3) ; M. Lengaigne (4) ; B. Sultan (5) ; J. Polcher (6) ; G. Drapeau (7) ; JL. Guyot (8) ; A. Ducharne (9) ; P. Ciais (1)
(1) LSCE, CEA, CNRS, UVSQ, Gif-sur-Yvette, France; (2) LOCEAN and Université Paris Diderot, Paris, France; (3) Instituto Geofisico del Peru, Lima, Peru; (4) LOCEAN, Paris, France; (5) IRD, LOCEAN, Paris, France; (6) CNRS, Lmd, Paris, France; (7) LOCEAN, Université Paris Diderot and PRODIG, Paris, France; (8) IRD, Brasilia, Brazil; (9) Sorbonne Universités, UPMC, CNRS, EPHE, UMR 7619 METIS, Paris, France

The Amazon basin plays an important role in regulating the local and global climate since the discharge at its outlet contributes nearly 20% of global freshwater inputs (Callède et al., 2010). Streamflow changes have been characterized by more severe extreme values on the main stream for about forty years. At Óbidos, the last gauging station before the outlet, the high flows significantly increase by 13% over 1903-2011 and exceed 250,000 m^3/s almost every year since the late 60s (updated from Callède et al., 2004). The low flows are stable over the period 1903-2011 but significantly decrease by 16% over the last twenty years. The resulting increase in the annual amplitude of discharge during the last two decades is marked by severe droughts (2005 and 2010) and floods (2002, 2009, 2012 and 2014), mainly attributed to large-scale oceanic and atmospheric circulation changes (Espinoza et al., 2012, 2013, 2014). The populations living near the rivers whose activity is regulated by the present annual cycle of waters are particularly sensitive to these extreme streamflow events. During high floods, boat trips are dangerous and the mobility of the populations is reduced. Severe low flows make the boat trips longer and increase fish mortality. Thus, food prices increase and directly impact the local economy. Given these facts, it is crucial to estimate the future of the hydrological extremes in the Amazon basin in a future warmer climate (between +1.5 and +5.0°C by 2100). The model ORCHIDEE (ORganising Carbon and Hydrology In Dynamic EcosystEms), the land component of the IPSL global climate model (GCM), is able to accurately simulate the present-time streamflow in many stations over the Amazon basin (Guimberteau et al, 2012). ORCHIDEE is therefore used to provide discharge projections at sub-basin scale under future climate. Climate change scenarios over the Amazon basin were built with the delta downscaling method approach from up to eight AR4 GCMs based on three emission scenarios for two periods of the 21st century. For the middle of the century under a medium-emission scenario, no change is found in high flow on the main stem of the Amazon River, but the low flows decrease by 10%. Contrasting discharge variations are pointed out depending on the location in the basin. In the western upper part of the basin, which undergoes an annual persistent increase in precipitation (P), more flooding events are expected (high flows increase by 7%). By contrast, simulated P decreases during the dry seasons over the southern, eastern and northern parts of the basin lead to significant low-flow decrease, especially in the Xingu River, where it reaches -50%. In the north, the

low-flow decrease becomes higher toward the east. Finally, the southern sub-basins, that have low runoff coefficients, will become more responsive to P change (increase in streamflow elasticity to P by up to 35%) than the western sub-basins, experiencing high runoff coefficient and no change in streamflow elasticity to P.

Interpreting the geological record of Amazon biomass combustion requires comparing charcoal accumulation rates in various biomes at different time scales. Charcoal accumulation rates, a proxy for palaeofire records, were obtained in sediment cores from Amazon lakes surrounded by several vegetation types and froma reservoir in an intense land use change region. The records presented in this studywere obtained in the following areas i) a reservoir in Alta Floresta region (northern Mato Grosso State); ii) Lago do Saci (southern Pará State), a lake close to Alta Floresta and located at the southern border of Pará State; iii) a bog in an ecotone area in the Humaitá region (southern Amazonas State); iv) lakes in lateritic iron crust of the Carajás Hills (southeastern Pará State); v) Lago Comprido, a floodplain lake close to the Amazon River and surrounded by tropical rain forest (Monte Alegre, Pará State; vi) Lagoa da Pata in the Morro dos Seis Lagos alkaline complex (São Gabriel da Cachoeira, Amazonas State) and vii) Lago Caracaranã, a secluded lake in the northern Amazon cerrado (Roraima State). The highest charcoal accumulation rates were observed for modern records related to an intense change in land use at Alta Floresta, which had no precedent during the Holocene history of the Amazon. High charcoal accumulation rates that were observed in the Carajás region during low lake level phases in the Amazon in the mid-Holocene were comparable to those at the onset of the human settlement in Alta Floresta region. An increase in charcoal accumulation rate was observed in the late Holocene when the lake level was high, suggesting an interaction between climates and human presence. Low charcoal accumulation rates are typical of modern high rainfall environments, as observed in Lagoa da Pata where the environment is not susceptible to occurrences of wildfires even during relatively drier climatic phases. Low charcoal accumulation rates also exist in the relatively dry cerrado (savanna type) biome even during relatively dry phases in the Caracaranã region where the savanna-type vegetation biomass is lower and thus generates less charcoal particles than forest ecosystems. The timing of fires correlated well with the mid-Holocene dry climate phase in Brazil. These events may be related to changes in the high-resolution record of CO2 in ice cores from the last 11,000 years. These records indicate an increase in CO2 concentration of 25 p.p.m.v. that occurred between 7000 and 1000 years BP. Anomalies of 5 ppm in the CO2 concentration in the atmosphere identified at the Taylor Dome station may similarly be related to the high variability in forest fire occurrence in the Amazon region recorded by the high charcoal accumulation rates that can be associated principally with human activity during the late Holocene, especially considering from higher lake levels that indicate a wetter climate compared to the mid Holocene.

Intense storm activity during the Little Ice Age on the French Mediterranean coast

L. Dezileau (1) ; P. Blanchemanche (2)

(1) Université Montpellier II, GeoSciences, Sciences de la terre de l'eau et de l'environnement, Montpellier, France; (2) CNRS, Université montpellier 3, Lattes, France

Understanding long-term variability in the frequency of intense storm activity is important for assessing whether changes are controlled by climate evolution. Understanding this variability is also important for predicting present and future community vulnerability and economic loss. Our ability to make these assessments has been limited by the short (less than 50 years) instrument record of storm activity. Storm- induced deposits preserved in the sediments of coastal lagoons offer the opportunity to study the links between climatic conditions and storm activity on longer timescales. In this study, we present a record of these extreme climatic events that have occurred in the French Mediterrannean coast over the past 1500 years. The identification of these extreme events is based on the analysis of sediment cores from Gulf of Aigues-Mortes lagoons that contain a specific sedimentary and geochemical signature associated with intense storms.

Overwash deposits do not show any evidence of intense storm landfalls in the region for several hundred years prior to the late 17th century A.D. The apparent increase in intense storms around 250 years ago occurs during the latter half of the Little Ice Age, a time of lower continental surface temperatures. Comparison of the sediment record with palaeoclimate records indicates that this variability was probably modulated by atmospheric dynamics. The apparent increase of the superstorm activity during the latter half of the Little Ice Age was probably due to the thermal gradient increase leading to enhanced lower tropospheric baroclinicity over a large Central Atlantic/European domain and leading to a modification of the occurrence of extreme wind events along the French Mediterranean coast. A complete understanding of the relationship between climate fluctuations, storm activity, and the coastal response will be crucial to predicting the impacts of future climate change.

O-1119b-04

Characterization of drought and soil moisture in context of climate change : results and operational applications of ClimSec project in France

JM. Soubeyroux (1) ; P. Josse (2) ; JP. Vidal (3) ; E. Martin (4) ; C. Pagé (5) ; F. Habets (6)

(1) Météo-France, Dclim, Toulouse, France; (2) Météo France, Direction de la Climatologie et des Services Climatiques, Toulouse, France; (3) IRSTEA, Lyon, France; (4) Météo France, Cnrm-game, Toulouse, France; (5) CERFACS, Toulouse, France; (6) CNRS, UMR 7619 Metis, université Pierre et Marie Curie, Paris, France

Evolution of water resource is one of the main stakes of climate change in France. The ClimSec project (2008-2011) focused on the impact of the climate change on drought and soil moisture over France by using a high resolution climatological reanalysis since 1958 based from a Soil Vegetation Atmosphere Transfer model, the Safran/Isba/Modcou suite.

The high-resolution 1958-2008 Safran atmospheric reanalysis was used to force the Isba land surface scheme and the hydrogeological model Modcou. Meteorological droughts are characterized with the Standardized Precipitation Index (SPI) at time scales varying from 1 to 24 months. Similar standardizing methods were applied to soil moisture and streamflow for identifying multiscale agricultural droughts - through the Standardized Soil Wetness Index (SSWI) - and multiscale hydrological droughts, through the Standardized Flow Index (SFI). Based on a common threshold level for all indices, drought event statistics over the 50-yr period - number of events, duration, severity and magnitude - have been derived locally in order to highlight regional differences at multiple time scales and at multiple levels of the hydrological cycle (precipitation, soil moisture, streamflow). Results show a substantial variety of temporal drought patterns over the country that are highly dependent on both the variable and time scale considered. Independent spatio-temporal drought events have then been identified and described by combining local characteristics with the evolution of area under drought have finally been used to compare past severe drought events, from multi-year precipitation deficits (1989-1990) to short hot and dry periods (2003). Results show that the ranking of drought events depends highly on both the time scale and the variable considered. This multilevel and multiscale drought climatology served as a basis for assessing the impacts of climate change on droughts in France.

At the end of the project, the new drought indices were adapted for the operational hydrological monitoring and used for the qualification of drought event in real time, namely for the 2011 spring drought.

These indices were also calculated in future climate from the various regionalized climatic projections available over France. Three particular experiences in socioeconomic scenarios, climatic models and downscaling methods have been run to estimate the relative importance different uncertainties for drought evolution.

In the same time, a diagnosis on drought evolution can be established with a schedule much shorter and more intense for the agricultural drought linked to the deficit of soil wetness than for meteorological drought in relation with the precipitation. The climatic projections suggest that France could know at the end of the XXIth century a quasi-continuous drought with a strong intensity, totally unknown in the present climate.

Analysis hydrometeorological events of floods in the watershed Mono shared Benin-Togo (West Africa)

E. Amoussou (1) ; Y. Tramblay (2) ; SH. Totin Vodounon (3) ; G. Mahe (2) ; JE. Paturel (4) ; P. Ribstein (5) ; L. Descroix (6) ; M. Boko (7)

(1) University of Parakou, Geograaphy, Parakou, Benin; (2) Université de Montpellier 2, Ird, laboratoire hydrosciences montpellier, Montpellier, France; (3) University of Parakou, Geography, Parakou, Benin; (4) IRD, HydroSciences Montpellier, Abdijan, Ivory Coast; (5) Université Pierre et Marie Curie, Laboratoire sisyphe, Paris, France; (6) UMR PALOC, Lmi pateo, campus international de recherches ucad/ird de hann, Dakar-Hann, Senegal; (7) University of Abomey-Calavi, Geography, Abomey-Calavi, Benin

The recurrence of extreme anomalies of precipitations involving of the floods or the droughts is a normal component of the natural variability of the climate. The harmful effects of the floods these last have strong incidences socio-economic and ecological and involved human losses of life and property damages. The vulnerability with these natural risks is high in West Africa and basin of Mono in particular, where the populations tend to occupy the most exposed zones more and more. The objective is to model the distribution of the risings entering to the dam Nangbeto thanks to hydrological model GR4J with the step of daily time to assess the risks of flood in the low valley of the river.

The data used cover the period 1961 to 2010. They is the daily outputs (m3.s-1), the evapotranspiration (mm/jour, calculated according to method FAO) and average precipitations on the basin (mm/day). The various methods of space interpolation of the rains were tested (linear, cubic, Thiessen, simple average). Model GR4J was useful with modeling of the risings upstream and the stopping of 1988 to 2010 to appreciate the effects of the dam.

The results show a marked variation in rainfall by increasing annual maximum daily followed by an increase in ETP. The rates recorded in output Nangbéto dam are equivalent to those recorded input, especially during floods, showing the weak regulatory role of the dam and the very limited capacity of the reservoir. The annual maximum incoming flow at the dam can be modeled by an extreme value distribution (GEV) Fréchet-type, while those measured at the outlet of the dam after a GEV law Weibull (bounded). The dominant runoff generation mechanism in the basin is the gradual rising waters associated with increased saturation of the soil, rather than isolated episodes of rainfall. The analysis of flood flows between 1988 and 2010 showed no increase in flood magnitude during this period. Finally the effectiveness of the model to reproduce GR4J flood flows has been tested showing that the observed floods are simulated during calibration. However, validation tests over several periods with different climatic characteristics show a degradation of performance criteria and the model as one moves away from the calibration period, showing the instability of the model parameters in the time. Under these conditions, the use of such a model to assess future risks future flooding is risky and it is necessary to consider alternative approaches.

Extreme rainfall analysis and water resources system sensitivity in Nigeria

O. Adeaga (1)

(1) University of Lagos, Geography, Lagos, France

Climate change poses unique challenges to global socio-economic development and growth of the societies due to multiple shocks and stresses concurrently faced. This call for studies to estimate the potential impacts of climate change on the society. Extreme rainfall events today pose a serious threat to many populated and urbanized areas worldwide since anthropogenic climate change is now widely considered to have the potential not just to cause perturbations in the weather but also to create major discontinuities in many complex natural and human systems.

Hence, the need for an accurate estimate of frequency and distribution of extreme rainfall events can significantly aid policy planning in the area of land use planning and water resources system design that suits the harmonizing plan of their enormous physical structure and hydrological system. Quality precipitation information remains an indispensable requirement for warning systems, hydraulic structures design, risk assessment and hydrological modelling. Hence, reliable spatial information on precipitation distribution and pattern at finer climate information scale remains an important tool towards attaining a sustainable socio- economic development of a region, in the wave of climate change and variability.

In this study an attempt was made to address the potential effect of extreme rainfall events on the water resources system sensitivity in Nigeria, in the aftermath of observed current global change scenarios. These analysis entails fitting of statistical distribution of the monthly rainfall dataset (1960 - 2005) for the analysis of extreme events and generation of rainfall intensity-duration-frequency curves. Also, the threshold level was used to evaluate the extreme conditions. This is necessary in other to address potential climate change effect in terms extreme rainfall

occurrence and water resources system sensitivity in Nigeria.

Groundwater induced flood estimation in extreme rainfall context; methodological approach applied to Somme basin (France)

N. Amraoui (1) ; JJ. Seguin (2)
(1) BRGM, Water environment & ecotechnologies division, Orléans, France; (2) BRGM, Orleans, France

Climate change is expected to modify hydrological cycle, and extreme events would be more frequent. Increasing extreme precipitation (frequency and intensity) projected in northern Europe and continental Europe (IPCC WG2 AR5 chapter 21) would result in an increase of flood risk. In chalky basins located in northern France (Somme catchment) and the United Kingdom (Pang and Lambourn catchments), groundwater flooding, with return periods superior to 100 years has already occurred in winter 2000/20101. The estimation of groundwater contribution to flood peak under extreme rainfall context remains difficult because of a lack of appropriate methods and data. Nevertheless, this estimation is a decisive element for policy makers to assess and manage the flood risks.

In the Somme basin, a probabilistic approach to develop «extreme» climate scenarios based on cumulative rainfall return period of 1000 years and hydrodynamic modeling of the groundwater and rivers system were used. A statistical extreme value analysis using a long rainfall time series allowed defining rainfall events of return period of 1000 years. Correlative analysis rainfall-discharge of the Somme river at the watershed outlet (Abbeville station) performed with cumulative rainfall over n days show that the best correlation is obtained with a total of n=180 rainy days. In addition, estimating the river discharge of return period 1000 years was made by fitting a probability distribution for extreme events (GEV law)

Several scenarios were simulated with the hydrodynamic model of the Somme basin; they differ in the temporal distribution of daily rainfall over the period of 180 days, the groundwater level at the onset of the rainy millennial episode, and the value of base flow of the river at the start of the rainy millennial episode.

The results highlight the rainfall distribution importance on the maximum discharges and the influence of the water table and the base flow of the river at the onset of the rainy period. It is also clear that for such climatic events, the groundwater contribution to the Somme river discharge remains important, between 65% and 72% of the flow according to the scenarios.

Paleoclimate reconstructions over eastern Andes of Perú and Bolivia based on stable isotopes □18O of speleothems

J. Apaéstegui (1) ; F. Cruz (2) ; A. Sifeddine (3) ; B. Turcq (4) ; JL. Guyot (5) ; JP. Bernal (6) ; JC. Espinoza (7) ; M. Vuille (8)
(1) Peruvian Geophysical Institute IGP, Lima, Peru; (2) Instituto de Geociências, Universidade de são paulo, São Paulo, Brazil; (3) Institut de Recherche pour le Développement - IRD, Umr locean (ird/upmc/cnrs/mnhn), Paris, France; (4) Institut de Recherche pour le Développement, LOCEAN, Lima, Peru; (5) IRD, Lima, Peru; (6) Centro de Geociencias, Universidad nacional autónoma de mexico, Querétaro, Mexico; (7) Instituto Geofisico del Peru, Lima, Peru; (8) University of Albany, Suny, Albany, United States of America

During the last years, especial efforts on paleoclimate reconstructions have shown interest in the behavior of South American Monsoon System (SAMS) during the last 2 ky. Since there is considerable concern that the SAMS dynamics will be significantly affected by increasing greenhouse gas concentrations in the 21st century, there is an urgent need to improve document and understand the causes of Monsoon variations in response to natural forcing during the most recent past period. For instance, climate modeling studies and additional paleoclimate records of ocean and atmospheric conditions are needed to best define the relationships between SAMS rainfall and ocean- atmosphere variability during the late Holocene.

In this sense, we have developed stable isotopes (δ18O, δ13C) and trace elements time series (Ex: Mg/Ca, Sr/Ca) from calcite speleothems collected in the eastern Andes of Perú (Rioja - San Martin, ~6° S) and Bolivia (Torotoro - Potosí, ~18° S). These records allow us to reconstruct past changes in the SAMS and local hydrological conditions during the Holocene with special interest through most of the last two millennia. Our results evidence different modes of SAMS variability arriving from decadal (64 yrs) to millennial timescales (1500 yrs). Comparison between Andean records and other South American proxies records reveals spatial changes in rainfall distribution and SAMS intensity over different time periods. Such variations in SAMS suggest interactions of oceanic - atmospheric modes triggering teleconnections associated with hydroclimate conditions reconstructed in the SAMS region.

Moreover, it is worth noting that is necessary to develop more proxies record in the southern hemisphere and key areas of the SAMS for better understand the climate system. Additionally, it is also important to reproduce these changes by coupled ocean-atmosphere models in order to define and recognize better relationships and mechanism that could affect this system. These approaches would bring invaluable tools for define possible effects of climate change in SAMS and reduce population affected by extreme events in South America.

P-1119-04

Extreme events effects on dissolved inorganic and organic carbon yields and fluxes in the watersheds of tropical volcanic islands, examples from Guadeloupe (FWI)

M. Benedetti (1) ; E. Lloret (2) ; C. Dessert (3)
(1) IPGP-SCP Univ. Paris Diderot, Aquatic Geochemistry, paris, France; (2) Université Lille 1, Lille, France; (3) IPGP-SCP Univ. Paris Diderot, Geochemistry and cosmochemistry, paris, France

Organic matter is an important factor that cannot be neglected when considering global carbon cycle. New datainclucling organic matter geochemistry at the small watershed scale are needed to elaborate more constrainedcarbon cycle and climatic models. The objectives are to estimate the DOC and DIC yields exported from smalltropical watersheds and to give strong constraints on the carbon hydrodynamic of these systems. To answer thesequestions, we have studied the geochemistry of eleven small watersheds around Basse-Terre volcanic Island in theFrench West Indies during different hydrological regimes from 2006 to 2008 (i.e. low water level versus floods).We propose a complete set of carbon measurements, including DOC and DIC concentrations, 13C data, and lesscommonly, some spectroscopic indicators of the nature of organic matter. The DOC/DIC ratio varies between 0.07and 0.30 in low water level and between 0.25 and 1.97 during floods, indicating that organic matter is mainlyexported during flood events. On the light of the isotopic composition of DOC, ranging from 32.8 to 26.2hduring low water level and from 30.1 to 27.2hduring floods, we demonstrate that export of organic carbon ismainly controlled by perennial saprolite groundwaters, except for flood events during which rivers are also stronglyinfluenced by soil erosion. The mean annual yields ranged from 2.5 to 5.7 t km 2 year 1 for the DOC and from4.8 to 19.6 t km 2 year 1 for the DIC and exhibit a non-linear relationship with slopes of watersheds. The flashfloods explain around 60% of the annual DOC flux and between 25 and 45% of the DIC flux, highlighting theimportant role of these extreme meteorological events on global carbon export in small tropical volcanic islands.From a carbon mass balance point of view the exports of dissolved carbon from small volcanic islands are importantand should be included in global organic carbon budgets.

Modeling the 2013 Typhoon Haiyan storm surge: Effect of wave coupling, offshore winds, and tidal level

PH. Bilgera (1) ; C. Villanoy, (1) ; O. Cabrera, (1)
(1) The Marine Science Institute, University of the Philippines, Diliman, Quezon City, Philippines

Super Typhoon Haiyan, with wind speeds exceeding 300 km h−1 generated a storm surge in San Pedro Bay reaching heights of more than 6m in Tacloban City. Severe winds and storm surge heights caused catastrophic structural damage and casualties. Delft Dashboard (DDB), an open-source standalone Matlab based graphical user interface, was used to develop a coupled flow and wave storm surge model to understand the Typhoon Haiyan storm surge development and propagation. Model results corroborated by field observations showed that as the storm center entered Leyte Gulf, strong northerly winds prevailing on the northern part of San Pedro Bay caused sea level to recede by 1–2m. This was followed by the development of the surge off the towns of Palo and Tanauan. This surge then propagated northwards to Tacloban and Basey as the winds shifted to the north when the storm center made landfall. Various idealized simulations were also designed to determine the effect of wave coupling, offshore winds, and tidal phase, with results highlighting importance of physical processes such as wave dissipation, wind-forced flow, and non-linear tide and surge interactions.

P-1119-06

Future trends of South American droughts: comparison between the reference period 1961-1990, and the RCM-CORDEX projections in the period 2071-2100

JD. Giraldo Osorio (1)
(1) Pontificia Universidad Javeriana, Civil Engineering, Bogotá D. C., Colombia

1 Introduction

The relationship between positive precipitation anomalies and the warm phase of ENSO phenomenon (El Niño – Southern Oscillation) has been broadly documented in the southern South America (Grimm and Tedeschi, 2009; Grimm, Barros, and Doyle, 2000). Nonetheless, the tropical region of the continent faces drought conditions when El Niño is turned on (Poveda and Salazar, 2004; Marengo, 2004; Fu et al., 2001). Another studies have shown the broad spreading of positive trends in temperature time series, and the negative trend of precipitation time series in some areas of Amazonian basin (Aguilar et al., 2005; Haylock et al., 2006). These positive trends for temperature, and erratic trends for precipitation, are consistent with the climate models projections (Marengo et al., 2009; Urrutia and Vuille, 2009; Cook and Vizy, 2008).

Given the scenario described above, some questions arise about what will happen with South American droughts. Li et al. (2008) showed that, according to the Standardized Precipitation Index (SPI), the Amazon region has been undergone to recurrent drought conditions since 1970s, which were particularly strong during the great drought of 2005 (Zeng et al., 2008). However, it seems that periods of drought in southern South America will be reduced because the spatial re-arrangement of precipitation. The objectives of this project are computing the Dry Spells Length (DSL) for different intensities of drought; as well as, computing trends and future changes on South American droughts using data from Regional Climate Models (RCM).

2 Methodology and Results

2.1 Data

Precipitation's time series from Delaware University database (Matsuura and Willmott 2012a; Matsuura and Willmott 2012b) were used in order to compute the climate model's bias from observed data. The future trends of droughts were estimated using RCM from CORDEX project (Coordinated Regional Climate Downscaling Experiment). The RCM were developed by SMHI (Swedish Meteorological and Hydrological Institute) under the RCP 4.5 and 8.5 (Representative Concentration Pathways). The spatial resolution of the models is about 50 km close to the terrestrial equator.

2.2 Drought definition

The SPI was chosen in the present work as drought's metric (Agnew, 2000). The SPI is among the most widely used drought index because its versatility, since it only uses precipitation data. The SPI could be computed using several temporal scales (e. g. 3, 6, 9 or 12 months). The more negative is the SPI, the more intense are the drought periods.

From the SPI, the depiction of the droughts was done in the reference time window 1961–1990 (also, 1961–1990 was the reference time window to compute the SPI), and in the projected future by the RCM (time window 2071–2100). The droughts were characterized using DSL with a minimal length of two months, together with several levels of drought intensities (through SPI values of 0, −0.5, −1.0, −1.5 and −2.0).

The dry spell length (DSL) time series were built in each grid point. From these time series were computed the mean length of dry spell for each drought intensity, the longest dry spell and was established the number of months in the time windows (i. e. reference and future periods) that were undergo an specific intensity of drought.

2.3 Preliminary results

Initial results show a rise of droughts severity, located in Los Andes mountains from Colombia, Perú and Ecuador. Also, more intense droughts conditions are predicted in the Amazonian basin (tri-border area between Colombia, Peru and Brazil), the Gran Chaco natural region, and southern Chile.

The drought trends are, in general, coherent with the predicted changes on annual mean precipitation, estimated with SMHI-RCM. However, in some regions (e. g. central area of Chile), the rise of drought conditions does not go well with the diminishing on mean precipitation, which suggests a re-arranging of annual cycle of rain.

P-1119-07

Future precipitation extremes are linked to changes in moisture flux anomalies

L. Harrington (1) ; S. Dean, (2)
(1) New Zealand Climate Change Research Institute, Victoria University of Wellington, Wellington, New Zealand; (2) National Institute of Water and Atmospheric Research (NIWA), Wellington, New Zealand

Understanding the response of precipitation extremes to anthropogenic climate change is currently based on a simple thermodynamic link to future warming (proportional to the Clausius–Clapeyron equation). While previous work has identified empirical links between observed flooding events and the occurrence of specific circulation patterns, often containing filamentary bands of anomalous moisture flux, the large-scale dynamics driving extreme precipitation remains poorly characterised. Here, we introduce a diagnostic measure of the explicit link between extreme precipitation events (>99.5th percentile) and incoming moisture flux anomalies. This represents a significant development over previous methods which sought arbitrarily defined 'atmospheric river' events. Robust links are found between anomalous moisture flux and corresponding extreme 24-hour precipitation accumulations, with a particular significance placed on meridional moisture fluxes of tropical origin. Using this metric, we explicitly calculate future changes to the likelihood of precipitation extremes attributed to changes in large-scale moisture and wind fields. Preliminary results of applying this analysis to the CMIP5 ensemble under an RCP8.5 warming scenario are considered, particularly for mid-latitude regions.

P-1119-08

Global Changes in Drought Historically and under Future Climate Scenarios

J. Kam, (1) ; S. Justin (1)
(1) Princeton University, Princeton, United States of America

Droughts are extremely costly hydrological events that can have multiple and long-lasting effects on society and ecosystems. Evidence has been put forward that the risk of drought has increased in recent years due to a changing climate and there is an expectation that droughts will become more severe in the future under projected climate scenarios in response to changes in precipitation and increases in atmospheric demand. Furthermore, direct human impacts on the water resources have already had large impacts on water availability locally and may have as much as, if not more, of an impact in the future. The

compound effect of increasing drought severity and increasing water demand is worrisome, especially for the most vulnerable populations.

This work quantifies and analyzes the evolution of drought during the instrumental period (back to the late 19th century) and under future climate projections from CMIP5 models. Drought is analyzed in terms of its characteristics (frequency, area, duration and severity) and the co-evolution of the forcings (precipitation and potential evaporation). The historical analysis is based on updated multi-model land surface simulations driven by a hybrid meteorological dataset that merges available station observations with reanalysis. Drought is quantified based on anomalies in precipitation, soil moisture and streamflow, representing different aspects of drought: meteorological, agricultural and hydrological. There are considerable uncertainties in long-term changes because of: uncertainties in changes in precipitation due to station sampling and errors in large-scale datasets (e.g. from satellites and reanalyses); uncertainties in changes in other less well observed surface meteorological variables such as humidity and windspeed, and in surface radiation that drive potential evaporation; and uncertainties among land surface models in how drought propagates from meteorological to soil moisture to hydrological drought. In particular, the uncertainties are highest in transitional to dry regions where the station density is generally lower and differences among land surface models becomes important.

Future projections of drought from CMIP5 models indicate an overall propensity towards increased drought severity in many regions due to changes in precipitation seasonality and atmospheric demand. In some regions, such as the Mediterranean and southern Africa, the changes are set against a background of increasing aridity. However, the magnitude of these changes is highly dependent on the climate model in addition to the emissions scenario. We focus on the uncertainty in drought projections with respect to climate model ability to replicate the observational estimates of land-atmosphere coupling as derived from our ensemble of land surface models. Results indicate that the representation of coupling in the models between soil moisture, evapotranspiration, and temperature plays a role in the uncertainty in future projected changes in evapotranspiration with implications for changes in available water and drought.

P-1119-09

Change of vulnerability towards flooding in the commercial sector

H. Kreibich (1)
(1) German Research Centre for Geosciences, Section Hydrology, Potsdam, Germany

Flood risks emerge from extreme hydrological events and exposure of human activities. Various studies have analysed past flood damage data for trends and tried to attribute it to specific drivers. A large part of the observed upward trend in damage is assumed to be related to socio-economic factors. Whereas changes in exposure are relatively well understood, there is hardly any knowledge about changes in susceptibility, particularly in respect to companies, which are quite heterogeneous but contribute a large share of damage.

Therefore, vulnerability data from companies affected by recent floods in Germany were analysed to gain quantitative information about changes in susceptibility during the last decade and how these changes are linked to flood experience and other physical and social drivers.

Preliminary results reveal that in the case of a flood event, most companies undertake emergency measures. The effectiveness of these measures is increased by recent flood experience, emergency plans, reliable warnings with long lead times, and low water levels. Additionally, larger companies that own their buildings seem to be more efficient in undertaking emergency measures. Additionally, many companies undertake precautionary measures after a flood, but still much more could be done. Perhaps the diversity of responsibilities in businesses and the institutional structure create hurdles as well as the level of uncertainty regarding which actions are most cost-effective and will provide significant damage reduction.

P-1119-10

Estimating extreme dry-spell risk in the Ichkeul basin northern Tunisia

M. Mathlouthi (1) ; F. Lebdi (2)
(1) Research Laboratory in Science and Technology of Water in INAT, National agronomic institute of tunisia (inat), Tunis, Tunisia; (2) National Agronomic Institute of Tunisia (INAT),, Génie rural, eaux et forêts, Tunis, Tunisia

Drought is a natural phenomenon that can occur in all regions. Climate variability and climate change in the longer term consequences of economic, social and environmental. It is likely that climate change increases the frequency and duration of droughts, which could contribute to land degradation. One develops the event-based approach tailored to the sub-humid climatic conditions. A dry period is defined as a series of days with daily rainfall less than a given threshold. Unlike the dry period, a dry event may last only one day. Dry events are considered as a sequence of dry days separated by rainfall events from each other. Thus the rainy season is defined as a series of rainfall and subsequent dry events. Rainfall events are defined as the uninterrupted sequence of rainy days, when at last on one day more than a threshold amount of rainfall has been observed. The case study of Lake Ichkeul in north of Tunisia, at a Mediterranean climate, is used to illustrate the approach. One focuses here on the evolution of dry events in duration and frequency in the region under the influence of a changing climate. It identifies the longest dry and wet events on the history. For planning purposes, the longest dry spells associated with the various statistical recurrence periods are derived on the basis of the fitted GEV type probability distribution functions. The event-based rainfall analysis is used to calibrate the precipitation models with little rainfall records, the study of the effects of climate change and to generate long synthetic rainfall event time series. The synthetic sequences of rainfall events and dry events are used to define and calibrate simulation models for realistic planning of reservoirs or for estimating water demand irrigation.

P-1119-11

Historical floods in North Algeria

M. Mohamed (1)
(1) Higher National School of Hydraulics, BLIDA, Algeria

the flood of 1974, which occurred in Kabylie and Algiers regions. This flood has produced 52 dead and 18 000 victims and enormous material damage in Kabylie. The corresponding rates for this event are 2972 m3/s (80-year return period), 2940 m3/s (92-year return period) and 2520 m3/s (130 year return period) at Baghlia, Belloua and Lakhdaria hydrometrics stations respectively in the region of Kabylie. The disaster also affected Algiers. Floods in eastern Algiers, and for the same period, has produced significant damage. At the Baraki station, a flow rate of 1,620 m3/s with a return period of 100 was raised. At the bottom of the Atlas Blidéen, the station of the Rocher des piégeons, a flow of 820 m3/s with a return period of 40 was recorded. The floods were followed a rain event, recorded at mountain pass Skamody (Atlas overlooking the Mitidja East) is 620 mm (58% of the annual total) in four days and 310 mm (30% of the annual total) in one day with 32-year return period. It is noted that the return period of rain is not as important as the maximum flow rates recorded for this period. The city of Azzazga in the Kabilye was also the scene of a spectacular flood in October 1971. The disaster killed 40 people. The return period of the recorded flow is 20 years and generator rain of this flood was 182.6 mm in one day with 300 years return period. The danger of these floods, which caused many deaths and material losses, is due to the combination of the nature of rainfall and the relief of the region. The region is characterized by rugged terrain very favorable to flow and the rapid progression of the flood wave.

In Western countries, the floods of Oued Rhiou, occurred in 1993, caused the death of 22 people. The recorded maximum flow was 719 m3/s with a return period of 17 years. In the same region, in 1965, major floods were recorded with 825 m3/s at Oued Rhiou station and 809 m3/s at Relizane station with a 30-year return period. Also on the west of the country (region I), the floods of October 2000 caused 4 deaths. The maximum flow was 550 m3/s with a return period of 80 years. The maximum rainfall recorded for this period was 85 mm with a return

period of 15 years. It finds that almost the maximum daily rainfall can not explain the dangerous flood but it should be considered a combination of relief and the moisture condition of the soil as important parameters in the genesis of these disastrous floods.

P-1119-12

A 2700 cal yr BP extreme flood event revealed by sediment accumulation in Amazon floodplains

P. Moreira-Turcq (1) ; B. Turcq (2) ; L. Silva Moreira (3) ; RC. Cordeiro (3) ; M. Amorim (3) ; JL. Guyot (4)

(1) Institut de Recherche pour le Développement, GET, Lima, Peru; (2) Institut de Recherche pour le Développement, LOCEAN, Lima, Peru; (3) Universidade Federal Fluminense, Departamento de geoquimica, Niteroi, Brazil; (4) IRD, Lima, Peru

Climatic conditions are one of the most important factors affecting hydrological processes in fluvial systems. Higher discharges are responsible for higher erosion, greater transport, and also higher deposition. Consequently, sediment accumulation in Amazonia floodplain river-connected lakes can be directly related to hydrological patterns of the Amazon River mainstream. In this context, we analyzed five sediment cores taken in two floodplain systems situated in the lower Amazon River, to investigate sediment accumulation patterns during the Holocene. Our records show abrupt fluctuations in sedimentation rates in lakes that can reach more than 2 cm/yr during some periods. We find that in all cores, sediment stratigraphy is characterized by packages of sediments of uniform age, which are typically 10-80 cm thick and present a variegated color. The 14C age of the upper package is about 2700 cal yr BP. During this abrupt event, sediment accumulation rates in floodplain lakes can be at least 200 times higher than those of "normal" periods. This sedimentation event is interpreted as being the consequence of one or several successive extreme floods. The 2700 cal yr BP event has been also observed in other sites in South America and other regions in the world, although different impacts can be observed in each system. This event probably corresponds to a conjunction of favorable conditions for extreme Amazon discharge associated with the Middle to Late Holocene increase of austral summer insolation and shifts of the Intertropical Convergence Zone (ITCZ) from northern to southern positions. In this context, a marked negative peak in solar irradiance at 2700 cal yrs BP seems to have provoked cooling on the continents and a southward shift of the ITCZ associated with a probable reduction in Atlantic Meridian Overturning Circulation.

P-1119-13

Critical erosion rates in mountain catchments during catastrophic events El Niño: from the west central Andes to the Pacific Ocean (Peru)

SB. Morera Julca (1) ; A. Crave, (2) ; JL. Guyot (3) ; A. Desiderio, (4) ; O. Grover, (5) ; S. Vilcabana, (6) ; C. Gálvez, (7) ; T. Condom (8)

(1) Institute Geophysical of Peru, Climate, lima, Peru; (2) Geosciences Rennes, Osur, cnrs, Rennes, France; (3) Institut de recherche pour le développement, Hydrology research, Lima, Peru; (4) Proyecto especial binacional Puyango-Tumbes, Hydrology, Tumbes, Peru; (5) Proyecto especial Chira-Piura, Hydrology, Piura, Peru; (6) Proyecto especial Zaña-Jequetepeque, Hydrology, Cajamarca, Peru; (7) Proyecto especial Chavimochic, Hydrology, Trujillo, Peru; (8) IRD, Lthe, Grenoble, France

Erosion rates and sediment flux from the Andes to the coast of Peru, is largely unknown. The aims of this study is to bridging the knowledge gap by quantifying and understanding the magnitude and signal frequency of sediment fluxes from the west central Andes mountains to the Pacific coast. A new extensive suspended sediment yield (SSY) database from short to long-term erosion was collected (1948-2012). Measurements were taken at piedmont stations of twenty sub-catchments (638-16949 km2) located between 2°S to 18°S. Statistical analysis of suspended sediment fluxes (SSF) time series at daily and sub-daily frequency revealed that, Suspended Sediment Concentration (SSC) response immediately to runoff during water discharge peaks. However, annual correlation coefficient (R) between runoff and SSF along the Peruvian coast show a wide range from 0 to 0.9 ($p < 0.05$). Results also show strong latitudinal and longitudinal runoff gradient ranges from 2.4 to 25.5 l.km-2.year-1 and a wide SSY range from 9 to 2 000 t.km-2.year-1. SSY in Peru increased dramatically during extreme events El Niño (1982-83 and 1997-98) from 10 to 60 times in comparison with historical mean SSY. Finally, extreme events El Niño control SSY in the north of Peru (from 2°S to 9°S). Meanwhile, factors which control SSY during normal years are not fully understood, further studies on this topic are conducted.

P-1119-14

Modeling of maximal spring flood runoff on rivers in Ukraine with using CCSM3 and HADCM3 for the medium (2030-2050) and long term (2070 and beyond)

V. Ovcharuk (1)

(1) Odessa State Environmental University, Hydrometeorological Institute, Odessa, Ukraine

Currently very relevant is the issue of changing the water cycle under the influence of global climate change. The main area of research is the study of the water balance components in general, such as surface runoff of rivers, underground flow, evaporation, etc. However, as the events of recent years, the quantity and quality of extreme events, such as catastrophic floods also significantly associated with climate change. Thus, the study of quantitative characteristics of maximum river flow rare probability of exceedance as well as their forecast for the near future (2030-2050) and long term (2070 and beyond) is an important scientific problem of modern science. The authors of this study are propose a variant of calculation formula of maximum river flow, that allows, on the one hand to count the maximum water flow rare exceedance probability (P=1,3,5,10%), and on the other hand - to predict possible changes in the values obtained using the data different models. In order to obtain predictive values of temperature and rainfall in the plains of Ukraine in the study were using simulation results of two different global climate models- HadCM3 (Meteorological Service UK MetOffice), and climate models (CCSM3) from National Center for atmospheric Research (NCAR, USA). The next task was to study the relationship between the predicted values (eg, annual precipitation) and calculated values - maximum snow supplies and precipitation during the flood. For the plain territory of Ukraine on data 103 weather stations (for maximum snow supplies) and 315 weather stations (for the precipitation) were obtained relevant dependencies that have high correlation coefficients, indicating the possibility of direct incorporation of climate change on flood runoff. The simulation results are presented in the form of the coefficients of runoff change. The value of the coefficient of runoff changes taken equal to 1.0 for current situation, respectively, the value of this ratio is greater than 1.0 indicate a possible increase in runoff, and less than 1.0 - the decrease. Comparing the results for different scenarios for the model CCSM3, we can mention that for the period 2039 three scenarios (A1B, B1, A2) give more or less similar results - no significant decrease in runoff spring flood in northern areas, and significant - in the southern. Conversely scenario COMMIT provides for increased discharges spring flood on rivers in zone of sufficient moisture (basins of Western Bug, Pripyat, Desna, Dnieper) by 10-20%, and on the rivers in the zone insufficient moisture (basins of Southern Bug and Seversky Donets) - reduction to 20%. As for Azov region rivers, for them, as well as in other scenarios expected to reduce runoff spring flood more than 50%. Analyzing the forecasting period from 2069 to 2099, it should be noted that the results differ significantly for different scenarios. So scenarios A1B and A2 on 2099 are predicting practical disappearance spring flood (water content decrease from 100 to 80%) on the rivers zone insufficient moisture, and to areas of sufficient moisture - reducing runoff by more than 50%. Slightly different results provide scenarios B1 and COMMIT. The scenario B1 for the period until 2069 predict is a gradual decrease in water resources of spring flood (from 20% to 50%), excepting to rivers Azov region, and on the period up to 2099 - a slight increase in the relative to 2069 for the rivers in area of sufficient moisture and stabilization - for rivers in area insufficient moisture. For rivers Azov region are predicting maximum loss of runoff in the spring - up about 80%. The scenario COMMIT, which implies that the

concentration of atmospheric greenhouse gases will be maintained at 2000 levels, predicted gradual increase in water content of rivers in northern regions from 10 to 20%, and a slight decline - for the rivers of the southern regions (10 to 20%). For rivers Azov region spring flood runoff will decrease by 50% to 2099.As already noted, the calculations of «climate amendments» were held in two models - CCSM3 and HADCM3. Simulation results for HADCM3 very different from model of CCSM3. Almost in all scenarios are projected sharp increase in water content (2.5-3 times) for the period until 2039, and then the same sharp decrease (especially for scenarios A2 and A1B) water content spring flood. The scenario B1 is predicted stabilization of water resources, ie, till 2099 coefficient of change of almost all rivers except the Azov region, is 1.0. As for the script COMMIT, there is projected to increase runoff of spring flood from 1.75 to 3.5 times by 2069.

P-1119-15

Extreme Hydrological Events, Vulnerability and Coping Mechanism for Sustainable Livelihood in Alaknanda River, Basin, Uttarakhand

BW. Pandey (1)

(1) University of Delhi, Department of Geography, Delhi, India

Extreme events are sudden calamities, which involve loss of life, property and livelihood. This paper presents a methodological approach for the integration of extreme events, climatic vulnerability, land use scenario modeling and flood risk assessment. Alaknanda river basin is located in the eastern part of the Garhwal Himalaya and represents one of the most acutely hazard-prone regions in the country. The important factor causing flood and also accelerate several hydrological hazards during monsoon periods in Alaknanda river are heavy rainfall, cloud burst, GLOF, landslides, Slope failure, earthquakes, deforestation, poor drainage due to urbanisation. These hydrological hazards are mainly responsible for several socioeconomic consequences (cultivated land degradation, infrastructure loss, human casualties, loss of transmission lines, and so on) in the Alaknanda river basin, Uttarakhand. Primary data from each hotspot has been collected through a questionnaire survey and a Participatory Research Approach (PRA) procedure that is based on the LIFE approach. The LIFE Approach is based on Livelihood options, Institutional participation in adaptation policy design and implementation, Food security and Empowerment parameters like health and education. These parameters are important in building resilience capacity and ensuring sustainable development pathways. The methodology will be consists of a number of steps with primary and secondary data analysis. This paper also provides various mitigation processes for the challenges faced and formulate sustainable development strategy for the development in the Alaknanda river basin, Uttarakhand.

P-1119-16

Hydrological extremes, food security and agriculture in western Amazon

J. Ronchail (1) ; T. Schor (2) ; M. Sabot (3) ; JC. Espinoza (4) ; N. Filizola (5) ; G. Drapeau (6) ; JL. Guyot (7) ; JM. Martinez (8)

(1) LOCEAN and Université Paris Diderot, Paris, France; (2) Universidade Federal de Amazonas, Nepecab, Manaus, Brazil; (3) Univesité Pierre et Marie Curie, Paris, France; (4) Instituto Geofisico del Peru, Lima, Peru; (5) Universidade Federal de Amazonas, Lapa, Manaus, Brazil; (6) LOCEAN, Université Paris Diderot and PRODIG, Paris, France; (7) IRD, Lima, Peru; (8) IRD, GET Laboratory, Toulouse, France

The water level of the Amazon and of its tributaries varies significantly from one season to another. For instance, at Iquitos station (Peru), the water level varies from 18 meters in May-June to 8 meters in September-October. That is why, during the low-flow period, cultivating becomes possible and is important on the riverbanks and in the inundation plains.

Agricultural production in a family-based system on the riverbanks and inundation plains is very important in terms of guarantee of supply for food security. In order to understand the important relation between agriculture, food security and hydrological system some characteristics of the local agriculture in the Amazonian region located between Iquitos (Peru) and the triple frontier between Brazil, Peru and Colombia are first presented using results from field observations, survey and data from the Peruvian and Brazilian Agricultural agencies.

Then, information about the interannual variability (1980-2014) of the hydrological cycle of the Solimões River are presented: discussion and definition of the dates of the beginning and of the end of the low-flow period, duration of the low flow period, velocity of the water level changes during the increasing and decreasing flow periods, presence of "false alarm" at the beginning or at the end of the dry and the wet period, ... This part is developed using water level data from the national hydrological services of Peru and Brazil and from the Environmental Research Observatory SO-HYBAM (Geodynamical, hydrological and biogeochemical control of erosion/alteration and material transport in the Amazon basin).

Finally, as a shorter than usual length of the low flow season, a rapid increase of the water level, a "false" beginning of the low water season, etc. are hazards that may put at risk sowing and plant development, hydrological parameters are related to yield values seeking possible correlations between extreme events and food security in the region.

P-1119-17

A mineralogical and organic geochemical overview of the effects of Holocene changes in Amazon River flow on three floodplain lakes

L. Silva Moreira (1) ; P. Moreira-Turcq (2) ; B. Turcq (3) ; RC. Cordeiro (4) ; S. Caquineau (5)

(1) Universidade Federal Fluminense, Departamento de geoquimica, Niterói, Rio de Janeiro, Brazil; (2) Institut de Recherche pour le Développement, GET, Lima, Peru; (3) Institut de Recherche pour le Développement, Lima, Peru; (4) Universidade Federal Fluminense, Departamento de geoquimica, Niteroi, Brazil; (5) Institut de Recherche pour le Développement, Bondy, France

A synthesis of the impacts of the Amazon River hydrological changes on the sedimentation process of organic matter (OM) in three different floodplain lakes (Santa Ninha, Maracá, and Comprido lakes) is presented in this study. Today the Santa Ninha and Maracá lakes are directly and permanently connected with the main channel of the Amazon River, in contrast to Comprido Lake, which is indirectly and periodically influenced by the Amazon River due to its greater distance from the main channel. All three lake sediment records showed a reduced river inflow due to dry climatic conditions during the early and middle Holocene followed by an increased fluvial input during the wetter late Holocene. In Santa Ninha and Maraca Lakes, the reduced river inflow period was recorded by sediments with a low abundance of smectite (on average ~20 wt.%), a clay mineral mainly transported by the fluvial system, and high total organic carbon (TOC) contents (on average ~8.2 wt.%). During the late Holocene, a higher smectite abundance (on average ~43 wt.%) and a lower TOC content (on average ~1.4 wt.%) pointed to greater dilution by riverine lithogenic matter. This change was accompanied by the increase in aquatic primary productivity, as shown by the increased δ13C values and by a C/N typical of algae, suggesting a higher lake water level. In Comprido Lake, a sedimentation gap occurred during the early and middle Holocene. The wetter late Holocene, from 3000 cal years BP onwards, a gradual increase of the TOC, chlorophyll derivatives and Aulacoseira sp. suggest an increase in the productivity and in water lake level due to the high water flow of the Amazon River and the catchment area as well. Consequently, our study shows that the sedimentation processes of organic matter in Amazonian floodplain lakes were strongly influenced by variations in the hydrodynamic regime of the Amazon River during the Holocene. However, the impacts of the variations on the three floodplain lakes were different depending on the distance of each lake from the main channel of the Amazon River.

Run-off events registered in East Pacific equatorial region during the late Holocene: analysis of possible causes through IPSL model transient simulation

B. Turcq (1) ; O. Marti, (2) ; P. Braconnot (2) ; M. Saint-Lu, (2) ; J. Leloup, (3) ; D. Gutierrez Aguilar (4)

(1) Institut de Recherche pour le Développement, Locean-ipsl/upch, Lima, Peru; (2) LSCE-IPSL, Gif-sur-Yvette, France; (3) LOCEAN - IPSL, Paris, France; (4) Instituto del Mar del Perú, IMARPE, Dirección General de Investigaciones en Oceanografía y Cambio Climático, Callao, Peru

An increase of clastic sediment inputs has been observed between 5 and 4 kyrs BP in lakes of the equatorial region of South America, in Ecuador and Galapagos islands as well as in marine sediments off Northern Peru. These changes in sedimentation have been interpreted as a strengthening of El Niño due to insolation change. Conversely, data from central and west-Pacific corals do not indicate a clear trend of ENSO change during the Holocene but strong centennial to millennial oscillations.

To help interpreting the climate change in this region we analyzed a transient simulation of IPSL CM5A LR global climate model from 6 to 3kyrs. The simulation indicates an increase of heavy rainfall events (monthly rainfall intensity) in the East Pacific (90-80°W, 0-6°S) since 5kyrs. Most of these events are linked to occurrences of El Niño events and the summer precipitations show a multi-decadal variability related with the variability of SST anomalies in El Niño 3-4 region.

However the model did not show important change in SST anomalies in ENSO 3_4 or ENSO 1+2 regions during this period although there is a 0.2°C increase of SST between 6 and 5kyrs. The comparison between 6 and 4 kyrs precipitation maps show that the main difference is a northern shift of ITCZ position during South Hemisphere summer that provokes more intense rainfall in the study region. This northern shift is also observed on the Atlantic Ocean in agreement with paleoclimate data from lakes and speleothems in Northeast Brazil. In conclusion the IPSL transient simulation suggest that the impact of El Niño events in term of precipitations in the East Pacific can have been modulated by shift of the ITCZ during the Holocene.

Extreme precipitation events trigger floods with devastating effects, causing several economic and environmental impacts, and even human causalities. To understand how extreme precipitation events propagate spatially to the river response is a high priority in the Mediterranean region, where heavy precipitation events are frequent, but they tend to occur randomly in space and time and our predictive capacity of these events is usually low. In recent decades, climate change processes have been identified in the Mediterranean region, affecting the magnitude of extreme precipitation events. Nevertheless, the evolution of extreme hydrological events may be different to that observed by precipitation extremes in past decades, given strong land cover changes and/or river regulation, water management practices and water uses.

To know the effect of the management of hydrological basins on the evolution of extreme hydrological events may help to adapt the society response to future climate change scenarios. In this study we analyse the evolution of extreme precipitation and hydrological events in the past five decades in three basins of Catalonia (NE Spain): Muga, Ter and Segre. These basins have their headwaters in the Catalan Pyrenees and they have been highly regulated by numerous dams in the second half of the twentieth century. Nevertheless, they are characterized by different water uses, land covers and management strategies and they include one of the main irrigated areas of Spain (the Segre basin), the Metropolitan Barcelona area in which there is large urban water demand (more than 4.5M people), and also high pressure tourism areas in the Mediterranean coastland.

Analyses have shown how the progressive increase of the natural vegetation coverage and mainly the increased river regulation enhance the missmatch between the frequency and magnitude of extreme precipitation and streamflow events. Nevertheless, very extreme high flow episodes have also been recorded in the three basins in the last decades, reinforcing the hypothesis that although damming and water management may control hydrological extreme events to some extent, the high flow risk will probably remain or even reinforce under climate change scenarios.

This study has been developed in the frame of the project: «LIFE12 ENV/ES/000536 Demonstration and validation of innovative methodology for regional climate change adaptation in the Mediterranean area (MEDACC)» financed by the LIFE Programme of the European Commission and focused on establishing adaptation strategies to mitigate the impacts of climate change on water resources in the three analyzed basins.

1121 - Air Pollution and Climate Change linkages and Health Impact Assessment

ORAL PRESENTATIONS

K-1121-01

Air Pollution, Climate Change and Human Health

P. Kinney (1)

(1) Columbia University, Mailman School of Public Health, Climate and Health Program, New York, NY, United States of America

Air quality is a major modifiable health burden around the world, especially in rapidly developing cities. Exposure to air pollution, including fine particles (PM2.5) and ozone, has adverse effects on human health throughout the lifespan. Adverse effects of air pollution include the development of chronic diseases such as lung cancer, chronic heart and lung diseases, as well as adverse effects on the reproductive system and on neuro-development. Action to mitigate air pollution brings immediate and lasting benefits for the health and well-being of the population. In addition, well-designed air pollution mitigation actions have the potential to reduce societal impacts on the climate system. In order to inform global, regional and urban scale air pollution and climate planning, there is a need for multi-scale health impact assessments that estimate the potential health impacts and/or benefits that may result from coordinated mitigation strategies. We describe several such recent and/or ongoing efforts of this kind. For example, the recently-completed AC-HIA project estimated the influence that policies aimed at reducing air pollution emissions could have on global, regional and urban public health in 2030 and 2050, compared to 2010, taking into account the influence of climate change and alternative air pollution mitigation scenarios. Assessments were carried out across three different geographic scales with increasing spatial

granularity, for the entire world, for Europe, and for the Paris metropolitan region. Two mitigation scenarios were evaluated: a business as usual scenario based on national regulations already on the books, and a maximum feasible reduction scenarios based on available technologies for air pollution control. The results showed the potential for substantial increases in global deaths due to PM2.5 and ozone under the business as usual scenarios, especially in south and east Asia. On the other hand, substantial health benefits could be achieved under the maximum feasible reduction scenario. In general, health assessments carried out at finer spatial scales yielded greater health benefit estimates. This and other studies are pointing the way to a new generation of tools for integrated air quality and climate planning.

Enormous health benefits can be achieved from well-chosen climate mitigation strategies that simultaneously reduce air pollution concentrations in the local and regional environments in which the emission reductions occur. However, to evaluate those benefits in relation to specific mitigation options, careful analyses are needed at appropriate spatial scales to link the air pollution reductions to locations of vulnerable populations. Through such analyses, alternative mitigation strategies can be compared and prioritized based on their potential health benefits, providing critical input to decision makers.

Public health response to climate change in twenty-two European countries

B. Menne (1) ; V. Kendrovski, (2) ; T. Wolf (3) ; S. Gerardo (2) ; J. Creswick (3)
(1) WHO, Program manager, climate change and sustainable development, WHO, ECEH, Bonn, Germany; (2) WHO, Bonn, Germany; (3) WHO, Cgs, Bonn, Germany

Introduction: WHO European Member States (53 countries) agreed on implementing the European Framework for action on climate change and health. One of the mandate is the assessment of health implications of climate changre and the development of national health adaptation plans, as a contribution to WHO and UNFCCC developments.

Scope: to assess the scale and content of the national adaptation plans and the assessments, to identify incremental, transitional and transformational approaches and to guide future political and scientific developments

Result: Between 2000 and 2014, twenty-two WHO European Member States, developed national adaptation plans with a health component; while 32 European Member States assessed the health implications of climate change. Most of the WHO European Region Member States have mainly focused on strengthening their health systems through a range of specific measures. All measures idenified mainly serve to address curent health problmes. Measures include: strengthened infectious disease surveillance; strengthened environmental health services, such as water, sanitation and vaccination; and nsynergise with the International Health Regulations. Fewer countries have been using new technologise and approaches, such as strengthened early-warning and disaster responses and integrated mapping. None has been using transfrmational approaches versus a 4 degree world, and large scale prevention of associated risks. Countries highlighted the need for health benefitting mitigation measures for adaptation: these include local community action, improving air quaility, greening health services and renewable energy technologise. Examples from MS will be illustrated

Discussion: Synergistic interventions on both adaptation and mitigation, can in particular be useful for health and well-being. The post 2015 development agenda will play an increasing important role. It will be important to provide an understanding of the wider dimension to health and environment decision makers.

O-1121-02

The impact of climate policies on European air quality in the 21st century

A. Colette (1) ; S. Schucht, (1) ; B. Bessagnet, (1) ; M. Holland, (2) ; Z. Klimont, (3) ; L. Menut, (4) ; S. Rao, (3) ; S. Szopa, (5) ; R. Vautard (6) ; JM. Brignon, (1) ; L. Rouil, (1)
(1) INERIS, Verneuil-en-Halatte, France; (2) EMRC, London, United Kingdom; (3) IIASA, Laxenburg, Austria; (4) IPSL, Palaiseau, France; (5) IPSL, Saclay, France; (6) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France

Climate change, long range transport of pollutants and surface air quality share multiple interaction pathways. Tailoring efficient air quality mitigation strategies over the long term requires taking into account such external factors whose variability can be neglected for short term projections. We designed, developed and implemented a new regional air quality and climate modelling system to account for the possible penalties of climate change and long range transport of pollutants on European air quality. In order to ensure its relevance for environmental policy making, this modelling system is embedded in a quantitative cost-benefit analysis framework.

The regional air quality and climate modelling suite allowed proposing an assessment of European air quality in 2050. We highlighted the dominating influence of mitigation of anthropogenic emissions of pollutants in Europe. But the penalty brought about by climate change on ozone pollution was also confirmed, and the large impact of long range transport at the 2050 horizon was emphasized. For particulate matter, long range transport is less important; the impact of climate change is significant but also uncertain.

Thanks to the use of air pollutant emission projections based on emission factors reflecting the current legislation, we could assess the costs of climate mitigation and air quality legislation. We point out the economic benefit of climate policies for air quality legislation due to a low carbon economy requiring less end-of-pipe technological measures against air pollution. The total cost of mitigation (air and climate) remains however higher under the mitigation than under the business as usual pathway.

The analysis of air and climate modelling results within a monetised health impact assessment framework allowed assessing expected sanitary benefits. It is important to highlight that the expected monetised sanitary benefits compensates the costs of climate mitigation, showing that air quality can be considered as a positive externality of low carbon policies.

O-1121-03

Global and European scale health impact assessment (HIA) of PM2.5 over the 21st century

V. Likhvar (1)
(1) CNRS, Paris, France

Multi-scale approach to health impact assessment (HIA) can illustrate the difference in direct consequences of costly mitigation policies. Although this approach provides results that may help decision-makers choose between different policy alternatives at different scales, it has several limitations, such as the choice of concentration-response function (CRF). The recently developed integrated exposure-response (IER) model (Burnett et al. 2014) combines global relative risk information from different combustion types of PM emissions, and can describe exposure-response relationships between PM2.5 and leading global causes of death, such as ischemic heart disease (IHD), cerebrovascular disease (stroke), chronic obstructive pulmonary disease (COPD), and lung cancer (LC). Using this model and ECLIPSE air pollution scenarios (current legislation (CLE) and maximum feasible (MFR)), we estimated future impact of PM2.5 on health at global and European scales in 2030 and 2050. Our preliminary results showed that 1/3 of total global burden of ambient air pollution on IHD deaths is associated with PM2.5 (488 000 deaths/year). If maximum reduction measures are implemented by 2030, this should be reduced globally by 17%; on the other hand, with the current legislation scenario the number of IHD deaths should continue to increase, and by 2030 will reach 586 000 deaths annually. However, these results may be greatly underestimated, as the PM concentration levels produced by the global model were much lower compared to the regional scale estimates.

O-1121-04

Evaluating air quality impact on mortality and crop yields in South Asia

S. Ghude (1) ; C. Jena (1) ; D. Chate (1) ; G. Beig (1)
(1) Indian Institute of tropical Meteorology, Pune, India

Climate change has been shown to increase surface O3 in many regions of the world and have raised concerns about the O3 impact on mortality and the magnitude of yield reductions, primarily occurring in the developing nations.

Demographically agriculture is the broadest economic sector, rank worldwide second in farm output and principle source of livelihood for more than 58% of 1.2 billion populations which plays an important role in the overall socio-economic fabric of India. We have quantified, for the first time, a district-wise impact of surface ozone on cotton, soybeans, and rice and wheat crops for all of India. On a national scale, we eastimate fractional relative yield loss for wheat of about 5.0 (±1.2) %, 2.1 (±0.9) % for rice, 5.3 (±3.1) % for cotton and 2.7 (±1.9) % for Soyabean, with the losses concentrated in central and the Indo-gangetic plains of north India. In terms of absolute production losses by weight, wheat is the most impacted crop, with losses of 3.5±0.8 Mt followed by rice (2.1±0.8 Mt) sufficient to feed 94 million people living below poverty line in India. Translating crop production losses into national economic damage, we estimate an economic loss of 1.29 ±0.47 billion USD. Sensitivity studies with the integrated model study reveals NOx as the key pollutant causing as much as 93% of the crop loss.

Significant portion of human population in India is believed to be regularly exposed to higher surface ozone (O3) levels. Here, we have also evaluate total, cardiovascular and respiratory mortalities and hospitalizations (COPD) caused by population exposure to surface O3. Attributable mortalities are quantified using health impact function of long-term relative risk estimates (population attributable-risk proportion) for O3 from epidemiology literature. We calculated total mortality of about 1125 thousands, 404 thousands by cardiovascular deceases and 176 thousands by respiratory deceases, and COPD cases of about 175 thousands caused by O3 exposure to population of India in 2005. The highest number of total, cardiovascular and respiratory mortalities and COPD cases are found in the highly populated Indo-Gangetic region followed by metro-cities and sub-urban and industrial areas.

O-1121-05

Impacts of Climate change and seed dispersal on airborne ragweed pollen concentrations in Europe

L. Hamaoui-Laguel (1) ; R. Vautard (2) ; L. Liu (3) ; F. Solmon (3) ; N. Viovy (2) ; D. Khvorostyanov (4) ; F. Essl (5) ; I. Chuine (6) ; A. Colette (1) ; J. Storkey (7) ; MA. Epstein (8)
(1) Institut National de l'Environnement Industriel et des Risques, Verneuil-en-Halatte, France; (2) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France; (3) International Centre for Theoretical Physics, Trieste, Italy; (4) Laboratoire de Météorologie Dynamique, CNRS, Palaiseau, France; (5) University of Vienna, Vienna, Austria; (6) Centre d'Ecologie Fonctionnelle et Evolutive, CNRS, Montpellier, France; (7) Rothamsted Research, Harpenden, United Kingdom; (8) Medical University of Vienna, Vienna, Austria

Common ragweed (Ambrosia artemisiifolia) is an invasive weed native to North America producing very allergenic pollen which causes serious health effects like rhinitis, asthma and atopic dermatitis. It was introduced in Europe since the mid-19th century and invaded large areas during the last few decades (Pannonian plain, Northern Italy and South-Eastern France). Furthermore, there is a high potential for ragweed spread in current suitable habitats and future changes in Climate and land use may increase the spread by altering the climatic niche determined by physiological thresholds or affecting cropping patterns. The rate of spread depends also on seed dispersal due to natural or anthropogenic processes and the efficiency of ragweed eradication policies. However, ragweed airborne pollen concentrations depend not only on plant infestation, but also on phenology, pollen production, release, dispersion and atmospheric transport.

Here, we present the first integrated modelling framework, based on an explicit representation of plant phenology, pollen production, and release to the atmosphere, to assess future changes in airborne pollen concentration under scenarios of climate and land use changes and seed dispersal. Two model suites are implemented differing in the atmospheric processing and in the driving climate models. The CHIMERE suite uses the Chemistry-Transport Model CHIMERE model, forced by regional climate simulations from the WRF model downscaling of the IPSL-CM5A-MR model. The RegCM suite uses the RegCM4 regional climate model forced by global climate simulations from HadGEM CMIP5.

We performed three types of simulations (50 km grid covering Europe), which are hind-cast (2000-2012), historical (1986-2005) and future (2041-2060) simulations. The hindcast simulations, forced by ERA-Interim reanalysis, are performed to calibrate and evaluate the modelling chain. The historical simulations are carried out using calibrated ragweed density to serve as a reference simulation for the future. We considered two contrasting RCPs (Representative Concentration Pathways) climate change scenarios including a high-end (RCP 8.5) and moderate (RCP 4.5) climate change scenarios and three seed dispersal scenarios (reference, slow and rapid).

We show that airborne pollen concentrations may drastically increase in 2050 by a factor of 4.5 under high-end (RCP 8.5) and 4.0 under moderate (RCP 4.5) climate change scenarios. This upsurge is largely dependent on the seed dispersal rate, making this increase vary in a range of factors from 2 to 12 according to the range of formulated assumptions. We estimate that about one third of the projected increases of pollen concentration are due to the on-going seed dispersal within the present niche regardless of climate change. Climate change will be responsible of two thirds of the future pollen loads increase. It will extend the habitat suitability for ragweed in Northern and Eastern Europe and result in higher pollen concentrations in established ragweed areas mostly due to a larger primary production with increasing CO2. Therefore, future increase of airborne pollen concentrations will be caused by the combined effects of climate change and ragweed seed dispersal in current and future suitable areas.

Our results indicate that controlling the current European ragweed invasion will become more difficult in the future as the environment will be more favourable for ragweed growth and spread, highlighting the need for the development of effective and regionally co-ordinated eradication programmes.

The Air Quality Improvement by Precipitation during the Spring Season

SH. Ahn (1) ; SW. Lee (1) ; JY. Kim (1) ; CH. Park (1)
(1) National Institute of Meteorological Research (NIMR), Research Planning and Management Division, Seogwipo-si, Jeju-do, Republic of Korea

Meteorological elements determining air quality are significant, given that many premature deaths each year are attributed to air pollution. The washout effect of summertime precipitation on air pollutants is of importance, since every spring yellow dust and high level of particulate matter (PM) in the Korean Peninsula has reduced visibility and threatened the health of the people. The air pollutant is a substance in solid, liquid, or gaseous form in the air, which is caused by natural action and human activities. Air pollution is a serious problem that threatens the health of the people, inflicts harm to plants or structures and causes toxic effects to the environment. These air pollutants are removed from the air by wet deposition process referring to precipitation, fog, and condensation. This study has analyzed air quality improvement with the concentration variation of four pollutants (PM10, NO2, CO, and SO2) during the spring season in the Korean Peninsula. During the period 2009 to 2013, we selected 56 cases that were accompanied by nationwide precipitation, and used the observation data on automatic air pollution from the Ministry of Environment (MOE) and the precipitation data from the Korea Meteorological Administration (KMA). We calculated the difference of air pollutant concentration during the

period with no precipitation and with precipitation. The concentration (PM10, NO2, CO, and SO2) during the precipitation period was lower (29.8%, 9.8%, 3.4%, and 21.5%, respectively) compared to that of during the no precipitation period. Furthermore, the air quality has greatly improved as the duration of precipitation increased. The result seems to imply that spring precipitation has a significant influence on the removal of the PM10, which penetrates the lung and threatens the health.

Aeolian flux quantification of the waste mining deposit: field measurement and empirical modelling. Case of the Hammam Zriba landforms (Zaghouan, Tunisia)

O. Amrouni (1) ; T. Ben Moussa (2) ; S. Abdeljaouad (3)
(1) National Institute of Marine Sciences and Technologies, Laboratory of Marine Environment, Carthage, Tunisia; (2) Faculté des Sciences de Tunis, Géologie, Ezzahra, Tunisia; (3) University of El Manar, Faculty of Sciences, Department of geology, Tunis, Tunisia

The aim of this study is the quantification of the air flux mining waste pollution throughout the human landforms. The study field, located on the lee side of Jebal Boukhrouh mountain (Hmmam Zriba Locality, Zaghouan), is mainly exposed to the frequent dust strom event which entrains the dispersion of the dams deposit. Using the vertical sand trap (type Rosen, 1978) along three cross profiles (from the dam to the olive tree field) under a dust storm event of May 12, 2013 (direction: west to west north west, speed ≥ 15 m/s) , we quantify the aeolian waste mining flux. Vertical distribution of sand transport flux was studied with the 39 sand samples. Results show that the volume of the aeolian flux indicates variation. In fact, the topography of the area and the nature of the sediments, land use and climatic conditions (wind speed, humidity, etc.) are limiting factors in the transport and dispersion of mining waste particle. Considering these parameters, the measured wind flow can reach 6.4 kg/m/min at the dune feet, accumulated on the olive tree obstacle. However at the dune summit measured flux do not exceed 1.4 kg /m/ min. The steep slope of the dune lee side causes an acceleration of the flow. Wind fluxes measured at the blowouts and the corridors are between 0.2 and 0.6 kg /m/min. It corresponds to turbulent areas where wind velocity becomes higher than 9 m/s. The values of moisture percentages vary between 2.5 and 3.5 for all our samples. Threshold friction velocities (u* t) are between 0.22 and 0.311 ms −1. Making corrections to the values of measured flow and moisture such as the humidity of sediments, u* t reached 0.606 ms−1, the Dr correlation index (calculated flux/empirical flux index) becomes much lower. This confirms the close relationship between the threshold friction velocity and wind flow. Although the semi-empirical formulas established by Bagnold (1941) and Zingg (1953) do not involve this parameter, the correction of the measured flux reduced the difference. Of the frequently used models that described vertical distribution of sand flux, Zingg's model produced the best values with the modified measured waste mining flux.

P-1121-03

PM carbonaceous fraction in relationship both to the atmospheric budget and the new technologies

P. Avino (1) ; G. Quartieri (2) ; P. Quercia (3) ; CB. Eric (4)
(1) INAIL, DIT, Rome, Italy; (2) IUSR http://www.unisrita.it, PHYSICS, SAN PIETRO INFINE (Caserta), Italy; (3) IBR University, Rome, Italy; (4) OIKOS, Rome, Italy

As part of the energy decisions that are being considered, the extent of the budget of organic carbon (OC) and elemental carbon (EC) assumes a primary importance. in particular, it is essential to measure the relative fractions for a correct evaluation of air pollution from combustion processes. The use of these measures is used to define a specific index of pollution from motor vehicle traffic. iInfatti, these measures become very relevant for the protection of the health of the population for the high permanence of carbon particles in the atmosphere and the many chemical and physical processes of transformation that they may undergo in the atmosphere.

The good correlation between the values of OC and EC shows that the area of the historic center of Rome the most important source of particulate carbonaceous fraction is in the motor vehicle traffic, ie an element typically anthropic, as indeed in the main industrial area source is the combustion. instead different situation is found in a remote area, where this correlation is reversed from the point of view of quality and is. decisasmente lower by quantitatively indicating the presence of natural sources.

the separation between EC, of primary origin, and OC, the source primary and secondary, is of fundamental importance for the study of the effects pneumoconiogeni and, more generally, for the toxic effects and for the study of the mechanisms of formation of photochemical pollutants. it follows that, on a microscale, the carbon becomes more important negative for human health than other natural environmental factors.

You can make a first distinction between risk and risk widespread local anthropogenic natural; However, the local risk tends to increase rapidly as evidenced by all the curves and the time series presented recently by several authors.

The anthropogenic component becomes more important and fundamental as to require choices and impose serious and important related to the lifestyle of the population.

Finally, in this horizon quite accurate plus future situations by having to still monitor: the conversion of coal, for example, of new industries are not yet known, especially how it affects the territory locale.in any case, new energy technologies, definitely interesting for the greater energy yield, should be evaluated from the point of view of environmental compatibility.

P-1121-04

Evaluation of the Spatial Relationship between Air Pollution and Respiratory Infections in Meknes City, Morocco

I. Boularab (1) ; O. Mouhaddach (1) ; MP. Kestemont (2) ; S. El Jaafari (1)
(1) Moulay Ismail University, Meknes, Morocco; (2) Catholic University of Louvain, Louvain-la-Neuve, Belgium

Background: With 3.7 million premature deaths in 2012, the World Health Organization indicates that air pollution is a major environmental risk. In Morocco, 41% of the morbidity associated to respiratory infections due to air pollution. Despite this health risk clearly linked to air pollution, there are few studies conducted in the relation air pollution- health in Meknes, the capital of the Meknes-Tafilalet region.

The analyses of geographical distribution of respiratory infections in Meknes city, as well as the study of its relation to potential environmental risk factors, have an important role to develop an efficient system for the monitoring and prevention of this type of diseases.

Methods & Results: The present study aims to elucidate the relationship between air pollution in the Meknes city and the spatial distribution of respiratory consultations as health indicator. First, we present an overview of the mobile and stationary sources of air pollution in the city, with measurements of key pollutants. What helped to reveal that Meknes city suffers from air pollution by diverse sources and characterized by spatial and seasonal variability.

Next, we analyze the epidemiological situation of the health indicator, depending on the age and time, and the spatial distribution of their accumulated incidence compared to sources positions. It follows that an increase in the number of new consultations is disclose specially in the Autumn-Winter period and between persons less than 15 years. This variability also observed in space distribution, with a net increase in neighborhoods in the vicinity of sources of air pollution, particularly those situated in the wind direction promoting the flow of pollutants.

Conclusion & Perspectives: Revealing the impact on the health of urban dwellers in the city of Meknes quite heavy, the identification of air pollution's risky areas and age categories is a milestone in the establishment of a support system for decision-making of air quality monitoring, for local authorities of Meknes city.

P-1121-05

Climate and risk of vector borne zoonotic disease emergence: examples of Rift Valley and West Nile fevers

V. Chevalier (1) ; A. Tran (2)
(1) CIRAD, Montpellier, France; (2) CIRAD, Es, Montpellier, France

Vector borne diseases have a major impact on human and animal health, but also on society economy. Due to their transmission routes, zoonotic or not, these diseases are very sensitive to climatic changes. Actors, conditions and processes requested for disease transmission are part of a complex and dynamic system whose behavior, influenced by climate but also by other environmental and socio-economic components, drive potential for pathogen transmission and outbreak occurrence. We illustrate this complexity through two examples, ie Rift Valley and West Nile fevers.

Rift Valley fever (RVF) is one of the most important viral zoonoses in Africa. Transmitted by mosquitoes and direct contact, RVF affects both livestock and humans. Due to global changes, RVF also threats Northern Africa and Southern Europe (Chevalier, Pépin et al. 2010). Depending on areas, the influence of climate may differ, ranging from determining to insignificant.

In Kenyan regions characterized by large depression areas called « Dambos » and a succession of dry and rainy seasons, RVF outbreaks occur every 5-10 years: a strong correlation was shown between outbreak occurrence and heavy rainfall events that favor both massive hatch and development of Aedes mcintoshi and Culex sp mosquitoes that are the main vectors of RVF in that region. Similarly, the Ferlo area located in Northern Senegal is characterized by a Sahelian climate and temporary ponds (small water bodies that are filled during the rainy season and then dry). But in this region, no correlation between outbreaks and extreme rainfall events has ever been demonstrated. However Soti et al (2012) showed that these outbreaks occurred when the abundance of the two main mosquito vectors in this region, namely, Culex poicilipes and Aedes vexans arabiensis, was higher than average: these abundances are directly linked to specific rainfall rhythms now well described (Soti, Tran et al. 2012). Nevertheless, herd management, herd renewal rates and nomadic herd movements that influence the immunologic coverage of herds, are probably also involved. These variables will have to be incorporated in existing models to refine them and allow for an accurate surveillance and prediction of outbreaks. In other countries that recently experienced RVF outbreaks, such as Madagascar or South Africa, heavy climatic perturbation could not be incriminated in RVF occurrence (Anyamba, Linthicum et al. 2010). In Egypt and Yemen, the role of socio-economic factors, along with climatic factors, was found to be determinant in RVF emergence and outbreak severity(Abdo-Salem, Tran et al. 2011; Xiao, Beier et al. 2015).

Also transmitted by mosquitoes, mostly from Culex genus, West Nile fever (WNF) is caused by a Flavivirus. Reservoir hosts are wild birds, mostly passerines. Human and horses are dead-end hosts. Introduced in New-World in 1999, the virus spread throughout the USA in few years. It is now endemic and transmitted till South of Argentina. Between 1999 and 2010, nearly 1.8 million people were infected; more than 12 000 neurological cases were recorded, from which 1308 were fatal (Kilpatrick 2011). In Europe, the virus has been recorded in the Mediterranean Basin since the sixties without any human or animal health consequences. However, the incidence of human and equine neurological cases suddenly increased, in particular since 2010. Two recent studies showed that an above normal temperature during the preceding months of outbreaks was strongly linked to this occurrence : this high temperature increases the vector competency of mosquitoes and provokes a an increase of the mosquito population densities (Tran, Sudre et al. 2014).

Ecological disruptions induced by climatic variations, but also by landscape transformation by human or socio-economical disturbances, are the main component of disease emergence. The understanding of mechanisms and conditions that underlie these processes is part of the major challenges that scientist and health policy makers will have to face to in the coming years.

Low cost portable sensors for measuring traffic related air pollution in tunnel

A. Gorin (1) ; S. Srairi (1) ; D. Guichon (1)
(1) CEREMA, Mobility department, Trappes en Yvelines, France

Air quality monitoring in tunnel has relied traditionally on static measurement stations. However these are expensive methods to capture pollution heterogeneities and identify pollution hotspots. In recent years, the development of portable sensing technology has attracted considerable interest because of the possibility to reduce operating cost of air pollution monitoring.

Despite this, they are few examples in the published literature of pollution measurement using portable sensors in tunnel. In this work, low cost portable sensors are used to measure traffic related air pollution in tunnel within the framework of the research operation "SERRES". The objective of this research operation is to produce recommendations and solutions to limit the impact of road traffic on the environment. Within this research operation, low cost pollution portable sensors are characterized and air pollution measurement are correlated with the traffic data of the tunnel.

The present project was divided into four phases. Phase one was the characterization of the portable pollution sensors. A full set of preliminay tests was realised in laboratory to evaluate the portable sensor reliability and to analyze its performances in terms of accuracy, autonomy and memory capacity. Based on this preliminary tests, two sensors were chosen for their performances: Observ' Air sensor and Cairsens sensor. Phase two, the portable sensors were fixed to a static SIREDO measurement station close to a road. The two sensors were installed for 24 hours. The traffic data recorded by the SIREDO station were used to analyze the link between traffic condition and air pollution. A correlation between the road traffic condition and the evolution of the air pollution was verified. Phase three was the selection and the instrumentation of a tunnel. The Guy Môquet tunnel was selected as an experimentation site because it had the following characteristics: easy instrumentation, simple access and close to a static measurement station (SIREDO). The tunnel is located in the Val-de-Marne district of south-east Paris. An instrumentation was realized inside the tunnel in collaboration with the Ile de France territorial division unit in charge of air quality. It involved placing and instrumentating four pollution portable sensors inside the tunnel. In phase four, experimental measurements were conducted and studied. A spatiotemporal analysis was made. The measures given by the portable sensors were compared to the results given by the static measurement station. A link between pollutant concentrations and road traffic condition was demonstrated.

Aknowledgment

This works is supported by the Technical Division for Territorial Development and Urban Planning of the CEREMA.

P-1121-07

Seasonal pattern of the associations between daily mortality and PM10 in Korea and Japan

H. Kim (1) ; Y. Honda (2) ; EK. Satbyul (1)
(1) Seoul National University, School of Public Health, SEOUL, Republic of Korea; (2) University of Tsukuba, 3faculty of health and sport sciences, Tsukuba, Ibaraki, Japan

Background/Aims: Many studies have shown that particulate air pollution exposures are associated with increased mortality. However, only a few studies in Asian countries have examined the modification effects by seasons on air pollution-mortality associations. The aim

of this study was to examine the air pollution–mortality associations within seasons in 13 cities, 6 cities from Japan and 7 cities from Korea, where with four distinct seasons.

Methods: We applied stratified time-series models to the data sets in order to examine whether the effects of particulate matter less than 10µm in aerodynamic diameter (PM10) on mortality was modified by four seasons, spring, summer, fall and winter. The effect of PM10 on daily mortality was first quantified within seasons at each location with a time-series model, and the estimates were then pooled through a random-effects meta-analysis using the maximum likelihood method.

Results: The daily means of PM10 in S. Korea were 69.98 □/□ for spring, 45.89□/□ for summer, 48.80□/□ for fall, and 56.94□/□ for winter. Every 10 □/□ increase in PM10 daily concentration was associated with an increase in non-accidental mortality of 0.17% (95% confidence interval [CI]: 0.05 to 0.29%) for spring, 0.44% (95% CI: 0.18 to 0.70%) for summer, 0.35% (95% CI: 0.13 to 0.58) for fall and -0.14% (95% CI: -0.06 to 0.33%) for winter for S. Korea. For Japan, the spring, summer, fall and winter daily PM10 means were 33.96□/□, 35.43□/□, 31.99□/□, and 27.93□/□, respectively. Percent change in daily mortality in Japan were 0.44% (95% CI: 0.18 to 0.72%) for spring, 0.15% (95% CI: -0.12 to 0.42%) for summer, 0.33% (95% CI: 0.15 to 0.52) for fall and 0.15% (95% CI: -0.23 to 0.53%) for winter, per equivalent increase in PM10.

Conclusion: The results showed that the effects of ambient air pollution on acute mortality differed within seasons and by locations. These findings may provide useful information to agencies for protecting local populations from adverse health effects of air pollution.

P-1121-08

Climate Change Epidemiological Health Reports in Michoacan State, Mexico since2009 to 2013

A. Molina-Garcia (1) ; C. Armendariz-Arnez. (2) ; L. Pacheco-Magaña. (2) ; G. Figueroa-Aguilar. (3) ; LA. Saavedra-Romero. (4) ; CE. Aranza-Doniz. (5) ; J. Martinez-Ponce. (6)
(1) State Commission for Protection against Sanitarian Risks, Ministry of health at michoacan state, Morelia, Mexico; (2) National University Autonomous of Mexico, Campus morelia, Morelia, Mexico; (3) State Laboratory of Public Health, Ministry of health at michoacan state, Morelia, Mexico; (4) Technical Secretary, Ministry of health at michoacan state, Morelia, Mexico; (5) Minister of Health, Ministry of health at michoacan state, Morelia, Mexico; (6) Ministry of Health, Ministry of health at michoacan state, Morelia, Mexico

Objective: To show the epidemiological reports of the impact on health with local and global environmental change. Data sources: our main reports were measured with parameters like temperature and precipitations during 1950-2000; and climate change scenarios projected to 2020-2030-2050. Also, ozone like air pollutant, 2009 pandemic A/H1N1 spring outbreak; floodings and acute respiratory and diaorrheal infectious diseases, dermatitis and conjunctival diseases related with contaminated food, air, water and soil after intense rainfalls; surveillance of vibrio parahaemolyticus; ocean pH and enterococcus.

Methods: Samples were obtained and sent to state public health laboratory in Morelia, Michoacan, Mexico. Meteorological reports were obtained and reviewed by the Delegational state of the National Commision of Water and analysed by the Athmosferic Science Center from the National University Autonomus of Mexico in Mexico City. Descriptive epidemiological reports were assessed to complete these reports from the epidemiological surveillance health system of michoacan.

Results: Acute infectious diseases were identified like A/H1N1 flu virus and ozone air pollutant in april and may in 2009. Respiratory and diaorrheal infectious outbreaks in heavy rainfalls and floodings in 2010 february in the Monarch butterfly biosphere region in East Michoacan. In the same year, in april an outbreak of vibrio parahaemolyticus were presented. And, recently in 2013 a serial reports related with a low level pH decrease in the Pacific ocean coast and the presence of enterococcus were measured. All these results were associated with temperature, precipitations and climate change scenarios since 1950-2000 and 2020, 2030 and 2050 measures in Michoacan.

Main Conclusions: Acute and infectious diseases were identified in places where our temperature and precipitations are increasing like world reports in ar4 and ar5 IPCC and others epidemiological data have been publishing.

P-1121-09

Pollen as a health indicator of climate change

S. Monnier (1) ; M. Thibaudon (1) ; JP. Besancenot (1) ; N. Michelot (2)
(1) RNSA, Brussieu, France; (2) MEDDE, Paris, France

Climate change, which is now scientifically proven and well known by everyone, influences plant growth, with unavoidable consequences on pollen. There are still a lot of uncertainties about the changes affecting pollination, but it is not disputed that the prevalence of allergies is on the rise for a number of years. Similarly, the timing and severity of allergic symptoms does seem to be related to climate variations. Indeed, it certainly appears that a warmer climate (both observed in the recent past and projected into the future) leads to more pollen grains in the air, to earlier flowering and pollination dates, to longer pollen seasons, and to poleward and upward shifts in ranges in plant species. Most of the observed increase in global average temperatures since the mid-20th century is very likely due to the observed rising levels in anthropogenic greenhouse gas concentrations. But the major greenhouse gas, i.e. the carbon dioxide (CO2) whose concentration has increased from a pre-industrial value of about 280 parts per million (ppm) to 400 ppm in 2014, has also a direct, extra-climatic effect. In fact, it acts as aerial fertilizer and helps plants thrive, causing increases in pollen production, in atmospheric pollen concentrations and, finally, in the number of allergy sufferers. The World Health Organization (WHO, 2003) classifies allergies as the fourth most important chronic disease in the world and considers that these diseases represent «a major public health problem in terms of quality of life, lost days of work or school, drug cost, and even mortality». Today, it is assumed that as many as 20 % of the French population currently have some form of allergy, about half of them suffering from pollen allergy (or pollinosis). Counting and identifying pollen grains over several years enables to estimate and, as a result, to predict the pollination dates of various plant families (in order to institute preventive actions for the benefit of allergy sufferers), but also to detect any changes in the pollen content of the atmosphere and alert the allergists. Moreover, it is well known that the prevalence of allergy in general and pollen allergy in particular has increased significantly in recent decades in industrialized countries. Exposure to environmental pollutants may partly explain such an upward trend. As a result of chemical pollution it is possible to observe a reduction in the sensitivity threshold to pollen, for example by deforming or breaking the outer wall of the grain, resulting in the dispersion in the environment of many fragments of pollen grains and cytoplasmic granules. Pollutants such as PM10, PM2.5, ozone and NO2 can also irritate airways and the increased airway responsiveness is able to reinforce the effects of pollen allergy. Phenological observations (occurrence of periodic, most often annual, life cycle events, influenced by seasonal and inter-annual variations in climate) are used to evaluate the influence of climate change on vegetation and biodiversity. These observations, when carried out on allergenic plant species, help to assess the influence of climate change on human health. At the request of ONERC (National Observatory of Global Warming Effects), RNSA (French Aerobiology Network) undertook in 2012 and then updated annually a study aiming at the construction of a health indicator in the Health and Society Chapter of the ONERC catalogue of climate change indicators. The results obtained from birch pollen data (high allergenic potential throughout Europe and sensitivity to long-term climate events) of six cities with different climates in metropolitan France, showed an increasing trend in pollen concentration with a rate of about 20 % during the last 20 years. This increasing trend has been associated with increasing regional temperatures, suggesting that climate change may already be having an impact on atmospheric pollen concentrations. In the future, global warming and rising temperatures could lead to a further increase in the amount of pollen in the air. This can only aggravate allergic hazards and thereby jeopardize public health. In view of the COP 21 conference in Paris at the end of 2015, the goal is to find solutions to limit the effects of climate

change on pollen and health. One of the main objectives pursued by RNSA is to inform the public on the risks and attitudes we must have in order to limit the health impact of pollutants and pollen on allergic sufferers. The missions of monitoring, warning and prevention of allergic risk given to the RNSA fit into this perspective and should allow the implementation of adequate policies by health authorities.

P-1121-10

Simulations of Pollutant Dispersal over Nairobi City, Kenya

G. Otieno (1)
(1) university of nairobi, meteorolgy, nairobi, Kenya

The current rapid deterioration of air quality in urban centres can be attributed to urbanization. Poor air quality has been associated with several negative effects on human health, climate and ecosystems. Most cities in developing countries, especially in Africa have poor or in some cases no air quality management systems in place despite having the fastest growing urban populations. City populations have high vulnerability to the impacts air pollution following high density of residents and economic activities as well.

Air pollution is evident in most cities; the case of Nairobi is an illustrative of this. The common air pollutants include carbon monoxide and total suspended particulates among others, the latter being the most widespread and the most serious for human health.

This study simulated air pollutant dispersal over the city using Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT), considering a case for emission of total suspended particles into the environment. The predominant wind speed over the city is 4-6 knots and the wind direction is easterly. The forward trajectory of a pollutant released in the city is generally observed to flow to the western side of the city. The pollutant is observed to be dispersed beyond 100 km from the city reducing the concentration of the same in the city.

The study thus recommends for a consultative planning process of the city that factors in the wind characteristics over the city; most industrial activities should be located to the extreme western side of the city to minimize concentration of pollutants over the city. The study further recommends studies that studies be carried out to ascertain the quality of rain water during the long rain season.

P-1121-11

Impact of hot weather on injuries and accidents in high income countries – a literature review

E. Otte Im Kampe (1) ; S. Hajat (1) ; S. Kovats (1)
(1) London School of Hygiene and Tropical Medicine, London, United Kingdom

Introduction: Given predictions of increased frequency of hot weather periods due to climate change it is crucial to have prevention measures in place to reduce the health burden of heat waves. Since injuries have often been overlooked in relation to hot weather the aim of this review is to summarize the evidence on the effect of hot weather on unintentional injuries in high income countries to inform policy and programme initiatives designed to reduce the burden of injuries. Methods: The following data bases were searched (28/02/2015): Global Public Health, Embase, Medline. Studies reporting heatstroke were excluded as the purpose of this review is to report on non-heat related injuries. Eligibility was assessed by one reviewer. 19 studies were included. Results: Preliminary results of this review showed for 15 out of 19 studies an increased risk of unintentional injuries during hot weather. A Spanish study reported that 60% (69) of all firefighter deaths due to a wildland fire entrapment occurred on high temperatures days. In the Netherlands an increase of 15% out of 354,150 trauma patients for each 10°C increase was observed above a threshold of 6°C. In France an excess mortality due to injury and poisoning in particular for people under 35 years was reported. Hot weather conditions in Italy showed higher risk for work-related accidents, in particular on early summer days. 3 studies from the US showed for high temperatures a strong increase in hospital admissions in accidental causes and an increased risk of fatality due to accidental cocaine overdose In contrast, 1 study from Australia did not find an association between emergency hospital admissions due to injuries during extreme heat events. Another Australian study reported decreases in sport accidents, falls and blunts in children and a decrease in motor vehicle related accidents among the elderly. Conclusions: To our knowledge, this is the 1st review of the effect of hot weather on unintentional injuries. Our review indicates that hot weather periods may increase the risk of unintentional injuries and accidents in high income countries. The results are valuable for health system planning and injury prevention strategies.

P-1121-12

Air Pollution Transport Processes and Human Health Impacts over the Middle Hill Urban Centers of Nepal Himalaya

RP. Regmi (1)
(1) Tribhuvan University, Central Department of Physics, Kirtipur, Kathmandu, Nepal

Urban centers of Nepal are mostly located in deep valleys, narrow river basins and in southern plain areas, more or less shaped like valleys and in proximity to the high mountains. The meteorological conditions associated with such topographic features have been found to be highly adverse and may build up severe air pollution even where the local emissions are low. In consideration with their associated topography and the meteorological conditions that could possibly prevail, Nepalese urban centers in the middle hills are expected to be highly vulnerable to air pollution. Prevalence of dust, particulate and other pollutants in the ambient air of these urban centers have already reached to an unacceptable level. The lack of necessary knowledge on air pollution emission pattern, the carrying capacity, mechanism of transport and formation of pollutant fields in these swelling urban centers have given rise to serious uncertainties with respect to the air quality degradation, development of control systems, and urban planning. Observations and numerical simulation studies on prevailing wintertime meteorology and air pollutants distribution and their dynamics have revealed that the bowl-shaped Kathmandu valley possesses high air pollution potential due to its adverse meteorological and topographic conditions particularly during the dry winter season. The poor dispersion power of the valley can easily reach into its saturation if substantial amount of air pollution is continuously loaded into its atmosphere. Concurrent investigation of human-air pollution exposure status based on the results of numerical simulation revealed that more than 52 per cent of total Kathmandu residents were living in areas with concentration above 40 µgm-3 of PM10. Significant health endpoints attributable to PM10 over the Kathmandu valley have been predicted. Other urban centers are developing in the same pursuits. In this paper, we will present the atmospheric transport processes over the middle hills of Nepal Himalaya and their role in pumping up the lowland pollutants up into the Himalayas including the prevailing wintertime meteorology, mechanism of air pollution transport and formation of pollutant fields, human exposure and health endpoints over the Kathmandu valley.

P-1121-13

Seasonal variations of aerosols in Pakistan: Contributions of domestic anthropogenic emissions and transboundary transport

MZ. Shahid (1)
(1) Institute of Atmospheric Physics, Chinese Academy of Sciences, Beijing China., State Key Laboratory of Atmospheric Boundary Layer Physics and Atmospheric Chemistry, Beijing, France

Air pollution has become a serious challenge for developing countries like Pakistan. Very scarce information is available regarding pollution levels in this geographic region. This study presents the first modelling work to simulate the spatial distribution and temporal variation of aerosol concentrations over Pakistan for using the Weather Research and Forecasting Model coupled with chemistry (WRF-Chem). Simulated aerosols species include sulfate, nitrate, ammonium, organic carbon, black carbon, and

PM2.5 (particles with a diameter of 2.5 mm or less), which are evaluated against ground-based observations and satellite measurements. In year 2006, simulated PM2.5 concentrations averaged over northeastern Pakistan (71–74.5°E, 28–34°N) are 55, 48.5, 31.5, and 98 μg m^{-3} in January, April, July, and October, respectively. The simulated highest PM2.5 concentration in October results from the relatively low temperatures that favor nitrate formation as well as the lowest precipitation that leads to the smallest wet deposition of all aerosol species. The simulated lowest concentration of PM2.5 in July can be attributed to the largest precipitation associated with the South Asian summer monsoon. Sensitivity studies show that transboundary transport contributes to PM2.5 aerosol levels in northeastern Pakistan by 10–20% in January and April and by 10–40% in July and October of year 2006. Wind over India and Pakistan is found to be the major meteorological parameter that determines the transboundary aerosol transport.

P-1121-14

Enhanced critical load capacity of soil due to buffering of atmospheric acidity through deposition of soil derived particulate matter in Delhi (India)

D. Sharma (1)
(1) Jawaharlal Nehru University, School of Environmental Sciences, New Delhi, Delhi, India

This paper reports air quality characterization using data of MODIS-derived aerosol optical depth (AOD) and measured Suspended Particulate Matter (SPM), NO2 and SO2 values across India. The levels of these pollutants were mapped using geospatial techniques. The results show significant differences in the levels of SPM, NO2 and SO2 across rural and urban sites. In general, districts of central and northern India show relatively higher SPM concentrations as compared to southern India. The SPM values were noted to have a significant correlation with the AOD values at different sites. Further a trend analysis of SPM, NO2 and SO2 in the Delhi region, which was carried out using the Central Pollution Control Board (CPCB) data, revealed a continuous increase in the SPM levels in the city. This lead to the calculation of the critical load of atmospheric acidity for nitrogen and sulphur in order to check the vulnerability of the soil systems in Delhi. A Critical Load approach similar to the one used in European method, was applied to assess the vulnerability of natural systems to the present day atmospheric pollution scenario in the capital city of Delhi. The calculated values of critical loads of sulphur (225 – 275 eq/ha/yr) and nitrogen (298 – 303 eq/ha/yr), for the soil system in Delhi, were calculated with respect to Anjan grass, Hibiscus and Black siris. According to the results, present loads of sulphur (PL(S) = 26.40 eq/ha/yr) and nitrogen (PL(N) = 36.51 eq/ha/yr) were found to be much lower than their critical loads which means that the present levels of acidity do not pose any danger the soil systems. The study indicated that the system is still protective due to high pH of the soil. The nature of buffering capability of calcium derived from soil dust can be considered as a natural tool to combat acidification in the Indian region. The results showed that the pollution status in Delhi is still within the safe limits. However, at the pace at which the city is growing, it is likely that in coming decades, it may exceed these critical values. The approach is very useful, not only in abating pollution but also in devising means of cost optimal emission abatement strategies, and can be applied the across entire Indian region.

P-1121-15

Characteristics of aerosol optical and physical properties during major dust storm and intense biomass burning events over a mega-city of Lahore (Pakistan)

S. Tariq (1)
(1) University of the Punjab, Remote sensing and gis group, department of space science, Punjab, Pakistan

Aerosol particles released due to natural and anthropogenic activities have very important effects on human health and climate of the region. In the present study aerosol optical and physical properties have been analyzed during major dust storm (March 2012) and intense biomass burning (October 2013) events over a mega-city of Lahore (Pakistan). In this work we have used AERONET data (level 2.0) to analyze the aerosol optical depth (AOD), Angstrom exponent (440/870) (AE), fine mode fraction (FMF), volume size distribution, single scattering albedo (SSA), real and imaginary parts of refractive index (RI), asymmetry parameter (ASY) and aerosol radiative forcing. We have also used available satellite based measurements during both events. ARL's HYSPLIT (Hybrid Single Particle Lagrangian Integrated Trajectory) model backward trajectories were also computed to understand the transport of aerosol particles during both the events. The daily average AOD value (2.17) at 500 nm was found to be highest on 20 March 2012 with corresponding FMF value of 0.27 indicating the dominance of coarse mode particles due to dust storm over Lahore. While during intense biomass burning event peak value (2.36) of AOD was observed on 9 October 2013 with corresponding FMF value of 0.97 pointing towards the fact that fine mode aerosol particles have greater contribution towards total AOD in the atmosphere of Lahore. Volume distribution was observed to be maximum (~1.7) at a radius of ~1.69 on 20 March 2012, whereas volume concentration (~0.33) was found to be highest at a radius of ~0.27 during 9 October 2013. Significant increase in SSA with wavelength was observed during dust storm while during biomass burning period it decreased with wavelength. Aerosol radiative forcing was found to be -265 and -199 Wm-2 during dust storm and biomass burning periods respectively.

P-1121-16

Numerical Characterization of the NOx Formation during MSW Incineration

AB. Timoléon (1)
(1) Faculté des Sciences, Université des Sciences et Techniques de Masuku, Chimie, Franceville, Gabon

A numerical model has been developed (Chemkin) to study combustion processes in a fixed bed reactor. The test section is divided into several successive Perfect Stirred Reactor (PSR). At the entry, the thermal degradation species of the solid are used as input and at the exit the exhaust gases are recovered. Comparison of previously experimental results and the current model output has been compared with good agreement. The study demonstrates that the NO formation and reduction is controlled by the combustion regime so are mainly dependant of the primary excess air of combustion. The model has been used to establish the reaction pathways of formation and reduction of the NOx at different locations in the reactor as a function of this parameter. This has allowed defining what is occurring at each specific location of the reactor. The reaction pathways and sensitivity study has shown that the production of NO is controlled mostly by local oxygen concentration, thus the location of the NO production region depends mostly on the primary air injection. From this description of the principal reacting zones and of the intermediate species it is possible to develop and to optimize primary technique of NOx reduction.

Global warming and sea level rise

A. Cazenave (1)
(1) CNES, LEGOS, Toulouse, France

It is now well established that the Earth's climate is warming because accumulation inside theatmosphere of green house gases produced by anthropogenic fossil fuel combustion and landuse change (mostly deforestation). Global warming has already several visible consequences,in particular increase of the ocean heat content, melting of glaciers, and ice mass loss from theGreenland and Antarctica ice sheets. Ocean warming and land ice melt in turn cause sea levelto rise. Sea level rise induced by global warming and its impacts in coastal zones has becomea question of growing interest for in the scientific community, and the media and public. Inthis presentation, we summarize the most up-to-date knowledge about climate change andassociated impacts on ocean warming, land ice melt and sea level rise. We also present sealevel projections for the 21st century under different warming scenarios, highlighting theregional variability that superimposes the global mean rise. Finally, we briefly discuss thecoastal zones case where climate-related sea level rise generally amplifies the vulnerability ofthese regions already impacted by many other factors due to natural phenomena and directanthropogenic forcing.

Greenland ice cores tell tales on the extent of the Greenland Ice Sheet during past warm climate periodes

D. Dahl-Jensen (1)
(1) Centre for Ice and Climate, Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark

Knowledge on the long-term response of the Greenland ice sheet to climate warming duringpast interglacials is essential for estimating the potential of future rise in sea level. Duringthe last million years, the Greenland Ice Sheet (GRIS) has waxed and waned in response toglacial and interglacial periods. The deep ice cores through the Greenland ice sheet containice from the time ice covered the site. Ice from the last interglacial period (the Eemian, LIG)130 to 115 kyears before present is present in most of the deep ice cores and can be used todetermine both temperature and extent of the ice sheet during this warm interglacialperiod.Going to the bed, basal material enclosed in the ice cores contain DNA remnants that can beused to determine the ecosystems present before ice covered Greenland.The reaction of the Greenland ice sheet to climate changes and the sea level change frommass loss from the Greenland ice sheet is discussed based on the ice core findings.

Uncertainties in Mass Balance Studies of the Arctic Sea Ice Cover

J. Comiso (1)
(1) NASA Goddard Space Flight Centeer, Cryospheric Sciences Laboratory, Code 615, Greenbelt, MD, United States of America

The longest continuous observations of the global sea ice cover are those derived from satellite passive microwave sea ice data starting with the launch of the Nimbus-7 SMMR in October 1978 and followed by a series of DMSP/SSM/I sensors launched from July 1987 to the present. These capabilities were further improved with the launch of Aqua/AMSR-E which provided higher resolution data from June 2002 to October 2011and followed by the launched of GCOM-W/AMSR2 which has been in operation from 2012 up to the present. Putting together an accurate time series data set has been a challenge because of differences in fields-of-view, antenna side-lobes, calibration and other physical attributes of the different sensors. Through comparative analysis of overlapping data, however, some of these problems have been minimized and the accuracy in the assessments of the variability and trends of ice extent and ice area has been optimized. The ice extent provides the sum of areas in the ocean that has ice cover of at least 15% ice concentration while ice area provides the actual area covered by ice and used to estimate the ice volume assuming that the average thickness of the ice cover is known. The current record from 1978 to 2014 shows a trend in ice area of about 4.3 ± 0.16% per decade for the yearly average but a more drastic change is observed for the thick multiyear ice the trend of which is about 14.9±1.6% per decade suggesting large declines in the average ice thickness of this ice type. Measurements of ice thickness have been the source of greatest uncertainties since accurate, continuous and consistent time series measurements of global ice thickness are not available. Historically, ice thickness measurements have been sparse and were done primarily using upward looking submarine sonar data which have been used to show a significant change in average winter ice thickness from about 3.6 m in 1980 to about 2.9m in 2000. Ice freeboard measurements from ICESat/GLAS (January 2003-February 2010) provide more extensive coverage and indicate a change in winter thickness from about 2.4 m in 2004 to 1.9m in 2008. More recent freeboard measurements from CryosSat2 (April 2010 to the present) provided a continuation of the satellite measurements and show a more stable ice cover. Although retrieve thicknesses from freeboard measurements have indicated relatively low biases (less than 0.1m) compared to in situ and other measurements, there are large standard deviations (0.7m) in the comparative analysis suggesting that more accurate snow thickness and ice density data are needed. The use of the improved measurements of average sea ice thickness separately for seasonal and multiyear ice in conjunction with passive microwave data would provide the desired estimate for average volume of the two major ice types. Time series of such data are needed in mass balance studies of the Arctic sea ice cover and uncertainties associated with the use of current data sets will be provided.

O-1122-01

What can we learn from the recent global warming hiatus about climate variability and climate models?

H. Douville (1) ; A. Voldoire (1)
(1) Météo-France, CNRM-GAME, Toulouse, France

The observed rise in global mean surface air temperature (GMST) has slowed down over the last 15 years, spurring outbreaks of skepticism regarding the nature of global warming and challenging the upper range transient response of the current-generation global climate models. Recent numerical studies have, however, tempered the relevance of the observed pause in global warming by highlighting the key role of tropical Pacific internal variability. Here we first show that many climate models overestimate the influence of the El Niño-Southern Oscillation on GMST, thereby shedding doubt on their ability to capture the tropical Pacific contribution to the hiatus. Moreover, model results can be quite sensitive to the experimental design. We argue that overriding the surface wind stress is more suitable than nudging the sea surface temperature for controlling the tropical Pacific ocean heat uptake and, thereby, the multidecadal variability of GMST. Using the former technique, our model captures several aspects of the recent climate evolution, including the weaker slowdown of global warming over land and the transition toward a negative phase of the Pacific Decadal Oscillation. Yet the observed global warming is still overestimated not only over the recent 1998-2012 hiatus period but also over former decades, thereby suggesting that the model might be too sensitive to the prescribed radiative forcings. Besides fully coupled ocean-atmosphere simulations, we therefore advocate the use of suitable partial-coupling techniques to control a fraction of the internal climate variability. This strategy could enable a more insightful comparison with the

observed climate variability and, thereby, lead to stronger observational constraints on model sensitivity to the prescribed radiative forcings.

O-1122-02

Eurasia winter cooling in a recent warming hiatus period of 1998-2012

C. Li, (1) ; J. Marotzke, (1)
(1) Max Planck Institute for Meteorology, The Ocean in the Earth System, Hamburg, Germany

The global-mean surface temperature (GMST) has shown a comparatively small warming trend over 1998-2012, termed a hiatus [Meehl et al., 2011; Flato et al., 2013; Kosaka and Xie, 2013]. In addition to the warming hiatus of GMST in the recent decade, Cohen et al. [2012] found a significant winter (seasons refer to those for the Northern Hemisphere hereafter) cooling trend on the Northern-Hemisphere (NH) extropical land surface temperature. However, the relative magnitudes of the contribution from temperature trend at different latitude bands and also the mechanism of the NH mid-latitude winter cooling are poorly understood. Here we investigate the spatial pattern of surface temperature trends and the contribution of surface temperature trend reduction at different latitude bands with observational data, and the causation of NH mid-latitude winter cooling with large ensembles of AMIP-type sensitivity simulations.

In addition to the tropical Pacific cooling over 1998-2012, we find the GMST warming hiatus is strongly influenced by a pronounced DJF cooling trend over 1998-2011 in NH mid-latitude, especially in Eurasia. However, an absent of the strong mid-latitude winter cooling trend in the previous simulations with restoring the observed SST over tropical Pacific in a coupled climate model Kosaka and Xie [2013] underlines that mechanisms other than cooling in the tropical Pacific must contribute to the warming hiatus in recent decade. In the present study, we explore the impact of the dramatic loss of Arctic sea ice on the NH large-scale circulation changes and the NH mid-latitude winter cooling trend. We found that the Arctic sea ice does not drive systemic changes on the NH large-scale circulation as Arctic Oscillation (AO), Pacific/North American Pattern (PNA) and the Eurasia winter blocking frequency in the past decades. And the observed DJF cooling trend over 1998-2012 is a random internal variability and belongs to a extreme climate events. Although the dramatic loss of Arctic sea ice does not drive systematic cooling trend of Eurasia winter climate, but it can enhance the variability of Eurasia winter climate, and thus increasing the possibility of the Eurasia winter reaching an extreme cold trend over 1998-2012.

O-1122-03

Impacts of External Forcing on the Decadal Climate Variability in CMIP5 Simulations

Y. Yu, (1) ; Y. Song, (1)
(1) Institute of atmospheric physics,Chinese Academy of Sciences, Beijing, China

Decadal climate variability is usually regarded as an internal variability in the climate system. However, using the coupled simulations from the Coupled Model Intercomparison Project Phase 5 (CMIP5), we have demonstrated that the external radiative forcing plays an important role in modulating decadal variability of the global mean surface air temperature (SAT). In historical runs, the standard deviations of the global mean SAT exhibit robust increases relative to pre-industrial runs, indicating that external forcing acts on decadal variability of the global mean SAT through enhancing amplitude and modulating phase. By comparing model results using different external forcing agents, we find the natural-forcing agent has the strongest impact on the decadal timescale. Every type of simulation (e.g., the pre-industrial, historical, natural forcing and anthropogenic forcing runs) from almost all the CMIP5 models exhibits a high correlation between the net shortwave (SW) radiative flux at the top-of-atmosphere (TOA) and the global mean SAT with a 13 month lag. However, after taking the multi-model ensemble mean for the TOA SW and the SAT, respectively, the correlations from external-forcing run are much higher than those from pre-industrial runs. This is because that the decadal SAT anomalies from multiple models cancel each other out in the pre-industrial runs without external forcing, but generally follow decadal evolution of the external forcing with a 13 month lag. The most significant responses to external forcing are found in the tropical Indian and Pacific oceans, through with different physical mechanisms for the natural and greenhouse gas forcing agents.

O-1122-04

Change Points of Global Temperature

N. Cahill (1) ; S. Rahmstorf (2)
(1) University College Dublin, Mathematical Science, Dublin, Ireland; (2) Potsdam Institute for Climate Impact Research, Potsdam, Germany

We aim to address the question of whether or not there is a recent "hiatus", "pause" or "slowdown" of global temperature rise. Using a statistical technique known as change point analysis we identify the statistically significant changes in four global temperature records and estimate the rates of temperature rise before and after these changes occur. In each case the results indicate that three change points are enough to accurately capture the variability in the data with no evidence of any significant change in the global warming trend since ~1970. We conclude that a hiatus or pause cannot be statistically justified.

O-1122-05

Impact of initial conditions and atmospheric model resolution in predicting "Climate Hiatuses"

S. Corti (1)
(1) National Research Council (CNR), Institute of Atmospheric Science and Climate (ISAC), Bologna, France

The results from a set of multi-year hindcasts carried out with the ECMWF coupled system at two different resolutions of the atmospheric component will be presented. The first experiment consists of a control series of ensemble hindcasts with the atmospheric model integrated at T255 with 91 levels in vertical (this is the current resolution of the ECMWF System4). The ocean resolution is the standard NEMO-ORCA1. In the sensitivity experiment the atmospheric resolution has increased to T511 (the ocean resolution is the same). By comparing the control and the sensitivity experiment we estimate the impact of the increased atmospheric resolution on forecast quality.

The impact of initial conditions relative to external forcings in multi-year integrations is further assessed using specifically designed sensitivity experiments. They consist, for each atmospheric resolution, of three sets of ensemble hindcasts for three initial dates in 1988, 1994 and 2002 using either the external forcings from the 'correct' decade or swapping the forcings between the three decades. By comparing the three sets of integrations, the impact of external forcing versus initial conditions on the predictability over multi-annual time scales is estimated. In particular we estimate the sensitivity of the model to initial conditions and horizontal resolution in predicting the multi-year climate oscillations that modulate the global warming trend, also known as "Climate Hiatuses".

Multi-model simulations of radiative forcing of aerosols and ozone during the 1990-2015 period

G. Myhre (1) ; BH. Samset (2) ; Ø. Hodnebrog, (1) ; RB. Skeie (1) ; Z. Klimont, (3) ; G. Faluvegi (4) ; D. Shindell (5) ; M. Flanner (6) ; D. Olivie (7) ; S. Tsyro (7) ; M. Schulz (7) ; R. Cherian (8) ; J. Quaas (8) ; J. Mülmenstädt (8) ; T. Takemura (9) ; J. Schnell (10) ; M. Prather (10)
(1) CICERO, Oslo, Norway; (2) CICERO, Climate System, Oslo, Norway; (3) IIASA, Laxenburg, Austria; (4) GISS, New York, United States of America; (5) Duke University, Durham, United States of America; (6) University of Michigan, Ann Arbor, United States of America; (7) Met.no, Oslo, Norway; (8) University of Leipzig, Leipiz, Germany; (9) Kyushu University, Kyushu, Japan; (10) University of California, Irvine, Irvine, United States of America

Seven global models have simulated the changes in aerosols and ozone over the 1990–2015 period, and the associated radiative forcing. The models have used updated emission data from the EU-project Eclipse. The modelled changes in aerosol abundance at the surface in terms of PM2.5 show broad agreement with observations, whereas they generally underestimate the overall increase in surface ozone over US and Europe. We focus on model-mean radiative forcing and the spread among the models, and compare this to estimated radiative forcing in IPCC AR5. The models show remarkably good agreement for the direct aerosol effect of sulphate, and for carbonaceous aerosols from fossil fuel and biofuel sources. However, for nitrate the differences are large. Over the 1990–2015 period, the models simulate a positive direct aerosol effect radiative forcing of sulphate and black carbon, due to a reduction the sulphate abundance and increase in black carbon abundance. The model mean shows relatively small changes in the indirect aerosol effect over the investigated period. It is indicated that including semi-direct effect of black carbon is important, even though few models have been able to quantify this forcing. Overall the models have a more strongly positive aerosol radiative forcing over the 1990–2015 period than IPCC AR5. Similarly the ozone radiative forcing over the same period is simulated in this study to have a more positive radiative forcing than IPCC AR5. Based on these multi-model simulations using updated emission data of aerosols and ozone, we find no indications that these forcing agents are driving the global warming hiatus.

Climate Change Engineering: An emerging pathway to address Climate Change Challenges

A. Batisha (1)

(1) Environment and Climate Change Research Institute, Cairo, Egypt

To survive in the future, the professional engineers should be qualified to deal with different and diverse subjects of climate change challenges. The focus of this work is to bridge the gap between the academia and the professional practice in the field of Climate Change CC. So, the professional engineers should have an adequate knowledge about wide and different Climate change engineering CCE disciplines. The focus of CCE is to promote Sustainability and optimally responding to CC challenges. CCE may be defined as the application of mathematical, scientific, environmental, and technical knowledge to invent, design, build, maintain, and improve structures, products, machines, devices, systems, materials and processes for the purpose of sustaining both the global and local properties of the Earth and its habitability. The paper focuses on the purpose, activities; and issues of CCE. The role of Climate change engineer has been addressed. The main finding of this article is to highlight CCE with invaluable insights into multidisciplinary engineering that help improve current operations and shape future strategies in the Era of Climate Change. The resultant conclusion is that the role CC plays in the success or failure of development efforts must be considered by applying CCE principles.

P-1123-02

Education on climate change through generation of local data

R. Curcoll (1) ; A. ÀGueda, () ; O. Batet, (1) ; S. Borràs, (1) ; L. Cañas Ramírez (1) ; C. Grossi, (1) ; M. Nofuentes Ramos () ; P. Occhipinti, (1) ; E. Vazquez, (1) ; X. Rodó (2) ; JA. Morgui (1)

(1) Institut Català de Ciències del Clima, Lab atmosphere & oceans, Barcelona, Spain; (2) Institut Català de Ciències del Clima (IC3), Climate dynamics and impacts unit, Barcelona, Spain

Education covers a key part in the global response to climate change. Understanding the behaviour of ecosystems, the role of the cities or the orders of magnitude of atmospheric greenhouse gases concentrations help scholars and citizenship to gain a more conscious and active attitude on the climatic challenge and its causes.

Researchers from the Laboratory of the Atmosphere and Oceans (LAO) at the Catalan Institute of Climate Science (IC3) have developed several educational activities of outreach and workshops with scholars and citizenship to make the population aware of the causes generating climate changes and how they can contribute in reducing it. All these activities share a common aim: scholars or citizens generate and collect quality data allowing them to better understand processes that happen in our environment, regardless whether they are biological or anthropogenic processes. Another important objective of these educational activities consists in making scholars and citizenship active participants of the scientific community discussing and studying the generated data with other groups.

The kind of measurements can be, for instance, atmospheric greenhouse gases concentrations, meteorological parameters or radiation measurements. Data generated from these measurements allow knowing the general greenhouse gases concentrations in the atmosphere and the relative increase due to fossil fuel combustions: this kind of studies makes the citizenship much more aware in understanding the role of cities in the global emissions or the relation of the ecosystems behaviour with water and temperature.

P-1123-03

Mainstreaming climate change into fisheries and aquatic sciences curriculum and training in tertiary academic institutions

J. Efitre (1) ; R. Ogutu-Ohwayo (2) ; W. Okello (3) ; K. Odongkara (4) ; V. Natugonza (2) ; L. Musinguzi (5)

(1) Department of Biological Sciences, Makerere university, Kampala, Uganda; (2) National Fisheries Resources Research Institute (NaFIRRI, Jinja, Uganda; (3) National Fisheries Resources Research Institute (NaFIRRI), Jinja, Uganda; (4) National Fisheries Resources Research Institute (NaFIRRI), , Jinja, Uganda; (5) National Fisheries Resources Research Institute (NaFIRRI, Fish habitat Management, Jinja, Uganda

Fisheries resources in Uganda contribute to food security, employment, income and livelihoods but are threatened by over-exploitation, pollution, habitat degradation, invasive species and climate variability and change. However, climate variability and change has been little studied yet it is adding to or interacting with other stressors to affect riparian ecosystems, fish habitats, aquatic productivity, fish yields and livelihoods. There is inadequate knowledge, training and institutional capacity to address climate change in fisheries in Uganda as in most African countries. There is therefore need to build capacity through mainstreaming climate change into the curriculum of tertiary training and research institutions. International, regional and national policies have recommended incorporating climate change into education and training from primary to tertiary institutions. Some training institutions in Uganda have curricula in basic and applied fisheries and freshwater science but many of these do not address issues of climate variability and change. This curriculum and manual was therefore developed to address this shortfall. Its overall objective is to mainstream climate change in inland freshwater systems and fisheries. The specific objectives are to: 1) develop a training curriculum and manual that will be used to train students in climate change and fisheries in tertiary education and research institutions and 2) mainstream climate change into the undergraduate and graduate fisheries and aquaculture curricula. This is expected to build scientific and technical capacity to: 1) anticipate and evaluate changes in climate and its impacts; 2) communicate information to stakeholders to enable them design, test and implement adaptation strategies and mitigation measures; 3) increase human resource capacity through reviewing and strengthening the national education system; and 4) promote science and technology

as stipulated in Uganda's National Development Plan (NDP) and Agriculture Sector Development Strategy and Investment Plan (DSIP). The manual is organized into six modules namely: Non-climate factors which together with climate change affect natural resources; Introduction to climate change; Climate change and physical, chemical and ecological properties and productivity of inland aquatic ecosystems and fisheries; Climate change and aquaculture; Socio-economic impacts, adaptations and mitigations; and Policy, legal and institutional frameworks. Each module consists of units to be delivered through lectures, brainstorming sessions, case studies, field visits, group discussions, computer exercises and seminar presentations. The training curriculum and manual was completed in 2014 and is ready for pretesting in tertiary academic institutions in Uganda.

P-1123-04

The Importance of Environmental Education for Sustainability

M. Eid (1)
(1) Suez Canal University, Faculty of Agriculture, Ismailia, Egypt

It is an undoubted fact that human beings are having a significant impact on the nature environment. As the global population continues to rise, human place more and more pressure on a finite number of resources. Human environmental impacts can largely be attributing to consumption patterns. However, the ability to meet the needs of the current generation while preserving the ability of future generation to meet their needs, it would be reasonable to search for way to minimize human impact on the environmental and to build a sustainable world for the future.

It is considered that the best way to raise awareness of sustainability and environmental issued and finally, changing behavior to more sustainable practices is through environment education. Therefore, environmental education is not just about learning, it is about understanding issues confronting our planet and changing individual attitudes values and developing a community of environmental aware towards achieving suitability for the future.

This poster will discuss approaches and principles of environmental education and study case.

P-1123-05

Teaching climate change: An interdisciplinary challenge

R. Engelhardt (1)
(1) School of Global Health, UCPH, Copenhagen Center for Disaster Research, Copenhagen K, Denmark

Climate change education is inherently interdisciplinary. It requires teachers to possess a broad range of competencies and to apply alternating teaching methods bringing into play the skills and knowledge of the whole classroom. If one defines interdisciplinary learning as the ability to know and coordinate a growing number of perspectives, it becomes the teacher's primary task to support students in their explorative and coordinative efforts. A research project running from 2013 to 2016 at the University of Copenhagen has investigated the pedagogical and didactical challenges in two interdisciplinary Master's Programs – one of them called 'Master of Disaster' (MDMa) at the Faculty of Health and the other 'Master of Science (MSc) in Climate Change' (CCIMA) at the Faculty of Science. Preliminary findings show a weak institutional support for interdisciplinary teaching and a lack of coordination among topics covered in the curricula. When worst, teaching becomes a kind of serial – or rather 'parallel disciplinarity' – where modularly formatted perspectives produce mutually incomprehensible monologues. When best, lead instructors use a variety of inductive teaching methods and provide an impartial overview of the conceptual schemes involved.

P-1123-06

Getting from here to a sustainable world: Why "handprint" measurement which drives pro-environment behavior be crucial to addressing climate change?

C. Hemani (1)
(1) Self employed, Ahmedabad, India

Exponential increase in human population from 5 million in 8000 BC to over 7 billion humans in 2012 coupled with unsustainable consumption and production patterns is putting an undue pressure on the limited natural resources. It's not planet and the diminishing natural resources but our own species at risk if we continue with this present model of development. Thus climate change is not an issue in isolation, but rather, a symptom of a broader challenge: humanity's systematic overuse of the planet's finite resources. This accelerating gap between human demand and nature's supply is leading to another crunch of bio-capacity.

In a world facing climate change issues and a bio-capacity crunch, the winning economic strategies will be preserving bio-capacity on the one hand, and reducing demand for it on the other which in turn would serve as the leading strategies for minimising climate change. But how is this possible? Climate change and high carbon lifestyles as a narrative of future gloom and doom only disempowers people to act. What if we focus on solution rather than problem? What if we focus on accounting positive actions powered by pro-environment behaviour to drive low carbon lifestyles? Sustainable development would require changes in the way we think and act. And education is one of the most effective mediums to bring about changes in values, behaviour and lifestyles required to achieve sustainability.

Scientifically driven and educative accounting tools like carbon foot print, ecological foot print measures our actions either in terms of amount of carbon dioxide released in the atmosphere or in terms of resources of the earth which would be needed to match our lifestyles and suggests our negative impacts on the environment respectively. While Handprint is a symbol of positive measure for what we can do individually or through collective effort to restore the balance between consumption and the planet's carrying capacity. Studies suggest that positive accounting not only presents hope but also suggests how it affects behaviour changes benefiting society to drive more positive actions. Handprint accounting is one such educative tool to drive pro-environment behaviour and actions.

It answers questions like how my changes in behaviour and actions would result in greenhouse gas reductions and would contribute to safe guarding environment, promoting sustainable development and thus would help in achieving climate change mitigation caps. Such measures would act as a roadmap to achieve a sustainable future.

This research focuses on developing a scientifically driven educational tool for handprint which in turn establishes links between measuring positive actions via handprint scores driving climate smart behaviour and climate change mitigation potential.

P-1123-07

Studies on research initiatives for developing strategic knowledge on climate change impacts in India

A. Kamavisdar (1) ; R. Kumar (2) ; N. Mendiratta (3) ; R. Singh (3) ; K. Samuel (3) ; A. Gupta ()
(1) Climate Change Programme, Department of Science & Technology, Govt. of India, New Delhi , India; (2) Access to Knowledge Division , Department of scientific and industrial research, New Delhi, India; (3) Climate Change Programme, Department of science & technology, New Delhi, India

This is well-known fact that Indian economy is based on its natural resources, agriculture and forestry, which are climate sensitive sectors. Considering the above India may expect considerable variations in vulnerability due to projected climate change phenomenon. In response to the same Government has prepared a National Action Plan for Climate Change (NAPCC) comprising of eight

different national missions. Amongst these eight national missions, National Mission on Strategic Knowledge for Climate Change (NMSKCC) is expected to build an active knowledge system related to climate change issues in the country, that may help national actions for responding effectively to the objectives of ecologically sustainable development. This NMSKCC mission includes various issues to address climate change science with region specific modelling related to national objectives, international cooperation and strengthening the plans for development of new technologies for adaptation and mitigation and also expected to cover knowledge gaps that are to be bridged. It also proposes to develop human and institutional capacity-building actions related to climate change issues. These activities are being considered necessary for designing policy responses and implementation approaches at the national level and also for providing inputs to negotiations at the international platforms. This mission will work as a support mission to other seven national missions by providing strategic knowledge. Since considerable data resources are already available with various Ministries, academic and research and development institutes in India, a credible data sharing mechanism is also proposed to be developed under this mission.

In this presentation attempts are being made to discuss the development initiatives for "Strategic Knowledge on climate change in India» that includes establishment of knowledge networks in the areas of climate change science with modelling as well as health. Amongst the various R&D projects supported, under this mission, in the areas of seas level rise, forests fire, agriculture, ocean acidification, glacier studies and sustainable livelihoods, a number of strategic reports are expected to be published. Under the programme of capacity building, training of high quality climate change professionals and state institutions have been supported. For the International bilateral cooperation schemes, S&T cooperation with Switzerland and Iceland have been finalized. In order to maintain speed with the state-of-the-art technologies emerging worldwide in the key sectors of economy, a programme named "Global Technology Watch Group" (GTWG) is also being initiated that emphasises the different areas relevant to other seven missions on climate change such as solar energy, energy efficiency, water, agriculture, etc.

P-1123-08

Climate change and Health- Training Resources for capacity building

V. Kendrovski (1) ; B. Menne (2) ; S. Gerardo (3) ; J. Creswick (4) ; T. Wolf (4)

(1) World Health Organization, Regional Office for Europe, European Centre for Environment and Health, Bonn, Germany; (2) WHO, health security and the environment, Bonn, Germany; (3) WHO, Bonn, Germany; (4) WHO, Cgs, Bonn, Germany

As climate change and its respective health effects are being observed across Europe, it is being suggested that development and implementation of adaptation strategies to protect human health should be accelerated and strengthened. Health adaptation to climate change involves knowledge and skills in a range of professions and across various sectors – not only technical but also skills involving personal interactions. A systematic training approach has been missing for many years. The available information is now presented in a structured modular collection in order to make these valuable resources accessible and to fill identified gaps in knowledge and capacity development. The WHO Regional Office for Europe has developed a collection of training resources for capacity building on climate change and health. The overall aim is to support the development of climate change and health strategies and action plans by providing scientific, technical, methodological and practical background information and training to member states. Thus, the training resources offer the opportunity to raise awareness among professionals with regard to observed and projected climate change in Europe, and related health effects, and to support health adaptation policy development and implementation in an intersectoral setting. The training resources (manual + suggested training materials) contain a structured compilation of existing and new training materials according to defined cascades of learning objectives. The three modular thematic blocks cover the basics of climate change and associated health effects – one presents a framework for the development of adaptation strategies and programmes of action – and draw attention to co-benefits of health of climate change mitigation measures in the health sector and in other sectors. Use of a range of training methods creates an interactive and participatory learning environment. These are intended to enable WHO European Member States to respond to and anticipate capacity building needs for climate change and health. Training resources can assist health policy-makers, planners and practitioners in the process of harnessing the potential of adaptation to climate change in order to meet health goals and targets.

P-1123-09

Does the public policy for influencing pro-environmental behaviour in the developed countries take into account people's common future under climate change?

LI. Udrea (1)

(1) Keele University, School of Politics, International Relations and Environment, Staffordshire, United Kingdom

Public policy in the richest countries regarding environmental protection is currently based on 'monetising' nature – regarding it as a form of capital. The UK government tries to tackle climate change using a multitude of approaches however; the most effective ones to influence pro-environmental behaviour in the long term are yet to be found.

In this paper, I will discuss the approaches followed by the UK government to influence people adopt a pro-environmental behaviour pursuing them to change their unsustainable lifestyle using financial incentives, nudging and population segmentation. These approaches give people strong reasons to take the 'right' actions in the short term; however, when the incentives are stopped, they need to find by themselves the motivation to act pro-environmentally. As a result, I state that the UK government does not set a straightforward connection between people's common future under climate change and the duty to protect the natural world.

In the UK context, individuals are not informed, but incentivised to act pro-environmentally via a series of price signals or nudges that encourage them to change their behaviour. I argue for the need to offer constructive feedback as a response to people's harmful behaviour and facilitate the necessary contexts to become aware of unsustainable daily actions.

Moreover, I state that environmental ethics are not often mentioned in the debate about influencing human action for climate change mitigation; even though morality is for the majority of us, a behaviour regulator that can motivate us to take the 'right' actions. Whatever the reason, there is not a lot of interest to bring to attention the interdependent relationship between human beings and the environment. Thus, many pro-environmental projects are implemented without having the discussion about what people's duties and responsibilities towards the environment are.

If people do not understand and assume the change they need to make, they will not acquire environmental attitudes to motivate them to act pro-environmentally in the long term. They will continue to act unsustainably whenever they are not guided by different governmental strategies or do not receive any financial incentive to take a pro-environmental action.

As a consequence, I propose a methodological innovation that explores an alternative form of motivation for pro-environmental behaviour: moral motivation. I am interested to test the capacity of morality to be skill knowledge. If we think of morality as a skill that can be trained and learnt, then we will have a starting framework for moral education. To that end I will develop the notion of a 'shared morality', or a form of considered 'common sense', which has the potential to inform and motivate individuals morally, irrespective of any particular normative theory they happen to have and, hence, to maximise the impact needed for environmental protection.

Correspondingly, by cultivating a sense of moral responsibility towards nature we might find an efficient way to address two current problems that concern environmental protection. On one hand, a sense of moral responsibility towards nature can help people calculate

the individual costs and impacts of personal actions on our shared environmental context and on the other hand, it will provide us with constructive feedback in order to understand the benefits of taking pro-environmental action in the long term.

At present, it seems easier to convince people to act pro-environmentally by working with their short term motivations for action, than helping them adopt sustainable habits in the long-term. As a result, the current UK governmental approaches to influencing pro-environmental behaviour have a negative impact on people's behaviour and might perhaps weaken their sense of moral responsibility towards nature, in the context of environmental degradation.

In conclusion, I hope that the 'shared morality' initiative in applied moral theory can become an ideational trend in environmental governance and policymaking that will offer activists and decision-makers alike grounds for an alternative approach to meeting the challenge of climate change mitigation and encouraging pro-environmental behaviour.

P-1123-10

Ciclania: Videogame for generating sustainable educational communities

B. Mauricio (1) ; J. Roa, (1) ; M. Mellado (1)
(1) Universidad Santo Tomás, Santiago, Chile

The challenges facing mankind today associated with the phenomenon global change put us in a scenario of crossroads, which will determine the conditions of our future together.

The increase in atmospheric temperature; biodiversity loss; changes in land use; problems of freshwater availability, ocean acidification; inequality and poverty are some of the effects of the phenomenon, widely studied by the scientific community and those who have sounded the alarm. (IPCC, 2013; Peters, 2011).

But this warning is not enough to change the countries and citizens behavior. During the last forty years we´ve learned that global change will not be solved solely by technological developments, but together with the creation of new citizens with transformed community living arrangements.

Thus, civic education on these matters becomes relevant in the transformation of sensitized responsible citizens. To achieve this transformation, the approach proposed by this work consists in civic education driven by the scientific education.

With this premise we develop Ciclania, a free game,build up from - and in accordance with-the science program for primary schools of the Ministry of Education of Chile. Ciclania includes 5 environments: beach, field, forest, industrial city, and Egopolis, the city of consumption. The player must explore the environment solving problems associated with global change. In addition to the game, we developed an interactive guide for teachers, which browses the game environments(without the need of playing the game) and experimental activities for the classroom, that will give teachers the knowledge and space to deepen the key concepts of global change.

The evaluation results, show that the use of Ciclania promotes learning and motivation in science through play and fun, but mainly promotes in children reasons why we need as a community a more harmonious relationship with the environment in order to battle the global change.

P-1123-11

Engaging Children for a Sustainable Earth: The Case with Global Climate Ambassadors

U. Muhammad (1)
(1) Centre for Renewable Energy and Action on Climate Change, Gusau, Zamfara, Nigeria, Federal Republic of

Introduction

The paper tends to look at the role of engaging children to make a difference in their communities especially taking actions that are climate friendly at local level and paper further examines how Global Climate Ambassadors GCA program brought together 17 organizations and 131 children from 7 countries to participate in the program in developing best practices on involving children and youth for a sustainable future thus; the paper also looks at how their participation in the 40th Planery Session of the IPCC change the entire landscape of climate change negotiations and awareness campaign among children.

Objectives

Is to empirically research on whether there is any impact of engaging children as change agents and also if the yardstick measure of the outcome of their engagement is applied, look at the significance of children's engagement in climate change negotiations and the impact it has for global sustainability. To understand if cross boundary programs of children can have a positive impact on sustainable development.

Methods

The research uses both primary and secondary data; relevant research works from scholars was looked at and give more emphasis on the report of the program. Thus; 7 children were interviewed to know the extent of their understanding in the program and how positively it has impacted their lives, if the connection and networking at their level has anything to improve their capacity at the intercontinental connections. The work adopts analytical and descriptive method as well.

Results

The analysis of the work has shown significant understanding of sustainable development and how climate change affect everyone on earth, among the 7 children interviewed 6 strongly agreed that the program has impacted positively in their understanding of what climate change is all about, and they all strongly agree connecting them with their peers out their countries will increase their chances of sharing ideas and learning from each other.

P-1123-12

An Open-Source Climate Change Curriculum for University Education Based on IPCC Synthesis Science

K. Nicholas (1) ; P. Ambros (2) ; N. Nasir (2) ; E. Redford, (2) ; C. Tsoi (2) ; MS. Weschke (2)
(1) Lund University, Centre for Sustainability Studies, Lund, Sweden; (2) Lund University , International master's programme in environmental studies and sustainability science, Lund, Sweden

In order to meaningfully participate in a civic society increasingly shaped by climate change, a climate-literate citizen should be able to read and understand the summaries for policymakers produced by the IPCC, which represent the current state of the art in the scientific understanding of climate change. However, although outreach and dissemination efforts have been increasing, to date we are not aware of any efforts to link the IPCC reports with curriculum design in higher education. Developing such links is essential to ensure that students are equipped with the skills and knowledge they will need. It can also improve teaching experiences through increased efficiency in course preparation, linking teaching and research, and in sharing best teaching practices with participating colleagues.

Here we develop a framework for teaching a comprehensive university course on climate change that is aligned with IPCC synthesis findings, assess how many of its core elements are addressed by courses offered at top international universities, and compile suggested teaching resources to fully equip students to understand climate change.

To develop the framework, we identified six core topics derived from scientific literature and syntheses, as well as research on effective climate communication. The six core topics were given the short labels: (1) It's climate, (2) It's warming, (3) It's us, (4) We're sure, (5) It's bad, and (6) We can fix it. The six core topics were then broken down into two to four major components (e.g., "Observed changes"

under "It's warming"), each of which consists of one or more concrete elements (e.g., "Atmospheric warming"). To finalize the components and elements, two independent researchers used qualitative analysis software to code the entire text and graphics of the 2014 IPCC Synthesis Report – Summary for Policymakers to ensure that all aspects of the essential messages of the IPCC findings were represented in our framework.

Based on analysis of syllabi available online or provided by course instructors from seventy university courses, we found that the majority (56%) covered only one of the six core topics; only one course (at Harvard University) covered all six topics. Within the core topics, the most commonly taught (by 60% of courses) was "It's climate," focusing on the functioning of the natural climate system. Less than 20% included climate change impacts ("It's bad"), and less than a third focused on climate change policy and solutions ("We can fix it.")

We contacted the instructors at the ten universities who taught four, five, or six of the core topics and requested their contribution of teaching and assessment materials, which we used along with other materials we identified to develop a comprehensive curriculum. The curriculum is based on the principles of constructive alignment, and includes a course syllabus, readings, lectures, labs, problem sets, and suggested learning and assessment activities. The curriculum will be freely available online as a teaching resource.

We have shown that there is a need for a comprehensive, research-based climate change course in higher education, which at present is largely unmet. Such courses are essential to promote deep student learning using thoughtfully designed teaching and assessment activities to promote intended learning outcomes, as well as the real-world illustration of the method of scientific inquiry applied to socially relevant problems. Ultimately, using scientific syntheses as the basis for university curricula would help close the gap between research and classroom learning, promote increased scientific understanding, and help ensure that the resources devoted to scientific synthesis efforts are translated to broader benefits for society.

P-1123-13

Socio-Scientific Teaching and Learning: Climate Change Concepts and Issues

M. Pagunsan (1) ; J. Omay (2) ; S. Delgado-Confesor (3)

(1) UNESCO Jakarta Office, Education Unit, Jakarta , Indonesia; (2) Sibalom National High School, Sibalom, Antique, Philippines; (3) University of Antique , Sibalom, Antique, Philippines

One of the challenges the teacher faces in introducing contemporary scientific developments into science lessons are the lack of available teaching and learning materials. Materials that are engaging enough that inspires, encourages and develops meaningful learning among students. This paper will present the collaborative project on the development of a Teachers' Guide Book in Integrating Climate Change Issues in Southeast Asian Schools. Specifically it will present the experiences, best practices and lessons learned in developing a science lesson exemplar through the partnership of teacher trainers and secondary school teachers in Malaysia. The developed science lesson exemplar has undergone students' try-out in Malaysian secondary school. Then, the implementation of the said science lesson exemplar in Philippines' secondary school will be highlighted. This paper will conclude with lessons learned in developing science lesson exemplars that integrates climate change concepts and issues. It will also present its usability, applicability and replicability implications as the Association of Southeast Asian Nations (ASEAN) gears towards the realization of ASEAN Community later this year.

P-1123-14

Climate Adventure: a strategy game to keep the greenhouse effect in balance

M. Prado (1) ; C. Josiel (1) ; J. Sousa, (1)
(1) Universidade de Lisboa, Lisbon, Portugal

This abstract describes the design and the development of Climate Adventure: A Game of Balance and Strategy©, a pedagogical tool created by a team of doctoral students in the Climate Change and Sustainable Development Policy program offered by the University of Lisbon. Recognizing that most people find the subject of climate change to be abstract and distant from their daily lives (according to literature findings), the team focused its efforts on answering the question: how can we make tangible the subject of climate change in an ethical way? The first step of the project was to identify a tool that could help people gain awareness. For that purpose, the team used creativity techniques. Our chosen vehicle was a game, one that would be fun to play, use movements, provide information, and operate with a minimum of strategy. These criteria were the basis for the next step: design the model and build the narrative of the game. The model is a card game played between teams with questions and answers, fulfilling steps to get to an end. The narrative is based on two arguments: scientific and ethical. The scientific argument considers the atmosphere, the greenhouse effect, and concentrations of greenhouse gases. The ethical argument considers human rights, distributive justice, and climate ethics. The development of the Climate Adventure© game required three more steps. The second step was to test the game using the technique of improvement by peers from the design thinking methodology. In November 2014 we invited doctoral colleagues to play the game, and three of them acted as direct observers with the responsibility of responding to a set of questions. The authors incorporated the direct observers' responses into the model and narrative of the game. The third step was to identify competing games in the marketplace and to analyze the products and how they were marketed. Our research identified games for children and adults, most of them strongly focused on cognition and competition. Our fourth step was to conduct an online survey among students of two classes at the doctoral program: the class that had participated in the game testing and another class that was completely unfamiliar with the game. The objective of the survey was to gauge people's perception of the game's attractiveness, color, name, and potential for learning and distribution. The authors have already registered the game at the Portugal government office Inspecção-Geral das Atividades Culturais – IGAC (General Inspection of Cultural Activities), which gives them a copyright on the game. Climate Adventure© is aimed at the general public (age 14 and up), and it is a parlor game whose aim is to keep the carbon dioxide (CO_2) in balance in the atmosphere so that weather conditions continue to favor life on Earth as we know it today. The two teams each begin the Adventure with an equal amount of CO_2 molecules; as they interact, they should finish the game with the same amount they had at the beginning, accepting a difference of +1 or -1. Throughout the game, the teams move from one space to the next by answering questions as they walk from the entrance to the exit gate of the atmosphere. During the game, the teams are able to use sources and sinks of carbon to keep their players in balance but they cannot exchange carbon with each other. The team that crosses the exit gate with their CO_2 in balance wins the game. The plan for the future is to promote Climate Adventure© as a capacity-building tool for employees at companies that have adopted social responsibility policies, and for public officials at municipalities that have adopted and are implementing climate-change adaptation/mitigation policies. It is the authors' conviction that when the general public can experience climate change as a tangible threat, they will be more active in seeking solutions to the social, political, and economic problems created when the earth's average surface temperature increases by +2°C or +4°C over the current 15°C. Therefore, the goal of Climate Adventure© is to give climate change tangibility. Santos; and concepts and fundamentals of communication theory and learning theory.

P-1123-15

The impact of the European Key Competences for Lifelong Learning on Sustainable Development

B. Sanchez-Royo (1)
(1) University of Brighton, Cultural Informatics Research Group, Brighton, United Kingdom

There is international consensus about the importance

of culture for global sustainable development. Europe's Intangible Cultural Heritage (ICH) – the skills, music, dance, drama, gastronomy, festivals, crafts, etc which have been passed from one generation to the next – is a hugely important resource that has an impact on sustainable environment in two ways. ICH is a 'product' for the cultural and creative industrial sectors (arts markets, design and crafts), and also as a 'process' for the economy and society as an inspiration for creativity and innovation (for instance, in education, science, tourism and social cohesion). Education plays a key role in safeguarding ICH as it enables its transmission, awareness raising and capacity building to a widest community. The connection between ICH, education and sustainable development is acknowledged by international organisations, academics and political bodies alike. In order to implement the concept of sustainable development effectively, it has to be linked with policies and measures. To this end, the Key Competences for Lifelong Learning (KCLL) in the European Reference Framework can serve as a common foundation for the development of ICH and education and ultimately to sustainable development. These competences cover all forms of behaviour that equip individuals to participate in an effective and constructive way in social and working life, and particularly in increasingly diverse societies, and to resolve conflict where necessary. This paper explores how KCLL contributes to activate a sustainable regional development. This paper is part of the 'ICH-Bildung' European research project on intangible cultural heritage and education funded by the Marie Skłodowska-Curie actions – Research Fellowship Programme.

P-1123-16

Integration of climate change education into school: A case study in Da Nang City, Viet Nam

T. Thi My Thi (1) ; P. Chau (2)

(1) Ha Noi University of Natural Resource and Environment, Department of Climate Change and Sustainable Developement, Ha Noi, Vietnam; (2) Department of Education and Training, Da Nang, Vietnam

Extensive damages caused by climate change are being reported daily all over the world, especially in developing countries like Viet Nam, where many people live in poverty, lack of infrastructure, lack of education, and limited access to technologies. The level of damages is highly dependent on the capacity of communities and individuals to response to climate change. Thus raising people awareness on climate risks, providing them with knowledge on local adaptation, and building their capacity to be resilient are the ultimate goals of climate change education (CCE). In order to find out appropriate approaches to promote climate change education in the specific context of Vietnamese education system, this research concentrates on two key important aspects including educational governance and educational activities. Educational governance includes activities related to educational management, policies, guidance, processes and decision-making on the application of climate change adaptation. Educational activities mentions to all teaching and learning activities in school, which target school students. The objective of the study is to maximize effectiveness of educational governance and educational activities in a way that help to facilitate and sustain climate change education in Viet Nam.

In the scope of this study, a case from Da Nang City will be presented. Da Nang is a coastal city of Viet Nam, which located in the central region. The city is considered as the largest education center of Central Vietnam and the third largest in the country. It is in top five provinces have the highest literacy rate and net enrolment rates at primary level. However, being a coastal city with three quarters of territory made up of hills and mountains, Da Nang is prone to frequent typhoons and heavy rainfall causing widespread flooding. In the last 10 years (2000 to 2010) there have been 21 typhoons directly hitting Da Nang with an average of two typhoons annually. In 2009, Typhoon Ketsana (Figure 4.17) directly hit south of Da Nang and left eight people dead; ninety-six injured, and damages costing 495 billion VND (about 25 million USD). In October 2013, Da Nang City was strongly hit by the typhoons Nari, which made landfall in Danang and Quang Nam areas with a Category 1 level on 15 Oct. It is reported that there was 11 injuries, 122 houses collapsed, 5449 house damaged/unroofed, 13 public buildings damaged. Aside from floods and typhoons, Da Nang was also impacted by droughts, river-bank and coastal erosion, and saline intrusion. Under the impacts of increased temperature and change of precipitation, droughts in Da Nang have become prolonged with more severe intensity.

Within this context, the Da Nang Department of Education and Training (DoET) has focused on preparing schools to reduce the impacts of climate change through improvement of CCE in school. The city has taken many steps foward such as developing plan for CCE, carrying out teacher training, strengthening the physical conditions of the majority of its schools located in vulnerable areas. However, at school level, the School Management Board appears to have taken very few steps towards reducing losses from disasters and ensuring the safety of their students. The performance of CCE in schools, in particular at primary level, remains inadequate. The capacity to respond to climate related disasters of school children and teachers is low, particularly the activities to return to normal teaching program after the disasters. This results in educational interruption and affecting educational quality.

By giving the overall pictures of existing conditions of CCE in Da Nang, it provides important insights to enhance the implementation of CCE into school through integrated approach. The result from the study shows that a coalescence of three approaches including textbook driven approach, symbiosis approach, and community-oriented approach will help to advance the level of CCE in Da Nang. The framework on how to consolidate these approaches in the application of CCE in school will be proposed.

P-1123-17

The potential for the implementation of an effective mechanism for improving local communities knowledge of adaptation to climate change

A. Vakhitov (1)

(1) Ecoforum of Uzbekistan, Tashkent, Uzbekistan

Climate variability is one of the many stresses faced by local communities. While it is not always the most important stressor or risk affecting a community, it should nevertheless be considered when designing and implementing a local-level project, particularly in communities characterized by climate- sensitive and/or natural resource-dependent livelihoods. The onset of longer-term climate change, which will compound existing stresses associated with climate variability, provides an added incentive for addressing climate risk in our research. Mountain territories not only are some kind of «barometre» of global climate changes, but their reaction have a significant impact on the further strengthening of these processes. People are faced with the need to find ways to adapt to the negative impacts of this phenomenon. Vulnerable populations will be different categories, depending on the projected effects: from scarcity of water resources will suffer all, but especially the affected populations, their livelihoods and earnings are directly dependent on the availability of water, such as farmers and rural residents; changes in temperature will affect the mode energy demand in winter for people who depend on uninterrupted power supply; negative climate change will impact on the country's biodiversity, and thus on the people for whom it is important to the existence of biological resources. In Central Asia, glaciers ensures the drinking water of mountain valleys and piedmont plains areas. Because of the reduction of ice resources now for the territory of Central Asia is characterized by severe water stress, and projected changes in climate here could cause a further reduction of water resources and reducing water consumption. In the period from 1955 to 2000 the surface area of glaciers has decreased from 70 thousand to 45 thousand km2. On the other hand, the human impact on environment is not always beneficial – poaching, felling of trees, no rational grazing, no rational use of natural resources. In this context, issues of adaptation of the population of mountains and others marginal areas to the impacts of climate change, development of policies and measures to prevent the adverse effects of climate change in the future are actual. But. In developing economics the State has not enough finances for environment and heath protection. Meanwhile, the situation has not become better from year to year. What to do? Who or what can help? We assumed that the best option in this case – the mobilization capacity at the community level. That is as an outlet could be mobilization of efforts of

local communities for protection of local ecosystems and its own health and budget. Why is this not being done or done insufficiently now? The reason, above all, in the absence of the local population aware that they can and should try to solve these problems themselves and to be able to raise these issues with the authorities. Mechanism for the implementation of this approach is to obtain the necessary information, the acquisition of relevant skills and knowledge. We offer that problems with training youth and adults can be solved not only at the state level, but also the help of local initiatives – at a local level, that under present conditions for developing countries more effectively. And, probably, it is necessary to begin from below – from family. Central research objectives – Identification of the potential for the implementation of an effective mechanism for improving local communities knowledge for adaptation to climate change. As a methodological tools used a public opinion poll, case study, a priori and statistical data, methods of observation; as one of the impact tools used brochure "Environmental safety of family and environment conservation". The case study include questions: 1. Identification of parameters (factors), climate change (oligohydramnios, drought, mudslides, avalanches, floods, land degradation, etc.) That affect the social aspects (function) – income, health, etc.; 2. Analysis of existing methods of mountain population adapting to climate change. 3. Identifying the needs of the knowledge and methods of influence. The next step of our research was to determine the feasibility of learning communities on an ongoing basis taking into account regional specificities. We analyzed a number of possibilities and we have offered cost-effective and accessible mechanism for improving local communities knowledge for adaptation to climate change. This experience can be disseminated and used in developing countries.

2201 - Between the cracks of future climate projections: exploring weather events and climate scenarios with no precedence

ORAL PRESENTATIONS

K-2201-01

Tales of Future Weather

W. Hazeleger (1)
(1) Netherlands eScience Center/KNMI/WU, Amsterdam, Netherlands

Society is vulnerable to extreme weather events and, by extension, to human impacts on future events. As climate changes weather patterns will change. The search is on for more effective methodologies to aid decision-makers both in mitigation to avoid climate change and in adaptation to changes. The traditional approach uses ensembles of climate model simulations, statistical bias correction, downscaling to the spatial and temporal scales relevant to decision-makers, and then translation into quantities of interest. The veracity of this approach cannot be tested, and it faces in-principle challenges. Predictability beyond 'weather' time scales is limited and physical consistency is often lost when downscaling. Alternatively, numerical weather prediction models in a hypothetical climate setting can provide tailored narratives for high-resolution simulations of high-impact weather in a future climate. This 'Tales of Future Weather' approach will aid in the interpretation of lower-resolution simulations such as produced in the Coupled Model Intercomparison Projects (CMIP). At this presentation a number of real-world cases will be presented where vulnerability to meteorological conditions was exposed. These are typically high-impact, not necessarily extreme, weather events. For instance compounded events of storm surges and extreme rainfall in the midlatitudes and of heat and drought in the subtropics. We will show how narratives of those analogues can describe the events in an alternative climatic setting to aid decision-makers. Producing the narratives is a transdisciplinary process where scientistis and decision makers co-develop the information needed. Arguably, 'Tales' potentially provides complementary, more realistic and more physically consistent pictures of what future weather might look like.

K-2201-02

No-analogue Climate Futures in the Tropics

R. Corlett (1)
(1) Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Center for integrative conservation, Menglun, Mengla, Yunnan, China

Climatic extremes in the tropics—cyclones, floods, droughts, and heatwaves—currently kill tens of thousands of people a year, and damage or destroy the livelihoods of many others. Wild species are presumably adapted to these extremes and, although individuals are killed, their populations usually persist, except when natural weather extremes interact with land-use change and other human impacts to change fire regimes and exacerbate floods and droughts. Climate models predict a further 1–2oC warming by 2050 and 1–4oC by 2100 for the tropics, but trends in rainfall and other variables vary between models for most regions. In much of the lowland tropics, this warming will create climates for which there is no existing analogue anywhere on Earth. Moreover, the low variability of tropical temperatures means that a rise in mean temperature of 2–3oC will bring routine maxima as high as today's extremes and new extremes that are higher than any that occur today. Although less certain, there are also good reasons for expecting increases in other climate extremes, including floods, droughts, and high-intensity cyclones. Predicting the responses of both human and natural systems to novel climate extremes is inherently difficult. Human societies have a considerable capacity to adjust to change, but exposure to climate change is likely to be greatest and adaptive capacity least among the poorest and most marginalized people. Predictions for natural systems depend on models, but we currently lack the data needed to assess their reliability when extrapolated beyond current conditions. There is an urgent need for both better models, built on a mechanistic understanding of the processes involved, and large-scale experiments.

O-2201-01

Future projection of precipitation associated with Cutoff Lows over South Africa in a Coupled Global Climate Model

A. Favre (1) ; C. Lennard (2) ; B. Hewitson (3) ; Y. Richard (1)
(1) Université de Bourgogne, Centre de recherches de climatologie, umr 6282 biogéosciences cnrs, Dijon, France; (2) University of Cape Town, Climate System Analysis Group, Cape Town, South Africa; (3) University of Cape Town, Environmental and Geographical Science, Rondebosch, South Africa

In South Africa, Cut-off Lows (CoLs) are known to be responsible for tempestuous weather and some remarkable precipitation events. This work presents how precipitation associated with CoLs may evolve in the region of South Africa in a context of global warming. Using the historical (1976–2005) and the Representative Concentration Pathway 8.5 (RCP8.5, 2006–2100) simulations of the Centre National de Recherches Météorologiques coupled global climate model (CNRM-CM5), the trajectories of 500-hPa CoLs have been constructed following the methodology presented in Favre et al 2013. During the historical period, we find that the geographical and seasonal distributions of CoLs' frequency over South Africa and surrounding oceans are well simulated by the CNRM-CM5. In addition, the main observed features of precipitation associated with CoLs are correctly reproduced by the model. According to the RCP8.5 simulation, drier conditions are projected over South Africa by the end of the 21st century and the CNRM-CM5 also presents a general decrease in annual precipitation, except over the plateau in the Northern Cape province. Precipitation associated with CoLs is projected to decrease excepted over the Northern Cape where heavy and extreme precipitation days (RR > historical 75th percentile and RR > historical 95th percentile, respectively) attributed to CoLs may be more frequent. These changes are associated with a slight reduction of CoL annual frequency of and with a slight equatorward shift of their domain of occurrence in the studied region. Over the 21st century, these changes are expected to develop in parallel with decadal variability and with an increase in the inter-annual variability of CoL's frequency.

O-2201-02

Polar lows and Medicanes: Understanding how intense mesocyclones and their impacts might respond to climate change

S. Len (1)
(1) NCAS-Climate, Department of meteorology, Reading, United Kingdom

Polar Lows and Medicanes are very intense, small cyclones that occur in the Norwegian and the Mediterranean Seas. Although small in size, Polar Lows and Medicanes can generate damaging winds that have substantial impacts on shipping, coastal communities and infrastructure. Polar Lows and Medicanes have very symmetric structures, often having a central eye-wall that has led to them being referred to as Arctic Hurricanes and Mediterranean Hurricanes. Polar Lows and Medicanes are too small to represent in typical climate models. This means that there are very large uncertainties in how Polar Lows and Medicanes will respond to climate change, despite their large socioeconomic impacts.

This talk will discuss progress in simulating Polar Lows

and Medicanes in global climate simulations performed at very high resolutions. The results of historical and climate change simulations with a 25km resolution version of the HadGEM3 climate model will be presented. The HadGEM3 simulations suggest that the frequency of both Polar Lows and Medicanes will decrease under climate change, primarily due to increases in the stability of the atmosphere over the Norwegian and Mediterranean Seas. However, there are some indications that when they do occur, Polar Lows and Medicanes may become more intense in a warmer climate. The potential for improving climate model projections of Polar Lows and Medicanes will also be discussed.

O-2201-03

Forecasting heavy precipitation producing cyclones in the island of Crete

I. Tsanis (1)

(1) McMaster University, Civil Engineering, Hamilton, Ontario, Canada

The intensification of the hydrological cycle due to climate change will produce intense meteorological events, causing higher precipitation in shorter time periods. The island of Crete is located in the Eastern Mediterranean and is prone to high precipitation events which cause an increased risk of flash flooding. The objective of this study is to obtain a better understanding of the hydrometeorological processes that produce heavy precipitation in the island of Crete and result in flash flooding. Effective forecasting for these natural disasters will increase public safety by reducing fatalities and changing the policy for a better flash flood risk management plan. For this purpose, images and datasets of the following parameters were used for the Eastern Mediterranean: (a) Meteosat Meteorological Images (Infra-Red IR-10.8, 3h); (b) Mean Sea Level Pressure ERA Interim (6h); (c) Wind at 500 hPa from ERA Interim (6h); (d) Vorticity at 500 hpa from ERA Interim (6h); (e) Lightning (USLN Lightning Network - 3h) and (f) hourly precipitation from Crete Meteorological Stations Network (3h). At present, the data from the 15-17th of November 2012 storm event has been analyzed. In this event, one of the precipitation stations located in the northwest part of the island of Crete, recorded more than 100mm of rain on 16/11/2012 and about 45mm of rain in the following day. More specifically, on 16/11/2016, 56.6mm of rain fell within one hour (14:00-15:00 UTC), and 27mm of rain on 17/11/2012 between 14:00-15:00 UTC. This severe rain event was caused by a cyclonic system approaching Crete from the Atlas Mountains, entering the Mediterranean on 15/11/2012, and moving to the east, with its center being located south of Crete. The spatio-temporal distribution of the relative vorticity, wind speed, mean sea level pressure, lightning and the time of precipitation are used to shorten the forecasting time of a heavy precipitation event, in a probabilistic sense. More cases will be analyzed and presented in the conference, in order to validate the forecasting precipitation results in terms of sensitivity, specificity and accuracy.

O-2201-04

Expansion of the tropics: evidence and implications

S. Turton (1)

(1) James Cook University, College of Marine & Environmental Sciences, Cairns, Australia

There is accumulating evidence that the tropical zone is expanding poleward in both hemispheres. The implications of a poleward tropical expansion are significant; subtropical arid, conditions may be seen in regions at higher latitudes which have historically enjoyed a more temperate climate, with implications for management of water resources and agricultural systems. However, some regions which currently border the equatorial zone may experience an increase in extreme rainfall, which could result in flooding, the displacement of communities and increased incidence of disease. The poleward expansion of the Tropics appears to be linked to a concomitant expansion in the tracks of tropical cyclones, potentially bringing cyclonic activity to regions which have previously not experienced such weather events. Changes to the tracks and activity of cyclones, and other extreme weather events, will impact on human health, biodiversity and the economy. The burden of vector-borne diseases on health and the economy of the Tropics may also increase as more regions become climatically suitable for insect vectors. The Tropics are the most biodiverse region on earth, with more endemic species and more biodiversity 'hotspots' than anywhere else. However research suggests that although many species are tracking climate changes, species in the Tropics may be lagging behind the rate of tropical expansion - meaning some species may not be able to sufficiently track their preferred environment and climate and may potentially risk extinction. This paper explores the implications of expansion of the tropics for societies and environments in the tropics, who are likely to experience futures with no precedence.

Assessment of Southwest Asia Surface Temperature Changes: CMIP5 20th and 21st Century Simulations

Z. Babar (1) ; XF. Zhi (2) ; G. Fei (2)

(1) Nanjing University of information Science and Technology, College of international students, Nanjing, China; (2) Nanjing University of information Science and Technology, Nanjing, China

Surface temperature variability in southwest Asia from CMIP5 20th century simulations and projected changes under three emission scenarios for the 21st century are assessed on the basis of a multimodel ensemble mean of seventeen CMIP5 runs and two observational datasets. Performance of individual model is also computed. Compared with observations CMIP5 models show seasonality in biases over southwest Asia. Cold biases over Himalayan range are significant in winter than in summer. Climatic warming during the 20th century is very well captured by the CMIP5 models. There is a limited agreement among the observations and CMIP5 models ensemble mean regarding the temperature trends and their spatial distribution over southwest Asia. Surface temperature variability over southwest Asia is best represented by three individual models i.e. BCC, HadGEM and NorESM. Temperature projections for the 21st century demonstrate that annual temperature rise for RCP 8.5 and RCP 4.5 scenarios is 0.55 C (10 year)-1 and 0.27C (10 year)-1 . RCP 2.6 scenario has the lowest warming rate at 0.11 C (10 year)-1. By the end of the 21st century annual mean temperature in southwest Asia is estimated to increase by 0.80 C to 4.85 C. Most of this warming is projected to take place around Pakistan and its surrounding areas.

P-2201-02

Investigation of uncertainty in the IPCC AR5 precipitation and temperature projections over Iran under RPC scenarios

N. Ghahreman (1) ; M. Tabatabaei (2) ; I. Babaeian (3)

(1) University of Tehran, Irrigation and Reclamation Engineering, Karaj, Islamic Republic of Iran; (2) University of Tehran, Irrigation and reclamation engineering dep., Alborz, Karaj, Islamic Republic of Iran; (3) Climatological Research Institute, Mashhad, Islamic Republic of Iran

Upon release of new scenarios based on Radiative Forcing which are known as Representative Concentration Pathway scenarios (RCP scenarios), by Intergovernmental panel on climate change (IPCC) in fifth assessment report (AR5), a new set of 42 global climate models (GCMs) have been proposed for future climate projections. By increasing number of available models for running and application to 42 which have been metioned in AR5, three main sources of uncertainty including: measurement error, variability, and model structure, have been explained and studied. The main aim of this study is to investigate the uncertainty of outputs of 37 Coupled Model Intercomparison Project Phase 5 (CMIP5) for precipitation and temperature data in Iran. Required data consist of two main groups: Simulated historical data and Observations. The observed data of rainfall and temperature were retrieved from three sources. Two databases namely; Climatic Research Unit (CRU) and NCEP/NCAR Reanalysis Project, and selected synoptic stations over Iran. Comparisons were made between the data reported in the climatic databases and those observed in synoptic stations using Root Mean

Square Error (RMSE) and Mean Bias Error (MBE) indices. The Monte Carlo simulation approach was used for uncertainty analysis of the simulated values of monthly precipitation and temperature and study stations observations. The results showed that there exists a close agreement between NCEP/NCAR Reanalysis Project data and observed ones, hence it was chosen as an alternate to observations for choosing the best models among the 37 selected GCMs. The latter section of study revealed that among the selected models, MPI-ESM-MR, MPI-ESM-LR, and NorESM1-M have the best performance in generating the rainfall and temperature data for baseline period of 1960-2000. Further studies using different sets of GCMs is recommended for more scrutiny.

The timing of summer climate departure in cities and its lethal impact

C. Mora (1) ; B. Dousset (2) ; C. Trauernicht (3) ; I. Caldwell (4) ; Q. Chen (1) ; C. Dau (1) ; B. Dietrich (5) ; R. Fang (1) ; R. Geronimo (1) ; E. Johnston (6) ; L. Li (7) ; M. Lucas (3) ; M. Mckenzie (1) ; F. Powell (1)

(1) University of Hawai'i at Manoa, Department of geography, Honolulu, United States of America; (2) University of Hawai'i at Manoa, Hawai'i institute of geophysics and planetology, Honolulu, United States of America; (3) University of Hawai'i at Manoa, Department of natural resources and environmental management, Honolulu, United States of America; (4) University of Hawai'i at Manoa, Hawaii institute of marine biology, Honolulu, United States of America; (5) University of Hawai'i at Manoa, Department of plant and environmental protection sciences, Honolulu, United States of America; (6) University of Hawai'i at Manoa, Department of botany, Honolulu, United States of America; (7) University of Hawai'i at Manoa, Department of atmospheric sciences, Honolulu, United States of America

Climate models for the 21st century predict a year-to-year variability in summer temperatures that lead to a significant increase in the occurrence, intensity, and duration of heat waves. These are especially deadly in urban areas that account for half the world population and are characterized by heat island effects, production of anthropogenic heat, and aging inhabitants. We investigated the projected times after which mean summer climate in large cities will shift beyond historical values, generating environmental conditions that will endanger human health. Data on urban extreme heat events and their related mortality during 1980-2010 were collected from an extensive literature review and relevant websites. When mapped, these data are predominantly distributed in the mid-latitudes, indicating either a more intense warming or/and a lack of available data in tropical regions. Climate variables and time of occurrence were extracted from actual data to identify the set of conditions that exceed human tolerance to extreme heat events. These thresholds were then combined with Earth System Models of the Coupled Model Inter-comparison Project phase 5 using different Representative Concentration Pathways (RCPs 2.6, 4.5, 8.5) to estimate the timing of lethal climates. Results indicate a strong association between climate anomalies and fatal weather events in the past and suggest that such events will occur periodically in all the largest cities of the world. Although it is possible that human adaptation and resilience to heat stress could reduce mortality, it is clear that ongoing climate change will pose a threat to human survival over vast areas of the world. The foreseeable urban summer climate departures call for a global and substantial reduction in greenhouse gas emissions. They also prompt for local implementation of sustainable mitigation strategies and for public health actions in order to reduce the lethal impact of climate change.

P-2201-04

Between the mazes of Climate Scenarios

B. Van Den Hurk (1)

(1) KNMI, Model Development, De Bilt, Netherlands

Climate scenarios, such as those prepared for the Dutch Climate Adaptation program, are useful instruments to cast a large collection of possible future evolutions in a generic reference framework. But these scenarios necessarily only describe the bigger picture, and miss the elementary details that govern every-day decision making. Challenging events are governed by a mixture of weather phenomena, infrastructure design, preparedness "on the ground" and compounding features. Here we illustrate a number of approaches relying both on past events and (synthetic) future weather cases that can provide the necessary additional "real life" material that is needed to support informed decision making.

2202 - Turn down the Heat: Climate Change Impacts, Development and Lock-in

ORAL PRESENTATIONS

K-2202-01

Development and the New Climate Normal

R. Kyte (1)

(1) World Bank, Washington D.C., United States of America

As the planet warms, heat and other weather extremes which occur once in hundreds of years, if ever, and considered highly unusual or unprecedented today would become the "new climate normal" as we approach 4°C. Ending poverty, increasing global prosperity and reducing global inequality, already difficult, will be much harder with 2°C warming, but at 4°C there is serious doubt whether this can be achieved at all. The urgency for action is even more critical, with growing evidence that warming close to 1.5°C above pre-industrial levels is locked-in to the Earth's atmospheric system.

The consequences for development would be severe as crop yields decline, water resources change, diseases move into new ranges, and sea levels rise. This presentation will look at the consequences of increased warming for the key geographic regions that the World Bank Group is engaged in, and action areas which are urgently needed to confront the development challenge. [A new global climate agreement in Paris this year needs to speak as loudly of economic transformation as it does of carbon emissions target. 2015 is a critical year for countries to re-think the way they manage their economies]. It's increasingly clear that smart policy choices can deliver economic, health and climate benefits. Come hear how the Bank is working with client counties to address this unprecedented challenge.

K-2202-02

The implications of climate mitigation policy for the impacts of climate change

N. Arnell (1)

(1) University of Reading, Walker institute, Reading, United Kingdom

The broad aim of climate mitigation policy is to avoid the dangerous impacts of climate change. The definition of 'dangerous' is of course contested, and there are many potential definitions. The Copenhagen Accord states the aspiration of limiting the increase in global mean temperature to 2oC above pre-industrial levels, and other groups are urging lower temperature targets. Meanwhile, existing and new pledges for future emissions will imply different - and probably larger - increases in global temperature. Most attention is given to the economic, technical, political and social implications of achieving specific emissions reductions, but it is also necessary to assess the impacts that are avoided or delayed by mitigation policies. This is partly because it helps define the benefits of climate mitigation, and partly because it highlights the impacts that remain: this helps inform

national and international adaptation policies.

This keynote talk will present results from the UK AVOID programme, which is concerned with both identifying and quantifying impacts of climate change under different potential emissions pathways and assessing the technical and economic feasibility of these pathways. The focus of this presentation is on the impacts avoided and delayed by climate mitigation. It considers global and regional impacts on a range of sectors including water resources, flooding, agriculture and energy demand, and evaluates how these impacts are affected – globally and regionally – under different mitigation pathways. The effects of climate change and mitigation policy are expressed in terms of the magnitude of impact and the risks of impacts exceeding specific thresholds.

The presentation concludes by reviewing the key issues involved in assessing the implications of climate mitigation policy for impacts, which include the representation of adaptation within global-scale impact assessments, the treatment of uncertainties, and the presentation of results in terms meaningful to climate policymakers and negotiators.

K-2202-03

Visions of Global Responses to Climate Change - Lock-in and Transformation

J. Dangerman (1)
(1) Potsdam Institute for Climate Impact Research, Potsdam, Germany

This keynote will discuss the central dynamics of complex systems that determine change and lack of change. Or, in more specific terms, that determine transformation and lock-in. It will also present a case that illustrates these dynamics and their effects in practice.

Important portions of yesterday's and today's socio-technological-political decisions extrapolate the past into the future and thereby profoundly constrain the possibilities of important systems to transform themselves non-catastrophically so that they can help mitigate their current and future effect on climate change and the ensuing impacts on nature and humanity. The transpiring rigidification of these systems is eminent from essential perspectives and in fact provides grounds for structural alternative decisions. However, the constraints caused are often underestimated and misinterpreted and the accompanying alternative decisions are frequently not so profoundly breaking with the past. The development of a key actor in climate change, the global energy system, provides ample examples of these instances and on a macro-scale shows the ensuing lock-in patterns.

This keynote therefore provides a simple and stylised view on the universal workings of the fundamental dynamics that determine the behavior of evolving complex systems, such as cells, the human brain, organisms, organisations, technologies, societies and economies. It uses the concepts of effectiveness & efficiency and chaos & organisation in the context of the cyclical and periodical behaviour of these systems to explain the dynamics of both transformation and lock-in.

It ends with a discussion of a research case about the role of energy efficiency policies in the building industry (called «Best Practice Policies for Low Carbon & Energy Buildings Based on Scenario Analysis, authored by the Center For Climate Change And Sustainable Energy Policy, Central European University) to elucidate the lock-in dynamics, their consequences and their implications for policy making. Three scenarios explain the potential for the buildings sector to mitigate energy consumption in China, the EU, India and the USA. The most ambitious scenario shows the benefit and necessity of taking today's best practice to a global scale.

O-2202-01

Hydrological variability, transboundary floods and institutions: an exploration of tomorrow's bottlenecks

M. Bakker (1) ; J. Duncan, (2)
(1) Utrecht University, Utrecht, Netherlands; (2) University of Vermont, Vermont, United States of America

Floods are among the world's most frequent and damaging types of disasters and annually affect the lives of millions all over the globe. Over time, human exposure and vulnerability to floods has increased with a growing and increasingly urbanized population. The projected effects of climate change on hydrology, aggravated by a range of social, economic and political processes will continue to increase this vulnerability. Nonetheless, vulnerability of societies and their institutions to floods remains poorly understood.

Purpose
Using global data, we examine the nexus of transboundary flood events and social vulnerability: which international river basins (IRBs) have experienced transboundary floods, i.e. floods that affect two or more countries, in the past, and which are forecast to experience increased hydrological variability in the future, but lack institutional provisions, i.e. river basin organizations and/or treaties, to deal with these shared events?

Methodology
Current data and research on institutional capacity deriving from treaties as listed in the Transboundary Freshwater Dispute Database (Yoffe, Ward and Wolf, 2000; De Stefano et al. 2012) will be refined by looking more specifically at the roles that river basin organization functioning and treaty composition play in flood management. IRBs will be stratified by the type of climate-related stress they may face in terms of hydrological change and the aspects of society most affected by flooding. Then, this updated information will be merged and weighted to produce a vulnerability ranking specific to floods and the institutions designed to manage them.

Results and conclusions
A global vulnerability ranking of IRBs and cities when it comes to transboundary floods, climate-driven hydrological variability and institutional capacity.

Societal relevance
The findings of this research will significantly increase our current knowledge on transboundary flood events, projected variability regimes related to the shared waters between countries, and flood-related international institutional capacity. These insights will help policy-makers of tomorrow identify and evaluate potential tipping points related to transboundary river floods.

O-2202-02

Past and future weather-induced risk in agriculture

J. Elliott (1) ; C. Müller (2)
(1) University of Chicago, Chicago, United States of America; (2) Potsdam Institute for Climate Impact Research, Potsdam, Germany

The global food system has seen increased volatility in recent years, with spiking food prices blamed for civil unrest on several continents. Rising prices for global commodity products like maize, soy, meat and palm are increasingly driving deforestation around the globe, and with agriculture increasingly interconnected to global food and energy markets, weather-related risk and supply-side shocks have become a key issue of concern for governments and businesses alike. Speculation about the risk of future large-scale extremes have led some authors to contend that more people will suffer in future from large-scale drought and heat events than any other climate-change-related disaster.

Using best-available archives of global crop and climate models from the Agricultural Model Intercomparison and Improvement Project (AgMIP) and the Intersectoral Impact Model Intercomparison (ISI-MIP), we look first at the impacts of 65 years of continental and global extreme events using observation-driven models and data. We identify the most severe historical events in caloric terms at national to global scales and evaluate the ability of models and model ensembles to identify weather-induced extreme years, correctly assess the magnitude of large-scale extreme events, reproduce historical country-level variability, and reproduce spatial patterns of losses under extreme drought.

We next consider these global crop models driven with large ensembles of climate model output (both under historical forcing and with future scenarios) to characterize present day risk and the extent of non-stationary risk in

global crop production. We find increasing, and in many cases accelerating risk, of extreme global loss events even in scenarios with little to no climate-induced long-term mean changes. In some cases, global-scale production loss events that would have recently been called 1-in-100 year events are estimated to occur every 30 years by mid-century, and ever 10-20 years by end-of-century.

We present these scenarios and consider regional and global protective measures that might be introduced, including increased trade, stock-hoarding, crop breeding, and improved forecasts, monitoring, and modeling. We also consider the extent to which aggressive carbon mitigation may decrease the risk of extreme loss events in future.

O-2202-03

Climate indicators of pace and perception of changes over the 21st century

Y. Chavaillaz (1) ; S. Joussaume (1) ; S. Bony (2) ; P. Braconnot (1) ; R. Vautard (1)
(1) LSCE-IPSL, Gif-sur-Yvette, France; (2) LMD-IPSL, Paris, France

In most studies, climate change is approached by focusing on the evolution between a fixed current baseline and a future period. They emphasize stronger warming and increasingly modified precipitation patterns as we move further from the current climate. This long-term vision is adopted in order to characterize quantitatively the magnitude and expected effects of mitigation policies across the globe, but is not well suited to discuss coming generations' experience. In this study, we propose an alternative approach that considers indicators of pace and perception of changes using projections of a General Circulation Model ensemble. It first consists in tracking statistics and their projected changes with a 20-year running baseline, defining the time evolution of the pace at which climate changes on the scale of a generation. Then, distributions of the following and previous 20 years are compared for each year to theoretically assess the perception of changes. We focus here on the annual and seasonal evolution of surface air temperature and precipitation.

Under the strongest emission pathway (RCP8.5), the warming rate and its perception become far stronger over the 21st century, with a maximum reached around 2060. While northern high-latitudes witness a higher temperature rise, all other latitudes highlight at least a doubling in the warming rate and indicators of perception are at their highest value in the tropics, especially in West Africa and South-East Asia.

As for precipitation under the same pathway, moistening and drying rates strongly increase at global scale. Regions with significant rate of change expand more and more over the 21st century. Moreover, rate patterns tend to spatially stabilize, making them persistent in some regions that also exhibit the largest rates and the largest increases of rate by 2080: e.g. the Mediterranean Sea, Central America, South Asia and the Arctic.

These trends are already visible in the current period, but could almost disappear if strong mitigation policies were quickly implemented. Only the strongest mitigation pathway (RCP2.6) leads to a global return to historical regime. This approach shows that, under strong emissions, one should be prepared for higher adaptation rates in the coming decades regarding temperature and precipitation change.

2202-POSTER PRESENTATIONS

P-2202-01

Mitigation and Adaptation are not enough: turning to emissions reduction abroad

A. Ayong Le Kama (1) ; A. Pommeret, (2)

(1) EconomiX, University of Paris West, Nanterre - La Défense, Nanterre, Cedex, France; (2) School of Energy and Environment, City University of Hong Kong, G5702, 5/F, Academic 1, Tat Chee Avenue, Kowloon,, Hong Kong

In this paper we focus on a long-term dynamic analysis of the optimal adaptation/mitigation mix in the presence of a pollution threshold above which adaptation is no longer efficient.

We account for accumulation in abatement capital, greenhouse gases, and adaptation capital in order to better capture the arbitrage between abatement and adaptation investments.

Pollution damages arise from the emissions due to the country consumption but also from the emissions of the rest of the world (ROW).

A pollution threshold is then introduced, above which adaptation is no longer efficient. We obtain that if this threshold is lower than the steady-state level of pollution, there is no way for the modeled economy to avoid it. In particular, such a situation will appear if the ROW's emissions are high.

Next step is then to introduce another type of investment allowing for lower ROW pollution ie. emissions reduction abroad through some mechanisms like CDM for instance. We obtain that CDM may be a means to avoid a pollution threshold above which adaptation becomes of no use.

P-2202-02

Two degrees or not two degrees: that is the question – interim results from ICA-RUS project

S. Emori (1) ; T. Kiyoshi (1) ; Y. Yamagata (1) ; S. Kanae (2) ; S. Mori (3) ; Y. Fujigaki (4)
(1) National Institute for Environmental Studies, Tsukuba, Japan; (2) Tokyo Institute of Technology, Tokyo, Japan; (3) Tokyo University of Science, Department of Industrial Administration, Noda, Chiba, Japan; (4) The University of Tokyo, Tokyo, Japan

Politically, the long-term target of climate change might not actually be a question at this moment. However, we have to repeatedly ask ourselves the question – whether it should really be "two degrees" and why – to ensure that the target is kept transparent, responsible and relevant.

We have tackled this issue from a risk management perspective in an interdisciplinary research project, called the Integrated Climate Assessment – Risks, Uncertainties and Society (ICA-RUS) since 2012, funded by the Ministry of the Environment, Japan. It has tried to integrate insights from the areas of climate risk assessment, energy economics modeling, energy-water-food-ecosystem nexus, and STS (science, technology and society). By a risk management perspective, we mean that the problem is framed as an informed, adaptive decision making under uncertainties (potentially including deep uncertainties), involving social value judgment.

We have supposed three "Alternatives left to humanity" represented by mitigation targets, 1.5, 2.0 and 2.5 degrees C, below which humanity tries to keep the global mean temperature increase relative to preindustrial levels at a probability of 50% (which roughly translate into 2.0, 2.5 and 3.0 degrees C targets at a higher probability like 80%).

For each alternative mitigation target, potential consequences have been assessed for various sectors including disastrous weather events, water resources, agriculture, health, ecosystem and tipping elements. The potential consequences are represented by a range taking into account uncertainties in climate, mitigation and socio-economics. Thus, for example, even if 2.0 degrees C target is set, the potential consequence includes a 3.0 degrees or higher global mean temperature increase associated with corresponding impacts, due to various kinds of uncertainties.

At the same time, possible combinations of mitigation options and associated mitigation costs have been assessed for each mitigation target with multiple energy economics models with different modeling assumptions. Various risks and opportunities (side-effects and co-benefits) associated with each mitigation option are also kept in mind.

Putting these assessments together, the project is currently in the process of characterizing the risks to be reduced and to be retained for each "Alternative" (i.e., each mitigation target). As a next step, adaptation effort needed

and potential effect of geoengineering consideration for each Alternative will be assessed. Possible public participation process in the risk decision to enhance social rationality is also being discussed.

P-2202-03

Modelling ecosystem response to present and future drought events in Western Europe with the CARAIB dynamic vegetation model

AJ. Henrot (1) ; M. Dury (1) ; A. Hambuckers (2) ; G. Munhoven (3) ; I. Jacquemin (1) ; L. François (1)

(1) Unité de Modélisation du Climat et des Cycles Biogéochimiques, Département d'astrophysique, de géophysique et d'océanographie, Liège, Belgium; (2) Biologie du Comportement – Ethologie et psychologie animale, Département de biologie, écologie et évolution, Liège, Belgium; (3) Laboratoire de Physique Atmosphérique et Planétaire, Département d'astrophysique, de géophysique et d'océanographie, Liège, Belgium

With unprecedented speed and extent, future climate change can be expected to severely impact terrestrial ecosystems due to more frequent extreme events, such as droughts or heat waves. These extreme events might lead to severe impacts on terrestrial plants functioning, implying reduction in net primary production and possibly plant mortality in many regions. The Inter-Sectoral Impact Model Integration and Intercomparison Project (ISI-MIP2) has been explicitly designed to evaluate the models' ability to reproduce observed historical variability, and response to present-day and future extreme climatic events, reflecting the interest of the community as well as stakeholders in this particular topic.

In this contribution, we analyse the results over Western Europe of the ISI-MIP2 simulations performed with the CARAIB dynamic vegetation model (Dury et al., 2011, iForest 4, 82-99), for a series of well-marked drought events in the simulated historical and future periods. This analysis is performed at the species level, using a set of 99 species (47 herbs, 12 shrubs and 40 trees), especially designed to represent the European vegetation. Model response to drought events is evaluated in terms of several important environmental variables, such as soil water and hydric stress, runoff, PFT/species abundance, net primary productivity and biomass, fire frequency, and turnover of soil organic matter. Some sensitivity tests are performed to study the impacts of changing some not well-constrained model parameters, such as thresholds and response times for plant mortality induced by soil water stress.

P-2202-04

When can we expect to see the benefits of climate mitigation?

B. Sanderson (1) ; B. O'neill (2) ; C. Tebaldi (3) ; G. Strand (4)

(1) NCAR, Climate Change Research, Boulder, CO, United States of America; (2) National Center for Atmospheric Research (NCAR), Boulder, CO, United States of America; (3) NCAR, CGD, Boulder, CO, United States of America; (4) NCAR, Boulder, United States of America

We present a two 30 member ensembles of possible future climate using a single climate model, CESM, to assess the question of when climate mitigation action becomes evident in the presence of irreducible internal climate variability. Our business-as-usual and mitigation ensembles assume the RCP8.5 and RCP4.5 scenarios respectively, and we find that although internal varaibility causes a comparable uncertainty to the differences in forced climate response until 2050, significant differences in the risk of extreme warm events are evident in as early as 2025 in the two scenarios for some regions (and for most regions by 2040). Furthermore, the following decades from 2050-2080 see largely separate temperature distributions in the two ensembles for most regions, although we do not see significant differences in precipitation between the two scenarios even for periods after 2060. Hence, in the CESM's representation of the Earth System for the latter portion of the 21st century, the risks of impacts related to temperature extremes in the next 20 years can be significantly reduced by greenhouse gas mitigation, even in the presence of internal climate variability.

P-2202-05

Influence of Water Resource Management on Altering Hydrological Drought under Climate Change

Y. Satoh (1) ; K. Yoshimura (2) ; P. Yadu (3) ; H. Kim (4) ; T. Oki (5)

(1) International Institute for Applied Systems Analysis, Water, Laxenburg, France; (2) The University of Tokyo, Atmoshpere and ocean research institute, Kashiwa, Japan; (3) Rutgers, The State University of New Jersey, Camden, United States of America; (4) The University of Tokyo, Institute of industrial science, Tokyo, Japan; (5) University of Tokyo, Tokyo, Japan

It is expected that global warming alters hydrometeorological cycle and influences on occurrence of drought. Future drought is projected to increase with high probability in some regions, such as the Mediterranean region, the west side of USA and so on, resulting in severer water scarcity. Nevertheless only few studies have investigated the effect of planned water management, such as dam regulation and irrigation, against drought. Understanding of the effect of existing infrastructures under changing water-environment is needed for our society to adapt to future climate changes. Therefore, this study aims to estimate the effect of the anthropogenic activities on terrestrial water cycle as well as the impacts of climate changes.

This study focuses on hydrological drought, particularly on stream drought. HiGW-MAT, a state of arts land surface model capable to reproduce energy and water cycle considering the anthropogenic water management, was used to simulate historical and future terrestrial water cycle under RCP scenarios. Five bias-corrected CMIP5 GCM outputs provided by ISI-MIP fast track for 1980-2099 were used to force a set of simulations.

Future drought was projected, and hot spots of climate change impact were detected with uncertainty discussion. It was found that number of hydrological drought days would increase and decrease over approximately 70 % and 25 % of global land. Increase of drought days in the first half of 21th century is larger than that of the second half in 19 out of 26 regions of IPCC regional classification. The effect of anthropogenic water management is depicted as a difference between simulations with and without anthropogenic components. As for time series variation, the difference showed that both of short-term variation and long-term change are alleviated by introduction of water management, though it was also suggested that exploitation of water from river due to water use accelerates drought. This model exercise presents a valuable preliminary evaluation of human impact for the purpose of planning of more practical assessment which provides optimal water management scenarios.

2203 - Defining dangerous climate change: Contributions from the AR5 ' Key Risks' and ' Reasons for Concern' frameworks and future directions

ORAL PRESENTATIONS

K-2203-01

The IPCC Reasons for Concern: History, current status, and future directions

B. O'neill (1)
(1) National Center for Atmospheric Research (NCAR), Boulder, CO, United States of America

The Reasons for Concern (RFCs) framework, developed in the Third Assessment Report (TAR) of the Intergovernmental Panel on Climate Change (IPCC), organizes scientific information to inform decisions relevant to implementation of Article 2 of the UN Framework Convention on Climate Change (UNFCCC). Article 2 contains the Convention's long-term objective of avoiding "dangerous anthropogenic interference with the climate system". The framework facilitates judgments about changes in impacts, risks, and vulnerability as a function of global mean warming by sorting and aggregating them into five categories viewed from a global perspective. The RFC framework and the associated "Burning Embers" diagram illustrating these judgments have been widely discussed and applied. We sketch the history of the use of the RFC framework in IPCC assessments and describe refinements made for the recent Fifth Assessment Report (AR5). In AR5, the RFCs were reframed to define all five categories in terms of risk. In addition, a more consistent approach to judging risk was used that was linked to the concept of Key Risks that was used across much of the Working Group 2 report. We also illustrate how risk judgments are grounded in the scientific literature and highlight remaining challenges to making such judgments. Useful improvements to the RFC framework include better accounting for alternative metrics of climate change beyond the level of global average temperature change, explicit incorporation of the future vulnerability of society and ecosystems, and better communicating the specific risks over which RFC categories aggregate.

K-2203-02

Reasons For Concern as a Tool for Assessing Dangerous Climate Change and their Utility for Climate Negotiations

L. Charles (1)
(1) Charles & Associates, Inc., St. George's, Grenada

The Reasons for Concern framework has been used by the IPCC to communicate its results to policy makers in a policy informative, but not policy prescriptive manner. It assesses the risks in light of the UNFCCC Article 2 – to avoid dangerous interference with the climate system – by presenting a continuous representation of how key risks change with temperature rise. The framework has been used in the UNFCCC negotiations as one of the key inputs to the process of the 2013-2015 review of the adequacy long-term global goal under the UNFCCC.

Key issues that I will explore in this context are (a) how well do the RFCs reflect the full scope of Article 2, including impacts on ecosystems, food production and sustainable development? and (b) The extent of its use in the UNFCCC review, the results obtained from its use and the utility of these results.

From a policy perspective, the RFC framework has approached the analysis of these risks through a global lens. However, policy responses to these risks take place at the national and regional levels, primarily through adaptation action. It is therefore very relevant to also review the framework's applicability in informing policy at the national and regional levels. This will be done from the perspective of Small Island Developing States (SIDS).

Key questions to explore in this context include:

- What is dangerous Climate Change from the perspective of SIDS? What are their key risks? How well do the RFCs reflect these risks?
- How are these RFCs, and the associated risk levels, perceived by policy makers and does that match with the scientific definitions? Are these consistent with SIDS experience of the impacts from these risks and their perception of these risks?
- Does this framework help SIDS to assess these risks? What kinds of decisions can policy-makers arrive at from using this framework?

In reviewing these questions, two major obstacles can be identified, which may be of general importance beyond the SIDS context. Firstly, is the somewhat different character of the RFCs. While RFC 1,2 and 5 (unique systems, extreme events and singular events) are clearly defined and understandable, this is not the case for RFC 3 and 4 (distribution and aggregated impacts), where the names of the RFCs may imply a different assessment than what is in the scope of the RFCs.

A second obstacle identified is connected to the question of the translation from regional to global risks and relates to the assessment of the specific risk levels. In particular, the step from moderate to high risks is crucial. While moderate risks reflect that "associated impacts are both detectable and attributable to climate change", high risks indicate "severe and widespread impacts". From the perspective of a region that is highly vulnerable but not widespread in terms of land area, this is not an intuitive categorization, since there is a lot between these two risk levels and the question arises re how high, or very high, local risks translate to global risks in such an assessment.

In my presentation, I will reflect on these issues and discus the pros and cons of the RFC approach giving special consideration to its usefulness for the UNFCCC process and for SIDS. I will also discuss a potential way forward for further improvements of the concept.

Key risks in the IPCC's Fifth Assessment Report: a basis for evaluating and responding to danger from climate change

K. Mach (1) ; M. Mastrandrea (1) ; V. Barros, (2) ; C. Field (3)
(1) Carnegie Institution for Science / IPCC WGII TSU, Stanford, CA, United States of America; (2) Universidad de Buenos Aires / IPCC WGII, Buenas Aires, Argentina; (3) Carnegie Institution for Science / IPCC WGII, Stanford, CA, United States of America

The Working Group II contribution to the IPCC's Fifth Assessment Report provides a cohesive and integrative assessment of key risks in a changing climate. The assessment informs judgments about danger from climate change, and it provides an actionable summary of the opportunities for response. This presentation will introduce the assessment framework developed, the resulting conclusions about risks and options across possible climate futures, and the implications for future research and assessment. In the Fifth Assessment Report, key risks are defined as potentially severe impacts relevant to Article 2 of the United Nations Framework Convention on Climate Change. They emerge from high hazard or high vulnerability or exposure of affected societies and systems. Across chapters of the assessment, authors identified key risks based on expert judgment using specific criteria, encompassing large magnitude or high probability of impacts, timing or irreversibility of impacts, persistent vulnerability or exposure contributing to risks, or limited potential to reduce risks through adaptation or mitigation. For key risks across sectors and regions, the assessment evaluates changing levels of risk over the next few decades, an era of some further locked-in

warming, and in the second half of the 21st century and beyond, a longer-term era of climate options. It considers the potential for risk reduction through adaptation along with the limits to adaptation. Throughout, the risk levels reflect probability and consequence over a full range of possible outcomes due to climatic and non-climatic factors. Key risks spanning sectors and regions include risk of severe ill-health and disrupted livelihoods from flooding and extreme heat, of food and water insecurity, and of ecosystem and biodiversity loss, as well as systemic risks from extreme events. Overall, the key risk assessment supports the report's overarching conclusion about risks globally with continued high emissions: increasing magnitudes of warming increase the likelihood of severe, pervasive, and irreversible impacts. The key risk assessment also highlights defining features of the climate challenge and priorities for future research. These include the importance of complex, multi-step interactions in shaping risks, the need for rigorous expert judgment in evaluating risks, the limitations in current abilities to quantify risks, and the centrality of risk perceptions, values, and goals in determining responses.

Measuring the dynamics of risks at the global and local level: information for transformative change

J. Birkmann (1) ; T. Welle, (1) ; W. Solecki (2) ; M. Garschagen, (3) ; M. Pelling, (4) ; J. Agboola, (5)
(1) Institute for Spatial and Regional Planning, University of Stuttgart, Stuttgart, Germany; (2) CUNY Institute for Sustainable Cities , New York City, United States of America; (3) United Nations University,, Institute for Environment and Human Security, Bonn, Germany; (4) King's College London, Department of geography, London, United Kingdom; (5) Lagos State University, Lagos, Nigeria, Federal Republic of

Key risks identified in the IPCC AR5 encompass various themes and dimensions, however, all these risks underscore the influence of climate change on hazards and the significance of exposure and vulnerability as determinants of risk. Based on selected risks identified in the AR5 the presentation examines how core determinants of these key risks and their dynamics, namely hazard patterns, exposure and vulnerability at the global and local scale, can be measured and quantified. Measuring changing hazard conditions, exposure of people and their vulnerability demonstrate that particularly increasing exposure contributes to increasing risks levels in various countries and urban areas (global overview). This global overview with national level resolution will be complemented by two local risk studies.

The second part of the paper examines risk configurations and changes in risk profiles for selected large-scale, coastal cities. Coastal cities are at the frontline of living with climate and socio-economic change. Existing adaptation and development visions that should address key risks tend towards policies for stability (resistance) or flexibility to protect existing core functions (resilience). There is increasing recognition in the academic literature that a third policy option of fundamental change (transformation) is needed in order to address key determinants of the key risks also named in the AR5. Against this background changes in local risk profiles and risk trends are examined and specific policy options to confront these risks are discussed. This part of the presentation draws from a Belmont Forum funded study, Transformation and Resilience on Urban Coasts (TRUC), that examines five coastal megacities to begin to profile transformative options based on the assessment of dynamics of hazards, exposure and vulnerability to climate change related risks.

Concrete examples of past and present risk patterns are presented using the case studies of New York and Lagos. In addition, methods and results of new scenario techniques are shown that underscore the importance of exploring future pathways of exposure and vulnerability next to climate change scenarios. Differences and synergies between quantitative and qualitative scenario techniques will be explored using the local level risk studies. In conclusion, we formulate recommendations on how to use this information on changing risk profiles for promoting resilience and transformative change at local level focusing on policy options for adaptation in the two case studies.

Malek, (8) ; R. Mechler (8) ; I. Meyer (5) ; I. Offenthaler, (4) ; A. Schaffhauser, (2) ; F. Sinabell (5) ; R. Spiekermann, (7)
(1) alpS Centre for Climate Change Adaptation, Innsbruck, Austria; (2) Zentralanstalt für Meteorologie und Geodynamik (ZAMG), Vienna, Austria; (3) Austrian Agency for Health and Food Safety (AGES), Vienna, Austria; (4) Environment Agency Austria, Vienna, Austria; (5) Austrian Institute of Economic Research (WIFO), Vienna, Austria; (6) Austrian Research Centre for Forests, Vienna, Austria; (7) University of Salzburg, Department of geoinformatics – z_gis, Salzburg, Austria; (8) International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria

IPCC's Burning Embers – Reasons for Concern illustrate the future global risk development split into five categories and visualize the trends. To date, this holistic concept has not been transferred to the local government level where risks associated with climate change are mostly still understood and analyzed in a sector- and hazard-specific manner rather than in a scenario-based way.

In the project ARISE (Adaptation and Decision Support via Risk Management Through Local Burning Embers) funded by the Austrian Climate Research Program, closing this gap is a research focus, and a decision support system for climate-sensitive iterative risk management as a key adaptation approach is developed. The City of Lienz in East Tyrol, Austria serves as a pilot site for ARISE. The project's overall objectives are (i) to contribute to identifying and bridging the gaps between global frameworks, research and policy related to climate change and disaster risk reduction and national, subnational as well as local risk management and adaptation needs and requirements by coupling and integrating information across scales, (ii) to downscale the "Burning Embers – Reasons for Concern" to the local level (LBE) with respect to hazard types and sectors including a consideration of key risk drivers, and (iii) to support the building of resilience and adaptation capacities at the local level via an LBE-integrated, iterative risk management approach that takes participatory processes and learning from practitioners into account.

In order to meet the project's objectives, user-oriented methods in the form of hybrid techniques (top-down and bottom-up, model-driven and participatory) are used. To date, interviews with various stakeholder groups have been conducted and a comprehensive desk review on global, regional and national frameworks has been completed. Based on this input, the generic framework for downscaling the Burning Embers – Reasons for Concern to the local level has been developed. To apply this framework to the study site, regional climate scenarios for the City of Lienz have been computed. Further methods for determining the LBEs include the building of regional socio-economic scenarios by focusing on region-specific knowledge and visions (by means of a scenario workshop), supported by socio-economic modelling. Moreover, a land-use scenario is being developed and indicators have been determined that also take confidence levels into account. In order to integrate the LBEs into the local risk management of Lienz and design tailored climate-sensitive risk management measures, a collaborative approach will be taken again, test runs will be conducted as well as a monitoring&evaluation concept devised. All information and processes will be fed into a dynamic risk information tool. The decision support system for climate-sensitive iterative risk management will be standardized to enable a wider application and roll-out.

In this presentation, an overview of the ARISE project and its concept will be given. The generic framework as as well as its application to the City of Lienz will be presented and challenges discussed. Additionally, an outlook on the next steps and expected findings to be obtained through the integration of the LBEs with risk management and adaptation strategies will be provided.

P-2203-01

A regional differentiation of climate impacts at warming levels of 1.5°C and 2°C

CF. Schleussner (1) ; T. Lissner (1) ; J. Wohland (2) ; E. Fischer, (3) ; K. Frieler, (4)
(1) Climate Analytics, Berlin, Germany; (2) Postdam Institute for Climate Impact Research, Potsdam, Germany; (3) ETH Zurich, Zurich, Switzerland; (4) Potsdam Institute for Climate Impact Research, Potsdam, Germany

Article 2 of the UNFCCC specifies that the aim of the convention is the "stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system". Limiting global mean warming below 2°C increase above pre-industrial levels has been widely accepted as a global goal in this context. However, many vulnerable countries, particularly small island developing states and least developed countries, have questioned whether this limit is sufficient to protect their interests, and as a consequence there is an international process underway to evaluate risks and damages at different levels of warming, including 1.5°C and 2°C. Studies of current and expected future impacts of climate change suggest that significant negative impacts, relevant to Article 2 of the UNFCCC may be felt at lower levels of warming than 2°C. Within the UNFCCC there is a formal process reviewing the 2° limit, and examining the possibility of changing it towards 1.5°C.

At present there is a gap in the scientific literature and methods to rigorously and qualitatively assess differential impacts at these levels of warming. Here we present a framework that allows for a differentiation of regional changes in climate impacts at different levels of global mean temperature (GMT) increase, focusing on the differences between 1.5°C and 2°C. Based on data from the CMIP5 archive as well as output from the ISIMIP project, we assess the climate impact projections for the 26 world regions used in the IPCC SREX report. We show results for several extreme event indices as well as projections of water availability and agricultural yields. Furthermore, we are able to test for statistical significance of changes in climate impact projections between the different warming levels across the model ensemble.

As climate impacts are not necessarily linear, it is important to understand whether a significant shift in the magnitude of impacts may occur between the different temperature levels and little attention has been given to such a shift at lower levels of warming. Furthermore, the consequences of average global temperature increase are not linearly distributed across regions. A differentiation of the spatial manifestation of change is therefore of high relevance for regional planning, in order to develop suitable coping strategies and adaptation options, as well as to inform decisions about the appropriate long-term global temperature goal.

P-2203-02

Defining dangerous climate change in accordance to international law: What is and is not "dangerous" and how to define "dangerousness"? International standards for certain basic considerations for "policy-makers", "policy-takers", scientist and jurists

S. Pena (1)
(1) Universidad Bernardo O Higgins, Law and Environment, Santiago de Chile, Chile

It has been a common theme among commentators the consequences for living forms on the change of climate. The main problem is to define "danger" before it comes to a natural disaster. Natural disasters have been faced in Chile and South American countries in the last ten years and they have been described since the beginning of the discovery by Christopher Columbus in 1492. The "El Niño" and "La Niña" environmental phenomena are some of the effects in the change of the weather defined by indigenous people and local communities. This might be described as the "minimum" danger, a danger that has been noticed clearly by none experts. On the other hand the "Chaiten" Volcano in 2008 and the Chilean Earthquake in 2010 show the degree of destruction of natural disasters. This might be described as a "strong" danger, a current one. In between is possible to find a danger that has been described but still is not defined by humans, it is subtle danger: Climate change is a "silence disaster" because it affects slowly but without capability to be aware of the danger and to contain the consequences that are established in between the defined basic change and the disaster, therefore in a moment it is necessary to define the concept of "current strong danger". This article will focus on the capacity of international law to present certain basic elements for policy makers and policy takers (defined as those that implement or propose change of policies and laws at the national level) in order to define "menace" on the human beings and on the plants, animals and microorganisms by the destruction of habitats when the change of the climate is able to destroy such habitats. In this sense rights and obligations between States, from States to human and "non-human" beings and for the Nature are proposals to define "current strong danger". When those rights to life have been affected by the modification of the climate a first approach towards the definition of "danger" will be in place. Therefore the process of prevention has to be detained and measures towards mitigation and recovery has to be established. International law and law in general has defined many of these words like equitableness, justice, "fumus bonis iuris" and now is necessary to define "danger" in a present and solid form based on international law. A first approach will be international conventions on climate change and economic rights of persons, human rights of the persons and possibly the Rights of Nature.

Detection of bifurcations in noisy coupled systems from multiple time series

M. Williamson (1) ; T. Lenton (1)
(1) university of exeter, exeter, United Kingdom

We generalize a method of detecting an approaching bifurcation in a time series of a noisy system from the special case of one dynamical variable to multiple dynamical variables. For a system described by a stochastic differential equation consisting of an autonomous deterministic part with one dynamical variable and an additive white noise term, small perturbations away from the system's fixed point will decay slower the closer the system is to a bifurcation. This phenomenon is known as critical slowing down and all such systems exhibit this decay-type behaviour. However, when the deterministic part has multiple coupled dynamical variables, the possible dynamics can be much richer, exhibiting oscillatory and chaotic behaviour. In our generalization to the multi-variable case, we find additional indicators to decay rate, such as frequency of oscillation. In the case of approaching a homoclinic bifurcation, there is no change in decay rate but there is a decrease in frequency of oscillations. The expanded method therefore adds extra tools to help detect and classify approaching bifurcations given multiple time series, where the underlying dynamics are not fully known. Our generalisation also allows bifurcation detection to be applied spatially if one treats each spatial location as a new dynamical variable. One may then determine the unstable spatial mode(s). This is also something that has not been possible with the single variable method. The method is applicable to any set of time series regardless of its origin, but may be particularly useful when anticipating abrupt changes in the multi-dimensional climate system.

2204 - A world above 2°C global warming: understanding risks and developing transformative solutions

ORAL PRESENTATIONS

O-2204-01

Transformative solutions to high-end climate change

D. Tabara (1) ; J. Jaeger (2) ; P. Harrrison (3) ; I. Holman (4)
(1) Independent consultant - UAB, ICTA, Barcelona, Spain; (2) Independent Consultant, Vienna, Austria; (3) Environmental Change Institute, University of Oxford, Oxford, United Kingdom; (4) Cranfield University, Cranfield, United Kingdom

Current trends in greenhouse gas emissions show that limiting global warming to the international target of 2°C is likely to be difficult. Despite the increasing plausibility of high-end scenarios, there are few studies that assess transformative strategies and solutions to address potential synergies and trade-offs between adaptation, mitigation and sustainable development. The latest IPCC AR5 report defines transformation as 'a change in the fundamental attributes of natural and human systems [...that...] reflects strengthened, altered, or aligned paradigms, goals, or values towards promoting adaptation that supports sustainable development, including poverty reduction' (IPCC 2014; WGII, SPM p.5). However, the notion and implications of transformation in climate science and policy are poorly understood. On the one hand, transformation is an autonomous dimension which does not depend on, or is not necessarily conditioned by, either mitigation or adaptation strategies. But on the other hand, transformative adaptation and transformative mitigation policies can contribute to the development of decisive systems' innovations to cope with high-end scenarios, while at the same time fostering sustainable development. To achieve this goal, knowledge and new modelling tools on how to develop and implement 'global systems of interconnected solutions' are urgently required. The new emerging Global Systems Science (GSS) is a promising approach which could support Integrated Climate Governance by looking at new modes of science appraisal, global governance arrangements and engagement with stakeholders. In particular, innovative climate strategies and solutions could take advantage of, and support, a number of global transformative forces already evident outside of the strictly climate domain. These include: 1. Increasing interest in the creation of a global citizenship, e.g., to redistribute global climate rights and responsibilities; 2. The development of win-win solutions to generate a global green low-carbon economy, to replace the brown economy; 3. Opening Human Information and Knowledge Systems (HIKS) and coupling them with Social-Ecological Change, to connect knowledge networks and agents globally to deal with specific sustainability needs and problems; and 4. The generation of distributed and conducive conditions for global cooperation and institutional capacity building, to ensure the equitable implementation of transformative strategies and policies in the long-term. This presentation will introduce this cluster of interconnected systems of global solutions, referred to as the 'Global Transformation Propeller', and suggest how it could be used to develop and implement transformative responses in the face of high-end scenarios. Our goal is to stimulate an open debate to explore the implications for climate science and policy of existing or potential transformative forces that can be connected to innovative solutions which are able to cope with HES while supporting sustainable development.

O-2204-02

Avoiding the impacts of climate change: Results from the BRACE study

B. O'neill (1)
(1) National Center for Atmospheric Research (NCAR), Boulder, CO, United States of America

Understanding the potential consequences of climate change for ecosystems and society is necessary for an informed response to the climate issue. A particularly important task is improving our understanding of how impacts differ across alternative levels of future climate change. Such understanding can help inform the balancing of the costs of climate change mitigation and adaptation with the benefits of reduced impacts. This talk will present results from a project led by the National Center for Atmospheric Research (NCAR) on the Benefits of Reduced Anthropogenic Climate changE (BRACE), which assesses the differences in impacts between two specific climate futures: those associated with Representative Concentration Pathways (RCPs) 4.5 and 8.5. The latter would lead to a likely global average temperature change of 3.2-5.4 C relative to pre-industrial temperatures by the end of the century, the former to a likely range of 1.7-3.2 C degrees of warming. This project is quantifying avoided impacts in terms of extreme events, health, agriculture, tropical cyclones, and sea level rise. Methodologically, it combines climate modeling, statistical analysis, and impact assessment to examine physical, ecological, and societal impacts, and draws heavily on the use of large initial condition ensembles of climate model simulations in order to better account for internal variability and extreme events and to develop new approaches to pattern scaling techniques. Results show that the benefits of reduced climate change vary substantially across sectors, and depend importantly on assumptions about future societal conditions.

O-2204-03

Understanding and Addressing Infinite and Existential Climate Risks

J. Rockström (1)
(1) Stockholm Resilience Center, Stockholm university, Stockholm, Sweden

Scientific evidence indicates humanity has entered a new geological epoch, the Anthropocene, where the world entreprise constitutes the largest driver of change at the planetary scale. Furthermore, we increasingly find evidence that the social and environmental response to rising human pressures on the planet are non-linear, and that the globalized world of the 21st century is associated with rising social-ecological turbulence. This raises the need to better understand risks of facing infinite or existential risks, i.e., risks that may affect a significant proportion of the global population or the entire world community. In this presentation a presentation is made of a scientific methodology to investigate infinite risks, including global climate risks, and a first assessment of global risks is presented, and compared, e.g,. with the WEF global risk report.

O-2204-04

Sensitivity of Amazonia to climate change: the main uncertainties are effects of Drought, Elevated Temperature and Elevated CO2

B. Kruijt (1) ; C. Von Randow (2) ; H. Verbeeck (3) ; P. Meir (4) ; DH. De (3) ; W. Jans (1) ; L. Rowland (4) ; B. Christoffersen (4) ; D. Galbraith (5) ; A. Rammig (6) ; C. Seiler (7)

(1) Alterra, wageningen UR, Wageningen, Netherlands; (2) Instituto Nacional de Pesquisas Espaciais, Ccst, Sao Jose dos Campos, SP, Brazil; (3) University of Gent, Gent, Belgium; (4) University of Edinburgh, School of geosciences, Edinburgh, United Kingdom; (5) University of Leeds, Leeds, United Kingdom; (6) Potsdam Institut fuer Klimaforshung, Potsdam, Germany; (7) University of Victoria, Victoria, Canada

Amazonia is under threat of the combined effects of unsustainable regional development and climate change. As summarised in the IPCC reports of 2007 and 2014, studies in the past ten years indicate that these pressures can lead to deforestation, regional and global disturbance of temperatures and the water cycle, as well as causing loss of carbon stocks and biodiversity. In turn, these transitions can result in forest loss, droughts, low river levels, floods, loss of hydropower energy and plenty of other ecosystem services. Even enhanced risk of livestock and human diseases and loss of agricultural productivity are inextricably related to these stressful alterations. Recognising that processes driving land-use change and fire in Amazonia are of overriding importance, here we address three biophysical uncertainties related to the impact of climate change on Amazonia: the effects of drought, elevated temperature and elevated CO2. Model experiments have shown repeatedly that these factors represent the highest uncertainly in projecting climate change impacts.

The EU-FP7 AMAZALERT project has investigated the threats through combining novel field measurements with modelling of feedbacks between Amazonian ecosystems, human-caused land-use change and the climate system. Field measurements indicate that leaf level maximum rate of photosynthesis is not significantly affected by temperature increases. Thus, also with climate change, trees may be well able to maintain high rates of photosynthesis, however, this negative temperature sensitivity is currently overestimated in vegetation models. Data from experimentally droughted forest and of dry years show that in particular large trees of some tree species, are vulnerable to drought, thus potentially risking significant biomass losses. Besides, prolonged (multi-year) drought appears to eventually lead to higher respiration rates, i.e., less efficient growth. However, basin-wide plot measurements indicate that at short timescales (months) forests are able to remain net primary production at constant level during, for example, the 2010 drought but photosynthesis was suppressed, autotrophic respiration decreased and carbon allocation patterns changed potentially leading to increased post-drought forest mortality. Such observations provide important insights for model development at the physiological level. The net effect means that under extended drought and warming, if no fire occurs, a long-term change in the species composition and structure of the forest is likely, together with an increase in the amount of dead and decomposing wood, potentially turning the forest into a carbon source.

The effects of increasing atmospheric CO2 on Amazonian forests can so far only be assessed from theory, which predicts that the forests may become more robust and may even grow through 'CO2 fertilisation', but this fertilisation effect is limited by the availability of nutrients such as nitrogen and phosphorus. At the same time, theory and some data sets predict that water use efficiency will increase, which may increase forest resistance but also l decrease water cycling, potentially causing a climate warming feedback. The magnitude of these limiting effects is still uncertain due to poor understanding of soil nutrient dynamics and this must be improved by rigorously combining measurements and new modelling approaches. Altogether, it is clear that new data are needed and it is essential that these processes will be investigated in a new, whole-ecosystem elevated CO2 experiment such as the AMAZON_FACE experiment which is currently being set up in the Amazon basin. These should be combined with other focused research projects further addressing drought and temperature dependence.

O-2204-05

Implications of growing CO2 emissions for staying below the 2°C limit

P. Friedlingstein (1)

(1) University of Exeter, Exeter, United Kingdom

Efforts to limit climate change below a given temperature level require that global emissions of CO2 cumulated over time remain below a limited quota. This quota varies depending on the temperature level, the desired probability of staying below this level and the contributions of other gases. In spite of this restriction, global emissions of CO2 from fossil fuel combustion and cement production have continued to grow by 2.5% per year on average over the past decade. Two thirds of the CO2 emission quota consistent with a 2 °C temperature limit has already been used, and the total quota will likely be exhausted in a further 30 years at the 2014 emissions rates. I present recent analysis showing that CO2 emissions track the high end of the latest generation of emissions scenarios, due to lower than anticipated carbon intensity improvements of emerging economies and higher global gross domestic product growth. In the absence of more stringent mitigation, these trends are set to continue and further reduce the remaining quota until the onset of a potential new climate agreement in 2020. Breaking current emission trends in the short term is key to retaining credible climate targets within a rapidly diminishing emission quota.

Climate change and very dangerous heat waves: Projecting frequency of high-mortality heat waves in 82 US communities in 2061—2080 under different climate, population, and adaptation scenarios

B. Anderson (1) ; K. Oleson, (2) ; B. Jones, (3) ; R. Peng, (4)

(1) Colorado State University, Environmental and Radiological Health Sciences, Fort Collins, CO, United States of America; (2) National Center for Atmospheric Research, Boulder, CO, United States of America; (3) CUNY Institute for Demographic Research, New York, NY, United States of America; (4) Johns Hopkins Bloomberg School of Public Health, Biostatistics, Baltimore, MD, United States of America

Certain rare heat waves, like the 2003 heat wave in France, can have devastating effects on a community's public health and well-being. Here, we built models to predict which heat waves are likely to be such "very dangerous" heat waves, based on characteristics of the heat wave (e.g., intensity, length) and of the community in which it occurred (e.g., population), using recent (1987—2005) data from 82 large US urban communities. We built twenty potential classification models and used Monte Carlo cross-validations to evaluate these models, identifying three models capable of predicting the occurrence of very dangerous heat waves. Using these three models, we predicted the frequency of very dangerous heat waves in these 82 communities in 2061—2080 under two scenarios of climate change (RCP4.5, RCP8.5), two scenarios of population change (SSP3, SSP5), and three scenarios of community adaptation to heat (none, lagged, on-pace). We found that the frequency of very dangerous heat waves was most strongly influenced by the pace at which communities

are able to adapt to their changing climates. We found that the frequency also depended somewhat on climate change scenario, while it was practically unchanged across different population scenarios, although these scenarios did influence projected person-days of exposure to very dangerous heat waves. Our results suggest that it is critical to consider adaptation scenarios when projecting health impacts of heat under climate change scenarios. Further, our findings suggest that community-level adaptation measures are likely to be a critical protection against future very dangerous heat waves.

P-2204-02

Early Entrants of Rainfall Index Insurance: Insights from Rural Households in Central West Nigeria

D. Awolala (1) ; A. Mbaye (2) ; J. Von Vraun (3) ; W. Fonta (4) ; S. Sanfo (4)
(1) Centre for Research and Development, Bonn, Germany; (2) Centre for Research and Development, West african science service centre on climate change and adapted land use (wascal), Bonn, Germany; (3) ZEF, Research, Bonn, Germany; (4) West African Science Service Center on Climate Change and Adapted Land Use (WASCAL), Competence center, Ouagadougou, Burkina Faso

Farmers have traditionally adapted to weather-induced production risks over time. The failures of subsidized crop insurance schemes and rising trends of climate extremes have increases their vulnerability to higher risks. With ideal levels of adaptation, some residual impacts from weather shocks would still lead to economic losses. Rainfall index insurance can transfer farmers' risks and increase supports for agricultural lending. This study used cross-sectional data to analyze potential demand for rainfall index insurance as financial adaptation to extreme local climate in central west Nigeria. The study shows that monthly distribution of rainfall uncertainties thereby constraining optimal planning within the available production period. Farmers' vulnerability to rainfall delay, early cessation, and occasioned long dry spell has consequences on resource use productivity. There is demand for rainfall index insurance as nearly 65% demonstrated willingness to insure in the programme. Over 70% are risk-averse but are positively disposed towards insurance. There is a very low confidence in insurance and finance service providers as means of financial adaptation towards resilience. Farmers' education, farming as major livelihood, production risk index, and start bid are significant on households' decisions to insure in rainfall index insurance but households' size, distance to weather station, awareness of agricultural insurance, previous drought experience have inverse coefficient. The more farmers' education, dependence on farm income, production risk index and start bid increases; the higher the probability to belong to both somehow willing and definitely willing category to be insured. Farmers who have access to seasonal forecast are somehow WTP an amount that is 31.7% lower than farmers who do not on average and ceteris paribus. For every unit increase in production risk aversion, there is an increase of 43.7% in the farmers amount WTP on average and ceterius paribus since they are willing to secure their residual risk through market based indemnity transfers. Those already aware of agricultural insurance practices are also somehow WTP 37.6% higher than their fellows with no prior knowledge on average and ceteris paribus to secure their 'residual' risk. Mean (N352.91and median WTP (N250) obtained from the interval regression are higher for the definitely willing category than the somehow willing. In overall, farmers in somehow willing category are more elastic to price while those in definitely willing category are more inelastic to prices of microinsurance policy. For every unit increase in production risk aversion, there is an increase of 43.7% in the farmers amount WTP on average and ceteris paribus since they are willing to secure their residual risk through market based indemnity transfers. Farmers already aware of agricultural insurance practices are also somehow WTP 37.6% higher than their fellows with no prior knowledge on average and ceteris paribus to secure their 'residual' risk. Mean (N352.91and median WTP (N250) obtained from the interval regression are higher for the definitely willing category than the somehow willing. Managing Catastrophic Climate Risks under Model Uncertainty Aversion

L. Berger (1) ; J. Emmerling (2) ; M. Tavoni (3)
(1) Fondazione Eni Enrico Mattei (FEEM), Milan, Italy; (2) FEEM, Milano, Italy; (3) Fondazione Eni Enrico Mattei , Climate change and sustainable development programme, Milan, Italy

We propose a robust risk management approach to deal with the problem of catastrophic climate change which incorporates both risk and model uncertainty. Using a two-period model of optimal abatement, we show how model uncertainty and risk aversion interact. We disentangle the impact of preferences towards different types of uncertainty from the structure of model uncertainty on the optimal level of abatement, by means of a simple measure of model uncertainty. With data from expert elicitation about climate change catastrophes, we show the relative importance of these two effects and calibrate an integrated assessment model of climate change. The results indicate that the structure of model uncertainty, and specifically the convergence of agreement across models are the key driver of abatement, and that model uncertainty aversion warrants a higher level of climate change mitigation.

Treatment of uncertainties in the IPCC's Fifth Assessment Report: Lessons learned for informing management of climate-related risks

M. Mastrandrea (1) ; K. Mach (1) ; V. Barros, (2) ; C. Field (3)
(1) Carnegie Institution for Science / IPCC WGII TSU, Stanford, CA, United States of America; (2) Universidad de Buenos Aires / IPCC WGII, Buenas Aires, Argentina; (3) Carnegie Institution for Science / IPCC WGII, Stanford, CA, United States of America

This presentation will discuss lessons learned through implementation of a common approach for characterizing the degree of certainty in findings of the assessment process in the Intergovernmental Panel on Climate Change's Fifth Assessment Report (IPCC AR5), with a focus on informing climate risk management in future assessments. Managing climate-related risks involves decision making in a changing world, with continuing uncertainty about how climatic and non-climatic factors will evolve and interact over time. Risks result from the interaction of climate-related hazards with the exposure and vulnerability of society, and vary substantially across plausible alternative development pathways. In the IPCC AR5, assessment of risks relied on diverse forms of evidence, including empirical observations, experimental results, process-based understanding, statistical approaches, and simulation and descriptive models. Expert judgment is critical in integrating such diverse evidence into evaluations of risks and in determining the extent to which risks can be quantified. The common approach used in the IPCC AR5 emphasizes assessment of the consequences and relative likelihoods of the widest possible range of future outcomes, including low-probability outcomes with large consequences, to inform risk management. It also emphasizes providing clear traceable accounts of the confidence in and support for assessment findings, describing an author team's evaluation of the type, amount, quality, and consistency of evidence and the degree of agreement underlying each finding. Clear traceable accounts ensure users of the assessment can understand the evaluation and integration of evidence supporting assessment findings. Further use of structured methods for organizing and quantifying expert judgment could aid future assessment efforts within and beyond the IPCC in delivering policy-relevant findings with clear traceable accounts and in quantifying climate risks based on a diverse evidence base mixing quantitative and qualitative information.

P-2204-05

Sensitivity of Natural Micro-Regions of North-East Hungary to Landscape Degradation

J. Mika (1) ; A. Kertesz (2)
(1) Eszterhazy Karoly University College, Envirinmnetal Sciences and Landscape Ecology, Eger, Hungary; (2) Research Centre for Astronomy and Earth Sciences Hungarian Academy of Sciences, Budapest, Hungary

The objective of our research is to survey degradation processes acting in each micro-region, as well, as to investigate the sensitivity of the micro-regions to degradation. A survey of land degradation processes has been carried out at medium scale (1:50 000) to identify the affected areas of the region. The methods include field work, analysis of topographic maps and remote sensing materials, statistical analyses, GIS methods and preparation of photo documents. The sensitivity of landscapes will change in the future because of global climate change. As a consequence of this, the extent and the intensity of degradation processes may change, too. Regional climate scenaria, based on GCM, RCM and empirical downscaling are all included and synthesized for the specified hilly region of ca. 20,000 sq. km. The scenaria, scoping at 50 years ahead with possible linear interpolation and extrapolation in time, include changes of seasonal means and expected changes in some extreme event, as well. The following land degradation processes are included in the database of the present and expected future states: (i.) Land (soil) degradation involving also mass movements (sheet erosion, gully erosion, wind erosion, mass movements, salinization, degradation due to soil structure changes, soil sealing). (ii.) Removal of vegetation due to deforestation and to the extension of urban, industrial areas, transport tracks, etc. (iii.) Degradation of waters. (iv.) Degradation of the scenic value of the landscape. (v.) Degradation due to land use change (other changes than those under (ii.)). (vi.) Wounds in the landscape (abandoned mines, open-cast mines, etc.). (vii.) Desertification. The sensitivity of the natural micro-regions to degradation are determined by applying sensitivity indices. Different factors are the driving forces of the various degradation processes and so different indices are created for each process with specific weighting of the identified factors, mostly based on empirical regression analyses. The concept of the index is based on the MEDALUS index (Kosmas et al. 1999). The factors included in the investigation are: (a) Soil properties (soil structure, soil water budget, organic matter content, salinity, soil parent material). (b) Climate properties (drought index, yearly precipitation, rainfall intensity). (c) Vegetation properties (forest fire risk, sensitivity of vegetation to drought, vegetation cover %). (d) Surface and subsurface water properties (ground water depth, flood risk, inundation risk). (e) Anthropogenic load (water use, waste disposal, population change, land use intensity). Finally the sensitivity index values are shown in maps. The sensitivity of natural micro-regions of North-East Hungary is also investigated under the circumstances of the expected climate change scenaria, applied to characterise landscape sensitivity in the future. The map of the existing land degradation processes, sensitivity maps of the present and simulated future climatic conditions are analysed by GIS methods. The map series and the evaluation provide important information about the state and sensitivity of the natural micro-regions and this information is useful for policymakers at different levels. The study has been supported by the OTKA-K108755 national project.

P-2204-06

The relative role of anthropogenic climate change on risk of heat mortality in the European heatwave of 2003

D. Mitchell (1) ; C. Huntingford (2) ; C. Heaviside, (3) ; S. Vardoulakis, (3) ; F. Otto (1) ; M. Allen (4) ; P. Frumhoff (5)
(1) University of Oxford, Oxford, United Kingdom; (2) CEH, Wallingford, United Kingdom; (3) Public Health England, Oxford, United Kingdom; (4) University of Oxford, School of Geography and Environment and Dept of Physics, Oxford, United Kingdom; (5) Union of Concerned Scientists, Cambridge, MA, United States of America

The 2003 European heat wave was one of the most extreme meteorological events in terms of loss of life in Europe in recent times. Estimates of excess heat-related deaths for this event could be as high as 70,000, with France being particularly affected.

The chaotic nature of the climate system is such that extreme meteorological events of this magnitude will to some extent always occur "by chance". However external factors may increase or decrease the frequency of occurrence. Such factors include climate change related to anthropogenic influences, such as greenhouse gas emissions and land use change, but also natural influences such as changes in solar output, and large volcanic eruptions.

Here we use a unique modelling capability to perform massive ensembles of climate model simulations ("climateprediction-dot-net: CPDN"), which enables assessment of any changing probabilities of particular meteorological extremes of interest. We compare scenarios representing the year 2003 (i) as it actually was (i.e. where both natural and anthropogenic conditions are used to drive the climate model; "scenario 1"), and (ii) as it could have been, if humans had not altered atmospheric gas composition (i.e. with only natural conditions; "scenario 2").

This study considers each aspect of the 2003 heat wave, from the inherent warmer atmosphere due to raised greenhouse gas concentrations, and to any additional confounding and related changes in probability of altered large-scale atmospheric circulation patterns. We use baseline health and demographic data to estimate associated mortality impacts on the local populations. An additional feature of CPDN is that each global simulation contains a high-resolution "nested" regional climate model centred on Europe. This high-resolution modelling capability allows us to perform much of the analysis at the city level. For Scenario's 1 and 2, we therefore show how heat-related mortality changed over Paris during 2003.

Climate Change Induced Excessive Heat Exposure Undermines Global Health Equity and Economic Development

M. Otto (1) ; B. Lemke, (2) ; T. Kjellstrom, (3) ; C. Freyberg, (3) ; D. Briggs, (3) ; O. Hyatt, (3)
(1) Nelson Marlborough Institute of Technology, Digital Technology, Nelson, New Zealand; (2) Nelson Marlborough Institute of Technology, Nelson, New Zealand; (3) Ruby Coast Research Centre, Mapua, New Zealand

The physiological limits of the human body in coping with high heat exposure and heat stress are relatively well established since several decades. However, the implications of climate change trends of extreme heat have only recently been analyzed. The health effects include heat exhaustion (which reduces work capacity and labor productivity), clinical heat stroke, exacerbation of certain chronic diseases and acute fatalities. Physical work adds in a major way to the heat stress because of the internal heat production from muscle work.

Our analysis compares the population based estimates of health impacts of heat for selected climate models applied to RCP8.5 (the current emission track) and RCP6.0 (what may be achieved with more stringent climate mitigation policies). The global mean temperature increase this century for RCP8.5 using various models generally ranges between 3 and 5 oC, while the RCP6.0 increase generally ranges between 1.5 and 2.5 oC.

Whichever health outcome is analysed poor people are always at highest risk as they are likely to be in heavy physical work and they cannot afford air conditioning to the same extent as higher income people. Poor people in low and middle income tropical countries are at particular risk as most of these countries already experience several months of extreme heat each year. The heat exposure levels expressed as «millions of person hours of exposure above agreed heat risk limits» are particularly high in these countries from a global health perspective. For example, working people in SE China without air conditioning at the prevailing ambient heat levels, will lose as much as 30% of the daylight work hours in the hottest month and the annual loss will be 8% as these hours are too hot for moderate level continuous work. In SE USA the equivalent losses are 5% in the hottest month and 2% annually. (more examples will be added in the final presentation)

The increasing heat impacts on clinical health and labor productivity are a growing threat to improvements in health equity at global, national and local level, as the people most vulnerable to heat stress are those with poor living and working environments and many of them already have a poor health status. The labor productivity loss also undermines local economic development and slow down any progress in poverty reduction programs.

P-2204-08

Climate analysis at local scale in the context of climate change

H. Quenol (1)
(1) CNRS- UMR6554 LETG, Université Rennes 2, Rennes, France

Issues related to climate change increasingly concern the functioning of local scale geo-systems. A global change will necessarily affect local climates. In this context, the potential impacts of climate change lead to numerous interrogations concerning adaptation. Despite numerous studies on the impact of projected global warming on different regions, global atmospheric models (GCM) are not adapted to local scales and, as a result, impacts at local scales are still approximate. Although real progress in regional climate modeling was realized over the past years, no operative model is in use yet to simulate climate at local scales (ten or so meters). It is therefore at a finer spatial scale, which considers land surface characteristics, it will be possible to assess the impacts of climate change. Our scientific approach aims to develop a methodology based on climatic observations in situ and on spatial modeling of climate, which permits to evaluate the spatial variability of atmospheric parameters at fine scales (mean values and climatic extremes). By completing the lack of data at local scales, this work allows to improve the understanding on climate changes that may appear at local scale and thus advance the assessment of the potential impacts. This methodology is developed and applied in agro climatology (viticulture) and in urban climatology.

In viticulture, the LIFE-ADVICLIM (LIFE13 ENV/FR/001512: ADapatation of VIticulture to CLIMate change : High resolution observations of adaptation scenarii for viticulture) project aims at observing climate at local scales in different European vineyards, representing the climate diversity in European wine regions ; simulating climate and climate change in order to produce a fine scale assessment of the climate change impacts, thereafter simulating scenarii of adaptation for viticulture. Climate modeling at fine scales will include (i) the output from numerical EURO-CORDEX models with a kilometer resolution (ii) the spatial modeling of climatic data from the measurement networks using multicriteria modeling at very high resolution (90 m), and (iii) the future climate simulations using meso-scale climatic model ran under different scenarios of climate change. (i) The coarse resolution output from numerical climate models require downscaling. We use the downscaling output of EURO-CORDEX. It will provide knowledge and understanding of climate variability at meso-scale in the different studied European wine regions. Climatic data from national weather station networks will be used to validate the outputs of modelled data. (ii) In order to construct fine-scale spatial temperature fields, the multicriteria modelling will be used. This approach takes environmental factors into account. Indeed, the role of topographic factors in the spatial variability of temperatures at fine scales, in addition to the influence of geographical location (latitude/longitude) at larger scale has already been demonstrated. This type of modeling will make use of the climatic data provided by the fine scale network. (iii) We use simulations of climate change scenarios (for Europe) carried out CORDEX program

For example, the results of the measurements and modeling adapted at terroir scales have permitted to highlight a strong spatial variability of climate at very small spaces. In terms of temperatures, the spatial differences generated by the local conditions (topography, etc.) are very often greater than the increase in temperatures simulated by the different scenarios of IPCC for the next 50 years. Vine growers adapt their practices to this spatial variability of climate that partly determines the characteristics and uniqueness of their wine. In the context of climate change, this approach of a spatial analysis could be a method to adapt to the temporal changes in climate, especially in the short and medium term.

In urban climatogy, the same scientific approach (measurement and modeling at fine scales) has been applied. The same methodology was applied in Rennes city. The results showed a strong spatial variability of the temperatures in relation to local characteristics of the city (eg green areas, densely built-up urban area...). In the context of global change, climate analysis at fine scales helps to define the development policies.

P-2204-09

The risk of drought in Ukraine under changing climate in the future medium term

I. Semenova (1)
(1) Odessa State Environmental University, Theoretical meteorology and meteorological forecasts, Odessa, Ukraine

The territory of Ukraine almost every year is exposed the drought of different intensity and duration. The country is belongs to main agricultural area of East Europe, therefore the drought in vegetation season can considerably worsen the productivity of grain crops. As studies shows, the seasonal (or agricultural) drought is the widespread in Ukraine with dominating in spring and summer time. In last two decades the full vegetation season droughts were observed in 1999, 2007, 2009 and 2012. Most important spring-summer (April-June) drought occurred in 1996, 2003, 2007 and 2012. In this years were fixed the large crop losses of winter wheat and spring barley – 10-43% from the trend.

Under the climate changing is become important the estimates of future drought risks, which is necessary for long-term economic planning. For assessment of the drought frequency in the future was used data of CMIP5 (Coupled Model Intercomparison Project, phase 5) for period 2020-2050.

Analysis of spatial and temporal distribution of drought was held using the index SPI. For its calculation has been used multimodel (32 models) monthly mean precipitation data for two boundary scenarios, which represents the RCP (Representative Concentration Pathways), experiment RCP2.6 and RCP8.5.

Under the scenario RCP2.6 surface air temperature anomaly in Ukraine until 2050 will be +0.7, +2.1degrees Celsius compared with a baseline period 1981-2010. According to the scenario RCP8.5 increasing of temperature can be up to +2.8, +3.1degrees Celsius. Precipitation will be slightly increased in both scenarios.

SPI was examined for three timescales 12, 7 and 3 months, in order to cover droughts of different duration.

The SPI12 analysis for local points showed that at the RCP2.6 some significant dry periods will be observed in 2020's and 2040's, but at the RCP8.5 expected increasing the intensity and duration of drought episodes after 2035. The most severe drought is projected in 2042-2045.

The SPI7 analysis during vegetation season (April-October) showed that at the RCP2.6 total number of drought will be several larger than at the RCP8.5. The frequency of weak and moderate droughts at the RCP2.6 averaged to 12-14 cases per 31 years, according to the RCP8.5 is 10-12 cases. Severe and extreme droughts under both scenarios are expected in 1 to 4 years, but not everywhere.

Analysis of drought frequency in different seasons using SPI3 showed that during 2020-2050 expected a slight increasing the total number of drought and its redistribution within the warm season. The increasing of the number summer-autumn droughts (August-October) and reducing of summer droughts (June-August) are projected, especially in mild scenario RCP2.6. The frequency of drought could reach up one per every 2-3 years across regions. Maximum number of droughts in all seasons predicted for the northeast and western regions of Ukraine, which in the present climate are not too arid. Contrariwise in the Steppe the total number of droughts almost not changes, but remains a high probability of severe and extreme drought.

P-2204-10

Modelling the ice dynamics of Himalayan glaciers

S. Shannon (1) ; T. Payne (2) ; R. Betts (1) ; A. Wiltshire (3)
(1) University of Exeter, Geography, Exeter, United Kingdom; (2) University of Bristol, Bristol glaciology centre, Bristol, United Kingdom; (3) Met Office Hadley Centre, Exeter, United Kingdom

In the Himalayan-Karakoram glacier melt contributes to the runoff of the Indus, Ganges and Brahmaputra rivers affecting the livelihoods of more than 700 million people[1]. Future glacier melting is of particular concern for high-end climate change scenarios because of the potential impacts on water supply. Projections suggest that runoff may increase until 2050, due to enhanced glacier melting combined with an increase in monsoon precipitation [2, 3]. The uncertainty in these estimates are associated with an over simplified treatment of glaciers and a poor representation of monsoon precipitation.

To assess the impact of glacier retreat on food and water security in the region, we are implementing a 1-D glacier flow model [4] into the Joint UK Land Environment Simulator (JULES) integrated impacts model. The purpose of the JULES impacts model is to allow for an integrated, internally-consistent assessment of impacts of climate change on glaciers, water resources and agriculture. The JULES impacts model is currently under development and includes a river routing scheme [5], an irrigation scheme and crop plant functions types[6].

In this presentation, we describe the initial stages of the model development. The glacier model requires two inputs; knowledge of the present day ice thickness and surface mass balance (SMB) as a function of elevation. Ice thickness is calculated using an inversion technique based on the principles of ice flow dynamics [7, 8]. This technique uses satellite observations of glacier outlines [9] combined with a digital elevation model. A time series of SMB generated by JULES is used to drive the glacier flow model offline. We show preliminary results of glacier flow simulations in the Himalayan-Karakoram.

Heat stress in a warming world: implications for human health and productivity under different climate scenarios

J. Syktus (1) ; C. Mcalpine (2)
(1) University fo Queensland, School of Geography, Planninga and Environmental Management, Brisbane, France; (2) University fo Queensland, School of geography, planninga nd environmental management, Brisbane, Australia

Projected changes in temperature and humidity over the course of the 21st Century will contribute to increased heat stress in many tropical and sub-tropical regions. Heat stress, arising from a combination of high temperature and humidity impacts on human health and wellbeing by causing illness and death, with the young and old the most vulnerable. Increased heat stress impacts workforce productivity, especially those engage in manual labour in open environments such as construction, mining and agriculture. These impacts will be of increasing concern during coming decades due to projected significant increases in the rate of warming and rapidly growing populations tropical and sub-tropical regions. We evaluated the impact of different emission scenarios on the heat stress conditions for the 21st Century in tropical and sub-tropical regions using wet-bulb globe temperature (WBGT) heat stress index. Projected changes in WBGT were used to assess the future impacts of heat stress by combining time-varying changes in heat stress and human population numbers. We found that people living in cities in coastal tropical regions and cities are highly vulnerable to changes in the number of heat stressdays, with these increasing in some instances from close to zero to two hundred days per year by 2100. West Africa, the Caribbean and the Indian sub-continent will be particularly hard hit. We show the benefits of mitigation by comparing the distribution of heat stress under RCP8.5 and RCP2.6.

P-2204-12

Estimated impacts of emissions reductions on wheat and maize crops

C. Tebaldi (1) ; D. Lobell (2)
(1) NCAR, CGD, Boulder, CO, United States of America; (2) Stanford University, Department of environmental earth system science, Stanford, United States of America

An ability to quantify the impacts associated with different emissions scenarios across a broad range of economic and environmental outcomes would be helpful for guiding policy on energy and greenhouse gas emissions. One outcome of particular interest, especially for food insecure populations, are effects on agricultural productivity. In this study we use empirical models of the relation between climate and CO2 concentration on the one hand, and changes in crop yields on the other, to characterize the differential impacts on the future productivity of two major crops of two level of forcings: those associated with RCP4.5 and those associated with RCP8.5. This study is part of a larger project on the Benefits of Reducing Anthropogenic Climate changE (BRACE). We consider differential effects on maize and wheat yields at the global scale from expected changes in mean temperature and precipitation under the two scenarios. We also characterize differential levels of exposure to damaging heat extremes. Several time horizons are considered, characterizing expected impacts over the short, middle and long terms over the 21st century.

P-2204-13

Evaluating the risk of hydrological drought to the irrigation sector under future climate scenarios: the case study of Puglia Region (Italy)

S. Torresan (1) ; P. Ronco (2) ; F. Zennaro (2) ; A. Critto (2) ; M. Santini (3) ; A. Trabucco (4) ; A. Marcomini (2)
(1) Centro Euro-Mediterraneo sui Cambiamenti Climatici, Risk Assessment and Adaptation Strategies Division, Venice, Italy; (2) Ca' Foscari University, Dept. of environmental sciences, informatics and statistics, Venice, Italy; (3) Centro Euro-Mediterraneo sui Cambiamenti Climatici, Impacts on agriculture, forests and ecosystem services, Viterbo, Italy;

(4) Centro Euro-Mediterraneo sui Cambiamenti Climatici, Impacts on agriculture, forests and ecosystem services, Sassari, Italy

In several regions, but especially in semi-arid areas, the raising drought events caused by climate change are expected to dramatically reduce the current stocks of freshwater resources, also used for irrigation purposes. The achievement of a sustainable equilibrium between the availability of water resources and the irrigation demand is essentially related to the planning and implementation of evidence-based adaptation strategies and actions. In this sense, the improvement (of existing) and the development of (new) appropriate risk assessment tools to evaluate the impact of drought events on irrigated crops is fundamental in order to assure that the agricultural yields are appropriate to meet the current and future food and market demand. The present study aims at assessing the risk of hydrological droughts due to climate change on the irrigated agronomic compartment that cover a large portion of Puglia, a semi-arid region with the largest agriculture production in Southern Italy. Based on the theoretical framework of Regional Risk Assessment (RRA) approach, the methodology is applied within a scenario-based hazard framework, where future climate projections provided by COSMO-CLM are considered under the radiative forcing RCP4.5 and RCP8.5 in two different timeframes (2021-2050 and 2041-2070). The run-off feeding the water stocks of the most important reservoirs for irrigation purpose in Puglia has been modelled by means of the Arc-SWAT model. The risk methodology followed four subsequent levels of analysis (i.e. hazards, exposure, vulnerability and risk assessments) where each step has been characterized by specific algorithms for their spatial and numerical quantification. Hazard scores have been modelled as the degrees of fulfillment of Reclamation Consortia irrigation demand when compared to the volume of available water supplied by the different reservoirs. Exposure assessment consists on the spatial characterization of the most valuable irrigated areas in Puglia Region, according to the specific crops that are cultivated. Vulnerability scores have been designed as function of three different factors that accounts for the agronomic and structural pattern of irrigation schemes (i.e. crop yield variation according to water stress; water losses along the irrigation network; diversification of water supplies other than the reservoirs' alone). Finally, relative risk maps (GIS based) and related statistics have been produced allowing the identification of hot spots and areas at risk as well as the spatial characterization of the risk pattern. The assessment allowed: the identification of Reclamation Consortia at higher risk of not fulfilling their irrigation demand in future perspectives (e.g. Capitanata Reclamation Consortia in RCP8.5 2041-2070 scenario); to identify the most affected crops (e.g. fruit trees and vineyards); and finally, to characterize the vulnerability pattern of irrigation systems and networks. According to these results, tailored and knowledge-based adaptation strategies and related actions can be developed, to reduce the risk pattern at both agronomic level (preferring crops with low vulnerability score, as olive groves) and at structural level (differentiating the water stocks and supplies and reducing losses and inefficiencies).

P-2204-14

The impact of high-end climate change scenarios over Europe

I. Tsanis (1) ; L. Alfieri (2) ; A. Koutroulis (1) ; M. Grillakis (1) ; L. Papadimitriou (1) ; L. Feyen, (2) ; M. Vousdoukas (2) ; E. Voukouvalas (2) ; M. Rozsai (3) ; A. Kitous, (3) ; P. Ciais (4) ; X. Wang (4) ; K. Wyser (5)

(1) Technical University of Crete, School of environmental engineering, Chania, Greece; (2) European Commission - DG JRC, Institute for environment and sustainability, Ispra, Italy; (3) European Commission - DG JRC, Institute for prospective technological studies, Seville, Spain; (4) LSCE, CEA, CNRS and UVSQ, Gif-sur-Yvette, France; (5) Swedish Meterological and Hydrological Institute (SMHI), Rossby centre, Norrköping, Sweden

The latest scientific evidence suggest that the increase in global mean temperature is likely to exceed the 2°C and target the 4°C to 6°C by the end of the 21st century. Furthermore, most of Europe is expected to warm more than the average global warming in the 21st century. The potential environmental, economic and social impacts of such high-end warming scenarios has drawn the attention of the scientific community, which has a crucial role in advising future policy making. In the framework of High-End cLimate Impacts and eXtremes (HELIX) FP7 project, five biophysical impact models are set up to investigate the effect of high global warming levels over Europe. Impact models are focused on water management (JULES), floods, water resources and droughts (Lisflood), coastal hazard (Liscoast), Energy (Poles) and crop (Orchidee). Models are tested and validated against large scale past extreme events such as major droughts and flood events that have occurred in the recent past. Calibrated models are then forced by the newly available Euro - CORDEX regional climate projections to evaluate changes in key indicators within the considered sectors over Europe. Output simulations are then used to examine possible implications of uncertainties in global patterns of climate change at 4°C for impacts at regional scales. Results are assessed and compared to the available CMIP5 based projections included in the Inter-Sectoral Impact Model Intercomparison Project (ISI-MIP) over Europe. Here, first results of the coordinated modeling effort are presented for the examined sectors.

P-2204-15

How does urbanization modify climate related risk in urban areas on global scale?

T. Welle, (1) ; J. Birkmann (1) ; M. Garschagen, (2)

(1) Institute for Spatial and Regional Planning, University of stuttgart, Stuttgart, Germany; (2) United Nations University,, Institute for Environment and Human Security, Bonn, Germany

Climate change and urbanization are two global megatrends that will influence risk to climate change as well as adaptation opportunities and constraints. Sea-level rise, storms and floods as well as droughts will be modified by climate change and most likely impact particularly urban areas in coastal zones in the future as the IPCC fifth assessment report (AR5) underscored. Since 1950 the world population has grown rapidly from 746 millions to 3.9 billion. Hence, today more than 50% of the population is living in urban areas implying new challenges for risk reduction and adaptation. Projections of urban population growth estimate that by 2050 additional 2.5 billion people will live in urban areas whereas 90 percent of this increase will take place in Africa and Asia. Against this background and also considering the discussion of sustainable develoment goals (SDGs) and the post-2015 framework for disaster risk reduction there is an increasing need to assess whether future urbanization will increase risks related to climate change or in contrast whether urbanization might provide a vehicle for risk and vulnerability reduction regarding climate related hazards.

Consequently the question of how urbanization influences core determinants of risk, particularly vulnerability - either in a positive or negative way - has not yet been clearly answered. The paper examines the nexus between urbanization, urban growth and vulnerability, based on new global remote sensing based land-use data for 140 countries. In this regard, vulnerability is defined as a combination of susceptibility, coping and adaptive capacities. The findings show among other issues that a high level of urbanization (>75%) and a low urban growth rate (<1%) at national scale in general implies a rather low level of urban vulnerability. In contrast, countries that are characterized by a low level of urbanization(<40%), but very high urban growth rates (more than 3%) often tend to be countries with a high level of vulnerability in urban areas. The paper presents in detail selected findings and methods used to assess urban vulnerability and risk patterns in various countries, also based on the WorldRiskIndex concept. The triangulation of different data, such as remote sensing data, hazard data and global available socio-economic indicators, is presented as well as constraints and limitations of it. Exposure, vulnerability and risk maps for urban areas with a national scale resolution will underscore that risk and adaptation strategies need to consider different urbanization types in order to improve regional management approaches.

Overall, the presentation provides new insights in risk and vulnerability data and respective assessment methods for urban areas. Based on these findings specific recommendations for policy making and new risk monitoring tools will be derived that also consider priority actions defined in the fields of climate change adaptation (programme on loss and damage) and disaster risk reduction.

Current structural changes in global economic network amplify heat stress-induced production losses

L. Wenz (1) ; A. Levermann (2)
(1) Potsdam-Institute for Climate Impact Research, Sustainable Solutions, Potsdam, Germany; (2) Potsdam Institute for Climate Impact Research, Research Domain Sustainable Solutions, Potsdam, France

Above a certain temperature threshold labor productivity has been shown to decline in exposed sectors such as construction and agriculture. Under future warming daily temperature will increase and thereby affect economic output. Here, we assess primary, secondary and higher-order losses from reduced labor productivity under past and present economic conditions under unabated climate change. Unsurprisingly, we find that relative damages increase linearly with rising temperatures.

Crucial for future adaptation strategies we observe that the structure of the global economic network plays an important role in absolute damage level. A new static network measure is found to represent the network's vulnerability to propagation of unanticipated damages well. This Global Adaptive Pressure (GAP) is shown to increase with the network's sensitivity to heat stress-induced damages.

From data of the global economic network we learn that the Global Adaptive Pressure has been steadily increasing since 1998 (with an exception for the post-financial crisis years 2009 and 2010). As GAP is a relative measure, this increase does not merely represent economic growth but a structural change.

Our finding suggests that the current evolution of the global economic network may amplify heat stress-induced damages and thus necessitate structural adaptation that requires more foresight than currently prevalent.

Mapping of risk interconnection under climate change

T. Yokohata (1) ; K. Nishina (1) ; T. Kiyoshi (1) ; S. Emori (1) ; K. Tanaka (1) ; M. Kiguchi (2) ; Y. Iseri (3) ; Y. Honda (4) ; M. Okada (5) ; Y. Masaki (1) ; A. Yamamoto (6) ; M. Shigemitsu (7) ; M. Yoshimori (7) ; T. Sueyoshi (8) ; K. Iwase (9) ; N. Hanasaki (1) ; A. Ito (1) ; G. Sakurai (5) ; I. Toshichika (5) ; T. Oki (2)
(1) National Institute for Environmental Studies, Tsukuba, Japan; (2) University of Tokyo, Tokyo, Japan; (3) Tokyo Institute of Technology Tokyo , Tokyo, Japan; (4) University of Tsukuba, Faculty of Health and Sport Sciences, Tsukuba, Japan; (5) National Institute for Agro-Environmental Sciences , Tsukuba, Japan; (6) University of Tokyo, Kashiwa, Japan; (7) Hokkaido University, Sapporo, Japan; (8) National Institute of Polar Research, Tokyo, Japan; (9) Nomura Research Institute , Tokyo, Japan

Anthropogenic climate change possibly causes various impacts on human society and ecosystem. Here, we call possible damages or benefits caused by the future climate change as "climate risks". Many climate risks are closely interconnected with each other by direct cause-effect relationship. In this study, the major climate risks are comprehensively summarized based on the survey of studies in the literature using IPCC AR5 etc, and their cause-effect relationship are visualized by a "network diagram". This research is conducted by the collaboration between the experts of various fields, such as water, energy, agriculture, health, society, and eco-system under the project called ICA-RUS (Integrated Climate Assessment – Risks, Uncertainties and Society).

First, the climate risks are classified into 9 categories (water, energy, food, health, disaster, industry, society, ecosystem, and tipping elements). Second, researchers of these fields in our project survey the research articles, and pick up items of climate risks, and possible cause-effect relationship between the risk items. A long list of the climate risks is summarized into ~130, and that of possible cause-effect relationship between the risk items is summarized into ~300, because the network diagram would be illegible if the number of the risk items and cause-effect relationship is too large. Here, we only consider the risks that could occur if climate mitigation policies are not conducted. Finally, the chain of climate risks is visualized by creating a "network diagram" based on a network graph theory (Fruchtman & Reingold algorithm).

Through the analysis of network diagram, we find that climate risks at various sectors are closely related. For example, the decrease in the precipitation under the global climate change possibly causes the decrease in river runoff and the decrease in soil moisture, which causes the changes in crop production. The changes in crop production can have an impact on society by changing the food price or food supply. Changes in river runoff can also make an impact on the hydropower efficiency. Comprehensive pictures of climate risks and their interconnections are clearly shown in a straightforward manner by the network diagram. We will have a discussion how our results can be helpful for our society to recognize the climate risk

2205 - Multi-sectoral analysis of risks to climate change (hot spots) at 2 °C warming

ORAL PRESENTATIONS

Cross-sectoral analysis in IMPACT2C and IPCC AR5 Europe Chapter

D. Jacob (1)
(1) HZG/Climate Service Center 2.0, Hamburg, Germany

Political discussions on the European goal to limit global warming to 2°C relative to pre-industrial levels, needs to be informed by the best available science on projected impacts and possible benefits.

Here we'll provide a recent update of the scientific evidence on which regional changes and associated impacts will be induced by 2 °C global warming.

First, original insights and findings from the FP7 project IMPACT2C will be presented and discussed. IMPACT2C identifies and quantifies the impacts and most appropriate response strategies of a 2oC global warming. IMPACT2C analyses a number of major cross-sectoral issues for Europe and three selected vulnerable regions: Bangladesh, Africa (Nile and Niger basins) and the Maldives

The IMPACT2C project adopts a clear and logical structure within climate- and impact-modelling, vulnerabilities, risks and economic costs. Detailed climate change scenarios are provided and tailored to the needs of various sectors. Here the information from the new EURO-CORDEX simulations will be presented. Furthermore, selected innovative methods (e.g. ensemble model selection which represent the entire ensemble's spread) and tools (e.g. web atlas) will be shown.

On the pan-European level this research is also linked to the Europe-Chapter from AR5, IPCC, which assesses evidence of climate change in a regional chapter and therefore could describe impacts across sectors and identify interactions between impacts. Regional information on climate, vulnerability and adaptation strategies are also major topics. The cross-sectoral decision making which is required to address climate change is reviewed in the Chapter. The main findings of the Europe chapter of WG II IPCC AR5 will be presented.

O-2205-01

Projected changes in drought at 4C and 2C of global warming: Impact of mitigation on regional drought hotspots

J. Syktus (1) ; C. Mcalpine (1)
(1) University fo Queensland, School of geography, planninga nd environmental management, Brisbane, Australia

We use the CMIP5 data from historical and RCP8.5 simulations to complete a multi-model assessment of changes in regional patterns of warming and precipitation changes at 4oC and 2oC of global warming. Inter-model agreement of projected changes in magnitude and sign of annual and seasonal precipitation has been calculated to illustrate the patterns of change in hydrological cycle. In addition projected changes in precipitation have been used to derive a meteorological drought using the Standardized Precipitation Index (SPI).

Analysis of multi-model distribution of SPI during the 21st Century show progressive increase in frequency of wet events in high-to mid-latitudes and increased frequency of droughts over large parts of Australia, Africa, south-east Asia, southern Europe, the Middle East and Northern and Southern Americas. Using this data we identified a key hotspot with extreme drought (SPI<-2) and computed regional statistics of drought frequencies at 4oC and 2oC in order to illustrate the regional benefits of climate mitigation. In addition we have completed regional analysis of join distribution of precipitation and temperature changes at 4oC and 2oC using standardized precipitation and standardized temperature index. We will also show results of analysis focusing on hemispheric contrast in SPI drought distribution during the 21st Century.

O-2205-02

Projection of Heat Waves over China under Different Global Warming Targets

G. Xiao-Jun (1) ; L. Yong (1) ; H. Jian-Bin (1) ; Z. Zong-Ci (1)
(1) Center for Earth System Science,Tsinghua University, Beijing, China

Global warming targets, which are determined in terms of global mean temperature increases relative to pre-industrial temperature levels, have been one of the heated issues recently. And the climate change (especially climate extremes) and its impacts under different targets have been paid extensive concerns. In this study,evaluation and projection of heat waves in China were carried out by twelve CMIP5 global climate models (GCMs). In evaluating the ability of GCMs, a new daily observed gridded dataset CN05.1 (0.5°×0.5°) was also used. And four indices (heat waves frequency, longest heat waves duration, heat waves days and high temperature days) were adopted to analyze the heat waves. Compared with the observations, the twelve GCMs and their multi-model ensemble (MME) have a remarkable capacity of reproducing the spatial and temporal characteristics of heat waves. The time correlation coefficients between MME and the observation results can all reach 0.01 significant levels. Based on the projection data of twelve GCMs, both the median year of crossing 1.5°C, 2°C, 2.5°C, 3°C, 3.5°C, 4°C, 4.5°C and 5°C global warming targets and the corresponding climate change over China were analyzed under RCP 4.5 and RCP 8.5 scenarios, respectively. The results show that when the global mean surface air temperature rise to different targets with respect to the pre-industrial times (1861-1880), the frequency and intensity of heat waves will increase dramatically.To take the high emission scenario RCP8.5 as an example, under the RCP8.5 scenario, the warming rate over China is stronger than that over the globe, the temperature rise(median year) over China projected by MME are 1.82°C(2023), 2.48°C(2038), 3.23°C(2049), 3.93°C(2059), 4.59°C(2069), 5.29°C(2079) and 5.97°C(2088) under 1.5°C, 2°C, 2.5°C, 3°C, 3.5°C, 4°C and 4.5°C global warming targets, respectively. With the increase of the global warming targets, the difference between global and China's temperature rise increases gradually. The linear trends of regional mean heat waves number, longest heat waves duration, heat waves days and high temperature days over China are 0.9 times/°C, 2.7days/°C, 8.0 days/°C and 7.2days/°C with the enhancement of global warming targets.It is noteworthy that the increase rate of heat waves indices under the latter global warming target relative to the former one is expected to decrease sharply as the global mean temperature rise increases from 2.5°C to 3°C. For example,the increase rates of longest heat waves duration under 2°C, 2.5°C, 3°C, 3.5°C, 4°C, 4.5°C and 5°C global warming targets are 45.77 %, 37.37%, 22.91%, 27.51%, 16.60%, 24.55% and 25.64 % , in relation to that under 1.5°C, 2°C, 2.5°C, 3°C, 3.5°C, 4°C and 4.5°C target respectively. Moreover,the areas with severe heat waves occurring display a vast expansion correspondingly.For example, the percentage of area with annual longest heat waves duration longer than 12 days will increase from 0.27% under a 2°C target to about 42.75% under a 5°C target. The percentage of area with annual heat waves days more than 30 days will increase from 0.45% under a 2°C target to about 49.64% under a 5°C target.

Impacts of a global 2 degrees C climate change upon European air quality

G. Lacressonnière (1) ; M. Engardt (2) ; M. Gauss (3) ; L. Watson (4) ; C. Andersson (5) ; M. Beekmann (6) ; A. Colette (7) ; G. Foret (1) ; B. Josse (4) ; V. Marécal (4) ; A. Nyiri (3) ; G. Siour (1) ; S. Sobolowski (8) ; R. Vautard (9)
(1) IPSL/LISA, Créteil, France; (2) Swedish Meteorological and Hydrological Institute, Norrköping, Sweden; (3) EMEP MSC-W, Norwegian Meteorological Institute, Bergen, Norway; (4) CNRM-GAME, Météo-France and CNRS, Toulouse, France; (5) SMHI, Norrkoping, Sweden; (6) LISA, CNRS/INSU, Créteil, France; (7) INERIS, Verneuil-en-Halatte, France; (8) Uni Research, the Bjerknes Centre for Climate Research, Bergen, Norway; (9) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France

Several policy statements, including the 2009 Copenhagen Accord, stated that global temperature rise should be held below 2 degrees C above pre-industrial levels in order to limit the impacts of climate change. In this context, the impacts of 2-degree increase in temperature have been analyzed in the European project IMPACT2C. The objective of the present study is to evaluate how these changes will have an impact on European air quality and will potentially affect human health, using four offline atmospheric chemistry transport models. The first step was to perform air quality simulations for the current climate, using two sets of meteorological forcings for each model: reanalysis of past observation data and global climate model output. The differences between the simulations allow to evaluate how global climate models modify climate hindcast by boundary conditions inputs. Among others, we analyze whether the chemical composition of PM is affected by the use of climate models. We then investigate the contributions of the changes in meteorological parameters (precipitation, temperature, boundary layer height, etc) on surface primary and secondary compounds of PM (Lacressonnière et al., under review). For the future scenarios, the time period that corresponds to a 2-degree C global warming, such as predicted from climate simulations using RCP4.5 scenario, was run; this time period varies depending on which global climate model is used. We separately calculate the effects of climate change and emission reduction scenarios, and show that the fate of European air pollution is primarily controlled by emission reductions. A 2-degree C global warming will not hinder beneficial effects of air quality legislation, albeit inducing small changes in ozone and particulate matter changes. We then evaluate the uncertainty associated to the air quality projection under regional climate change, with a focus on annual PM2.5 and SOMO35, two indicators commonly used for health assessments (Lacressonnière et al., under preparation). We assess the robustness/uncertainty of model predictions, by comparing the inter-model spread to the climate change signals. Our results highlight that the inter-model variability is mainly due to differences in regional climate projections, affecting several meteorological parameters, which are crucial for air quality. Beyond the model uncertainty, climate penalty or benefit have been made evident over different European areas. The use of four different models, and additional uncertainty evaluations, make our study one of the most comprehensive ones up to date to assess the impact of regional climate change on air quality and health.

Studying the climate change impact at 2 degree warming on Water Resources for the island of Crete: A cross-sectoral approach

I. Tsanis (1) ; A. Koutroulis (2) ; M. Grillakis (2)
(1) McMaster University, Civil Engineering, Hamilton, Ontario, Canada; (2) Technical University of Crete, School of environmental engineering, Chania, Greece

Ensemble pan-European projections under a 2°C global warming relative to preindustrial period reveal a more intense warming in south Eastern Europe by up to +3°C indicating that impacts of climate change will fall disproportionately on certain regions. The Mediterranean is projected as one of the most vulnerable areas to climatic and anthropogenic changes with decreasing rainfall trends and a continual gradual warming leading to a progressive decline in the average stream flow. Many Mediterranean regions are currently experiencing high to severe water stress induced by human and climate drivers. Changes in average climate conditions will increase this stress notably because of a 30-50% decline in freshwater resources. For small island states, where accessibility to freshwater resources is limited the impact will be more pronounced. Here we use a generalized cross-sectoral framework to assess the impact of climatic and socioeconomic futures on the water resources of an Eastern Mediterranean island. Crete, the fifth largest Mediterranean island covers more than 6% of Greece with an area over 8,000 square km. Total water use is estimated to be about 420 million cubic meters (6.3% of total precipitation). The majority of the water use (over 80%) is used for irrigation while the rest is distributed to other uses such as domestic, tourist, and industrial uses. A set of representative regional climate models simulations from the ENSEMBLES and EURO-CORDEX initiative driven by different RCP2.6, RCP 4.5, A1B and RCP8.5 GCMs were used to form a comparable set of results and a useful basis for the assessment of uncertainties related to impacts of 2 degrees warming and above. A generalized framework of a cross-sectoral water resources analysis was developed in collaboration with the local water authority exploring and costing adaptation measures associated with a set of socioeconomic pathways (SSPs). Transient hydrological modeling was performed to describe the projected hydro-climatological regime and water availability for each warming level. The robust signal of less precipitation and higher temperatures that is projected by climate simulations results to a severe decrease of local water resources. Adaptation to water scarcity includes a group of measures ranging from soft measures to infrastructure investments for achieving safe and secure water futures.

Carbon Sink in the Timbered Biomass for Mountainous Tropical Wildlife Reserve using Geospatial Approach

K. Amit (1) ; T. Vandana (2)
(1) Haryana Institute of Public Adminstration, remote sensing, gurgaon, India; (2) Haryana Institute of Public Administration, Remote sensing, Gurgaon, India

Carbon storage and biomass sequestration are the two important terms that come across when it is talked about our forest or plant ecosystem. It has been found that very little research had been conducted on the potential of carbon storage in trees of the region having low rainfall. Here Remote Sensing can play a vital and useful role by its vast usage in ecological application as it is quick, accurate, cost-effective as well as a time effective method for vegetation cover mapping and modeling. In this study the objective was to quantify the above ground biomass accumulation and carbon storages in the various species found in Ranthambore Tiger Reserve. For this purpose the satellite data of LISS III (2014) is used giving precise information of vegetation through reflectance value. For assessing the carbon sequestration potential of plantations, individual above ground biomass models were developed and scaled to stand level. Thereafter the carbon content of the different layer of soil was assessed in sample plots. The result shows that the total amount of carbon stored in by Anogeissus pendula is higher than that stored by the other three forest type. The result also showed that the carbon storage is higher in thorn as compared to the deciduous trees in the region of low rainfall.

P-2205-02

The 2°C global warming threshold and associated hydrological changes over France

G. Dayon (1) ; J. Boé (1) ; E. Martin (2)
(1) URA1875, Cerfacs/CNRS, TOULOUSE, France; (2) Météo France, Cnrm-game, Toulouse, France

The Copenhagen Agreement states that the global temperature should increase less than 2°C to prevent dangerous changes on the climate system. The 2°C threshold offer to climate scientists an easy way to communicate and present their results close to policy decisions and meaningful for the public. However, it hides strong differences and uncertainties at a regional scale. This study focuses on impacts of the 2°C level and above on the continental hydrological cycle over France.

An ensemble of Global Climate Models (GCMs) simulations from the Coupled Model Intercomparison Phase 5 (CMIP5) is downscaled with a statistical method developed in a previous study (Dayon et al. 2015). Atmospheric variables obtained on a 8 km grid over France are used to drive the Isba-Modcou hydrological system developed at Météo France and Mines Paris-Tech. Isba is a land surface model that calculates the energy and surface water budgets. Modcou is a hydrogeological model that routes the surface runoff given by Isba and computes aquifers and river flow evolution.

Future impacts of climate change on the hydrological cycle of the main French rivers basins are evaluated as a function of global temperature warming. The respective importance of uncertainties from the internal climate variability and climate models is adressed thanks to large ensemble of simulations used in the study. Hydrological changes are also compared among the Radiative Concentration Pathway (RCP, mainly RCP4.5 and RCP8.5) to ensure the independence of results to emission scenarios.

Finally, based on a large ensemble of simulations on the historical period (28) and long-term river flow observations, future hydrological changes are put into perspective with past hydrological variability. Those elements will might allow to reach a conclusion on the meaning of the 2°C global warming threshold for hydrological changes over France.

Climate change will impact carbon balance of old-growth temperate rainforests of southern South America

AG. Gutierrez (1)
(1) Universidad Austral de Chile, Instituto de Conservación Biodiversidad y Territorio, Valdivia, Chile

Understanding how forests might respond to climate change is important because of their role in storing and sequestering carbon, sustaining biodiversity, and providing ecosystem goods and services. There is a growing body of evidence indicating that ecological effects of climate change on forests are apparent and may vary among regions of the world. Little is known about future changes that climate change could exert on temperate rainforests of southern South America (SSA). Here, I present results of a process-based, dynamic forest model. The model integrates climatic variability and allows projecting forest responses to climate change in this region. Using the developed model, I projected potential futures for temperate rainforests of SSA given likely climate change scenarios. I focused on primary, old-growth temperate rainforests of SSA located on Chiloe Island (~42°S, Chile). Drier climate predicted for this century will alter forest

structure, leading to decreases in above ground biomass by 27% of the current value. Compared to current climate, mean net primary production will be reduced in ~30% for year 2100 (from 7.6 to 2.4 tC ha/year). As a result of warming alone, i.e. without accounting for the direct effects of carbon dioxide, temperate rainforests in SSA will become sources of carbon during this century (average among forest stands of -3.7 tonnes of carbon -tC- ha/year in 2100). These results inform the debate about forests responses to future climate in SSA. Future research should focus in developing experimental and long-term monitoring still not available in this region. In the meantime, models provide a useful synthesis of current knowledge that allows exploring these and other additional effects of global change on hitherto overlooked regions of the world, such as southern temperate rainforests

P-2205-04

Seepage Processes in Permafrost near a Hydro Unit in a Changing Climate

S. Milanovskiy (1) ; S. Velikin (2)
(1) Institute of Physics of the Earth, Russian Academy of Science, Moscow, Russia; (2) Vilyui Permafrost Station of the Permafrost Institute , Ras siberian branch, Chernishevski, Russia

Regular water and energy supply in permafrost areas are vitally important conditions for inhabitants of the large North territories of Russia, Canada, US and Alpine areas of China. Dam and flank shore stability is the key point for safety of reservoir (power pool, water supply, tailing pit, etc.). In permafrost areas stability of many engineering structures, including hydraulic work, associated with thawing – freezing process. Emergency situation of the unit we have when seepage occurs in originated permeable talik zone adjoining to reservoir. We present original results of long-term geophysical study on hydro technical objects of Western Yakutia analyzing problems associated with use of geophysical methods for the study of rocks in permafrost area. The primal problems of studies were focused to I) eliciting and checking of a position of talik zones and places of filtering of water in a body of foundation and coastal contiguity of Sytikan dam and Vilui HPS (constructing and operating reservoirs) dams; II) estimation of dynamics of seepage progressing processes for a development of a complex of measures, directional on exception of losses of water from reservoir and supply of stability of a body of a dam. Due to a difficult and hardly predictable geocryological situation in this area, the geophysical methods were included into the system of local monitoring. From ground-level methods of studies in composition of operations were included high frequency electric profiling, electric profiling on a method of a natural field, georadar, seismic profiling and seismic sounding. Down-hole observations on dams included long-term regime temperature measurements and complex of logging studies (resistance, flow meter survey, gamma logging, neutron gamma logging, caliper measurement, radio wave cross-borehole testing). On the ground of geophysical studies the detailed geological section was studied and the binding of seepage spacing to definite lithologic horizons was established. The purpose of geophysical investigations was, first, to control the thawing of frozen rock (talik) within the coastal zone of the reservoir and to assess the dynamics of the process, and second, to identify and to locate places of the most intensive thawing and filtration of water from the reservoir. Alongside field studies, numerical evaluation of permeable talik zone (thawing) origination and development in a broad zone around a dam was made. The non-steady problem of heat-mass transfer in fractured-porous saturated frozen media, interbedded in frozen impermeable strata is discussed. The model takes into consideration the main conditions causing initiation and development of talik near a reservoir: annual temperature and snow cover variation, seasonal water temperature distribution with depth in the storage basin adjacent to the dam and evolution of permeability in rock due to thaw-freeze processes. The results of 2D heat-mass transfer modeling indicate that the development of talik formation depends on the specific thermal and hydraulic material parameters, thickness of the frozen layer covering talik and winter snow blanket insulating ground rocks, seasonal and global temperature trend as well as of presence of fractures in frozen rocks. It seems that proposed model can be used to analyze situations like rapid drainage of ice-rich permafrost-dammed lakes, Alpine frozen slope instability as well as the role of global temperature change influence on a system “ice-rich permafrost-aquifer”.

P-2205-05

The Challenges of Communicating Unwelcome Climate Messages

T. Rayner (1)
(1) Tyndall Centre for Climate Change Research, School of Environmental Sciences, Norwich, United Kingdom

As a recent report on communication of climate science has noted, ‘[t]here is widespread public acceptance of the reality of climate change, but not of the urgency and scale of the challenges that the science indicates it represents’ (UCL 2014: 14). This discrepancy, the report suggests, derives from psychological factors and from cues from influential elites and the media. Communication efforts based on the linear-rational model have failed sufficiently to motivate either publics or political decision makers. Better engagement of policymakers and society more generally with climate scientists and other experts, to evaluate scientific evidence and determine adaptive responses, requires new narratives to be found. With the probability that global temperature rise can be kept below the 2oC target continuing to diminish, the urgency of this task increases. How best to engage individual citizens and organisations with the kind of knowledge about the likelihood and implications of severe future impacts that few want to hear becomes an acute issue. How can adaptive responses be encouraged – by individuals, organisations and policymakers – rather than denial, fatalism and withdrawal?

This paper presents the findings of a workshop organised to bring together climate scientists, social scientists, policymakers, consultants, communications specialists, psychologists, the private sector, the media and artists etc., to wrestle with the challenges of communicating findings from research into high impact scenarios, in a world where the 2 degrees limit is increasingly in doubt. As well as ‘the public’, the paper considers how best to engage with other audiences, including infrastructure planners who may not yet be in the habit of ‘climate proofing’ particular investments, and politicians and policy makers who would prefer to ignore the full, transformative implications of the climate crisis. It also reflects on the need to move discussion beyond the narrow framings offered by the geosciences, which tend to provide legitimacy and credibility to catastrophic framings that reinforces the message of climate change as ‘an unfolding, almost predetermined, disaster’ (O’Neill et al. 2010: 1000), to incorporate insights from a wider set of disciplines.

O’Neill, S.J., Hulme, M., Turnpenny, J. and Screen, J. (2010), ‘Disciplines, geography and gender in the framing of climate change’, Bulletin of the American Meteorological Society, 91, pp. 997-1002.

How significant is the climate impact of Black Carbon?

BH. Samset (1) ; G. Myhre (2) ; Ø. Hodnebrog, (2)
(1) CICERO, Climate System, Oslo, Norway; (2) CICERO, Oslo, Norway

Mitigation of Black Carbon (BC) aerosol emissions is an attractive policy option, due to co-benefits on climate and air quality. However the climate impact of present day BC emissions is not well constrained.

BC interacts with the climate directly, through absorption and scattering of incoming sunlight; indirectly, through modification of cloud properties; and semidirectly, through changes to atmospheric stability. To gauge the net effect of BC, these processes need to be well understood and coherently treated. Regional emissions of BC, and how it ages and is transported in the atmosphere, must also be known.

Since the publication of the IPCC AR5, several studies have indicated that the atmospheric lifetime of BC may be overestimated in present climate models. Through comparisons of flight measurement data with model calculations, both geographically and vertically, we show how models tend to overestimate BC concentrations

aloft, where it has the strongest direct radiative forcing efficiency.

Other studies have improved our understanding of the semidirect effect of BC, which tends to counterbalance the positive BC direct radiative forcing. We show the vertical dependence of direct, semidirect and net BC forcing efficiency, and illustrate how the interaction of the direct and semidirect effects can lead to a virtually unchanged net BC forcing even for a doubling of emissions.

Based on these recent results, we here present an updated, holistic view of the present and historical climate impact of BC. We present policy relevant values of BC impact metrics, i.e. its radiative forcing per gram of emission, constrained by recent observations. We also argue that while further work is needed to constrain all mechanisms of BC-climate interactions, present emission inventories remain a dominating source of uncertainty in BC climate forcing.

In conclusion, we argue that the climate impact of BC may be lower than has been assumed in recent assessments. While its impact on air quality is clear, this makes BC less attractive for use in climate mitigation policy.

Water Quality Index for the Evaluation of Irrigation Water Quality and its Impact on Climate using MODIS Sensors' Based MOD13A1-NDVI Data

K. Swati (1) ; P. Kumar, (2)
(1) Banasthali University, Remote Sensing, Tonk, India; (2) Banasthali University, Remote sensing, jaipur, India

Ground water quality has reflective outcome on crop yield potential in semi-arid zones. Water can be poor quality due to salinity it contains as impurities present. Excessive salinity of irrigation water leads to interdiction of crop growth while smaller concentration of salt abates the water infiltration process. Water quality index has an ultimate goal for obtaining maximum production per unit of available water supply along with significance for remedy of domestic, industrial and irrigation water supply. Natural water body's response environmental conditions which have been studied by scientists for identify sources and fates of contaminates. Water Quality Information Center provides electronic access to information on water quality and agriculture. The most important water quality directive on crop yield efficiency is the water salinity hazard as measured by electrical conductivity (ECw). The high ECw generally leads to physiological drought. The higher the EC, the less water is available to plants, even though the soil may appear wet. Geospatial technology plays a vital role in geospatial data acquisition of the water quality index at local, regional, and global scale. The advantage of Remote Sensing and GIS is that it helps in getting wide area observation, periodical and continuous measurement, and availability of digital data for processing standardization. This research paper focuses to assess the water quality for irrigation practices. The data of MOD13A1-NDVI (A Moderate-Resolution Imaging Spectroradiometer derived 16 day composite normalized difference vegetation index product, with spatial resolution of 500 m). (September, 2013) was used in GIS frame. Geospatial technology helps in getting spatial distribution of chemical parameters using inverse-distance weighted and modified Shepard's method for spatial interpolation. This research paper illustrate statistical multiplication of water quality in terms of suitability index using pH, total dissolve solid, total hardness, alkalinity, sodium, chloride, nitrate, electric conductivity, and express the impact of water quality on regional crop yield. Higher water quality index depicts the best appropriateness for irrigation practices. In order to strengthen the crop productivity, we have suggested the diversified triple-based cropping systems with satellite mounted sensor derived NDVI products shown in Figure 1 as a holistic and feasible monitoring approach.

The Effect of Climate Change on Cocoa Production in Ekiti and Ondo States of Nigeria: A Co-Integration Analysis

O. Thompson (1)
(1) The Federal University of Technology, Akure, Ondo State, Nigeria, Agricultural and Resource Economics, Akure, Ondo, Nigeria, Federal Republic of

The study examined whether or not there is short run and long run equilibrium relationship between cocoa output and climate change variables (i.e. Rainfall, Temperature and Humidity). This is to ascertain the effect of climate change on cocoa output both in the short run and long run in the study area. The short run was considered to be within the period of 1971-1990 and 1990-2010, while the long run was considered to be within the period of 1971-2010. It was established at the long run that cocoa output and rainfall were non-stationary among the three selected climate change determinants (i.e. Rainfall, Humidity and Temperature.). In the long run, both at 1% and 5% level of significance, their absolute values were greater than the critical values (i.e. for cocoa;-2.855384>-3.610453 & -2.938987 and for rainfall; -1.591781>-3.610453 &-2.938987). Also, the co-integration test was carried out in the long run; the trace statistic test revealed that at both 1% and 5% level of significance 2 and 1 equations were co-integrated. The Max-Eigen values also revealed that at both 1% and 5% levels of significance, that at most 2 and 1 equations were co-integrated, since their absolute values 25.27>15.41 and 20.04; 20.61>14.07 and 18.63,. This corroborated the trace statistics, therefore, it was concluded that there is a long run equilibrium relationship between cocoa output and rainfall. The results established the fact that cocoa is highly susceptible to drought and the pattern of cropping of cocoa is related to rainfall distribution in the study area. Therefore, the study recommended that drought management policy through information systems about changing climate conditions and patterns, preparatory practices and options to deal with eventuality of drought must be set in place.The study examined whether or not there is short run and long run equilibrium relationship between cocoa output and climate change variables (i.e. Rainfall, Temperature and Humidity). An integrated approach for assessing climate change impacts on the European electricity sector

I. Tobin, (1) ; FM. Breon (1) ; W. Greuell (2) ; S. Jerez (3) ; F. Ludwig (2) ; F. Prettenthaler (4) ; M. Van Vliet (2) ; R. Vautard (1)
(1) Laboratoire des Sciences du Climat et de l'Environnement, Saclay, France; (2) Wageningen University, Wageningen, Netherlands; (3) University of Murcia, Department of physics, Murcia, Spain; (4) University of Graz, Joanneum research, Graz, Austria

Due to the development of new technologies and the necessity for reducing greenhouse gases emissions, the electricity sector is expected to hold a large share in the future energy activity sector. However, this sector is vulnerable to changes in climate in several aspects both on the supply and demand sides, which may affect the supply-demand balance. On the supply side, wind power generation could be affected by changes in surface layer

wind speed, solar power by changes in solar irradiance and temperature, alteration of the hydrological cycle with temperature increase could impact both the potential for hydropower and the availability of cooling water for thermo-electric power plants. On the demand side, temperature increase will reduce electricity demands for heating while the use of air-conditioning is expected to increase. This study aims at investigating the potential impacts of climate change on the European electricity sector by integrating the different effects of changes in climate variables on wind and solar photovoltaïc power, thermo-electric and hydropower supply along with the effects on electricity demand. Climate information is taken from a multi-model ensemble of high-resolution regional climate model projections (CORDEX) over Europe. Impact models are then used to compute changes in power generation and demand due to changes in climate variables. Several electricity mixes are considered (current mix, contrasted mix scenarios). The assessment is conducted for a +2°C and a +3°C global warming to quantify the impact of climate change limited or not to the +2°C target.

This study has been carried out in the framework of the European FP7 project IMPACT2C.

P-2205-10

Space-time distribution of China's water resources under the global climate change

H. Xia (1)
(1) East China Normal University, School of geographic sciences, shanghai, China

The water resource is the basic proposition of agricultural and industrial development in China because of our big population. It is noteworthy that what climate change will effect on Chinese future water resource. The influence of climate change includes precipitation and evaporation, of which the former is more discussed and the latter is readily ignored. This article is based on the regional climate model (RegCM4) which is developed by NCAR/PSU(National Center of Aatmospheric Research/University of Pennsylvania). We made a simulation to estimate the future climate change in China with A1B scenario. And got the spatial distribution characteristics of temperature and precipitation in historical period (1981-2000 average annual value) and future period(2041-2060 average annual value). The P-M evapotranspiration model recommended by the FAO is used to calculate the evaporation. And the moist degree is used as the index of water resources. In general, the results showed that water resources in China present latitude zonal distribution, gradually reduce form south to north. From the trend of the change, the water resources in the south of Yangtze river will decrease in the future, on the other hand, in the north of Yangtze river , especially in the north of the Huai-he river , the water resources condition will get better. The most obvious regions for the growth of water resources include the western of northeast China ,Huai-he river basin, Si-chuan province and the south of Tibetan autonomous region.

(1) University of Nottingham, Nottingham, United Kingdom; (2) University of Nottingham, School of Geography, Nottingham, Nottinghamshire, United Kingdom; (3) Met Office, Exeter, United Kingdom; (4) Center for Global Environmental Research, Tsukuba, Japan; (5) Norwegian Water Resources and Energy Directorate, Oslo, Norway; (6) Max-Planck-Institute for Meteorology, Hamburg, Germany; (7) Potsdam Institute for Climate Impact Research, Potsdam, Germany; (8) Center for Environmental Systems Research, University of Kassel, Kassel, Germany; (9) Civil Engineering Department, The City College of New York,, New York, United States of America; (10) Department of Physical Geography, Utrecht University, Utrecht, Netherlands; (11) Potsdam Institute for Climate Impact Research (PIK), Potsdam, Germany

We present an innovative application of intelligent computing that constrains simulations of river discharge from an ensemble of multiple global hydrological models (GHMs) against observations for 110 large catchments across the globe to provide a single estimate of discharge that is both more robust and better informed than more traditional, simplistic techniques such as the ensemble mean. The approach uses evolutionary algorithms (EAs) through symbolic regression (SR) to develop catchment-specific multi-model combination (MMC) solutions that combine simulated discharge values from seven GHMs participating in ISI-MIP1 (Inter-sectoral Impact Model Intercomparison Project). The MMC algorithms are optimised by evaluating individual models (GHMs) performance against observations and then weighting and/or discounting GHMs accordingly in the MMC. In addition, the performance of the ensemble mean in simulating the observations is explored. A numerical integrated metric, ideal point error (IPE) with the privilege of assessing different behavioural aspects of the models simultaneously, is used to measure the performance of GHMs, MMC technique and ensemble mean approaches. Comparisons between simulated and observed discharge show that the optimised MMC algorithms can outperform the simulations of discharge from the best performing GHMs by reducing simulation error up to a magnitude of 30%. The MMC technique also outperforms the ensemble mean method in virtually all of the 110 catchments. Our analyses demonstrates the value of evaluating climate change impact model performance and using the results to provide indicators of hydrological change from multi-model ensembles that are more informative than traditional ensemble averaging techniques.

2206 - The World in 2050 – What does it look like and how do we get

ORAL PRESENTATIONS

K-2206-01

The Sustainable Development Pathway

J. Sachs (1)
(1) Columbia University, Earth institute, New York, United States of America

The world has several partial pathways towards sustainable development that cover specific areas, such as agriculture or climate change. Yet, we do not have an integrated pathway that demonstrates how the economic, social, and environmental imperatives of sustainable development can be achieved in harmony with one another. Such a pathway would inter alia have to stay within global "planetary boundaries", allow all countries to meet national development objectives, and maintain social inclusion. Moreover, a global pathway will need to be downscaled to major regions and demonstrate that every region can achieve sustainable development.

Working with my collaborators on "The World in 2050" we will partner with major modeling organizations to establish an integrated sustainable development pathway. We will use the Sustainable Development Goals proposed by member states of the United Nations as a shorthand form of objectives for sustainable development.

This presentation will focus on the economics of sustainable development. A key research question is how mid- to longer-term economic models can incorporate the SDGs. This will be illustrated using a few examples from the emerging research.

K-2206-02

The World in 2050

J. Rockström (1)
(1) Stockholm Resilience Center, Stockholm university, Stockholm, Sweden

One of the most pressing issues facing the global community post 2015 is how to realize the benefits of future global economic development within a safe and just operating space of a stable planet.

The World in 2050 Project will explore the implications of the necessary transformative sustainable development pathways and the possible 'degrees of freedom' to meet economic development goals within a safe operating space of a stable planet.

The project will generate the 1st generation of global scenarios that meet the twin objectives of economic growth and planetary stability and thus provide improved evidence, including macro-economic assessments, to political leaders in the SDG process, and other key decision makers, on the feasibility, challenges and opportunities associated with meeting long-term development goals, i.e., development goals that are truly sustainable at a global scale.

K-2206-03

Beyond Paris to 2050 and thereafter - multiple benefits of a global transformation toward sustainable futures

N. Nakicenovic (1)
(1) International Institute for Applied Systems Analysis (IIASA), Laxenburg, Austria

An objective of The World in 2050 Initiative is to explore the transformative development pathways at the global and regional scales that achieve convergent economic and social development within planetary boundaries. The presentation will focus on the main drivers of the transformation, their relationships including some of the Sustainable Development Goals (SDGs) and their targets, on policy measures, and on technological and social changes that would be needed for achieving the transformation toward the "safe and just space" that characterizes sustainable futures.

An important research question is how high are the degrees of freedom in achieving this transformation, what are the prerequisites and implications. In other words, are there multiple transformative pathways especially at regional levels. For example, Global Energy Assessment (GEA) developed 41 transformative energy pathways toward sustainable energy futures that included universal access to energy services for all, improvements in energy efficiency and decarbonization needed to stabilize climate change at two degrees Celsius above pre-industrial levels. Energy is one of the SDGs, but the challenge is to assess to what extent different SDGs, such as energy and water, can enhance each other and to what extent tradeoffs will be required in achieving different SDGs.

Finally, the presentation will conclude by assessing multiple benefits and opportunities that would emerge from the transformative changes toward sustainable futures. A key question to explore is the potential for achieving co-benefits and/or trade-offs of addressing multiple SDGs at the same time, which can provide critical information for policy and investment decisions, their synergies and possible conflicts among them.

K-2206-04

The World in 2050 – the contribution of model-based scenarios

D. Van Vuuren (1) ; E. Kriegler (2) ; K. Riahi (3)
(1) PBL Netherlands Environment Agency, PBL, Climate, air pollution and energy, Bilthoven, Netherlands; (2) Potsdam Institute for Climate Impact Research, Potsdam, Germany; (3) International Institute for Applied Systems Analysis, Energy Program, Laxenburg, Lower Austria, Austria

In 2012, governments worldwide renewed their commitments to a more sustainable development that would eradicate poverty, halt climate change and conserve ecosystems, and initiated a process to create a long-term agenda of action by formulating Sustainable Development Goals (SDGs). These SDGs will be agreed upon in 2015. Studies that depict pathways that relate near-term actions and a long-term vision could help implementing the SDGs by 1) providing a link between the 2030 SDG targets and an inspirational vision about a sustainable world in 2050 to a medium-term set of sustainable development goals (say by 2025 or 2030), 2) exploring what efforts would be needed to realize the goals and 3) providing information on the inter-linkages (synergies and trade-offs) between the achievement of the goals.

Integrated assessment models have been used extensively in the last few years to develop model-based scenarios to depict possible future trajectories with respect to human development and environmental consequences. They have also been used to develop scenarios that achieve certain future goals (e.g. the 2oC climate target). Most of these studies have looked into specific topics, but there has also been studies that took a broader set of goals comprising both environment and development targets such as the Global Energy Assessment, the Global Environmental Outlook and the study "Roads from Rio+20". Overall, these studies have shown that it is possible to achieve an ambitious set of sustainable development targets simultaneously. However, this will require fundamental changes in the energy and food system. There are also important synergies and trade-offs between different objectives that depend on the specific strategy that is used to achieve them (e.g. specific technologies, different types of management and the role of lifestyle changes).

In the proposed presentation, we will discuss how integrated assessment models can provide further insights into the question how to achieve the a set of sustainable development objectives (including the SDGs) in the 2030 / 2050 period, among others by using specific examples from existing studies. We will also discuss how the Shared Socio-Economic Pathways (SSPs) can be used within the context of such an exercise.

2207 - Ocean Change: Understanding and projecting the impacts of warming and acidification on natural and human systems

ORAL PRESENTATIONS

K-2207-01

Ecological challenges for life in a rapidly changing ocean

JP. Gattuso (1) ; T. Ocean 2015 Initiative (2)
(1) CNRS and Université Pierre et Marie Curie, Laboratoire d'Océanographie de Villefranche, Villefranche-sur-mer, France; (2) Institut du développement durable et des relations internationales, Paris, France

Ocean warming and acidification share the same primary cause, which is the increase in atmospheric CO2. The fossil record indicates that the rate and magnitude of the present, human-generated carbon perturbation leads to changes potentially unparalleled in the last 300 My of Earth history. Ocean warming and acidification are two key global environmental drivers that challenge marine organisms and ecosystems. Responses can be influenced, often exacerbated by other drivers, such as hypoxia, eutrophication, habitat loss and overexploitation of resources.

A large range of approaches are used to assess the present impacts and project future risks: paleo-observations,

observations in natural gradients and around CO2 vents, perturbation experiments in the laboratory and in the field, as well as modelling. All approaches indicate that the effects of ocean warming and acidification on individual organisms are or will be widespread, and that they propagate at the ecosystem level. Warming induces shifts in the abundance, geographic distribution, migration patterns, and timing of seasonal activities of species, generating changes in the composition of ecosystems. Such distributional shifts will continue in the coming decades, increasing species richness at mid- and high latitudes and decreasing it at tropical latitudes. This will result in a global redistribution of catch potential for fishes and invertebrates, with implications for food security. A wide range of sensitivities to projected rates of ocean acidification exists within and across diverse groups of organisms, with a trend for greater sensitivity in early life stages. A pattern of positive and negative impacts emerges. The rate of calcification decreases in most, but not all, sea floor calcifiers such as reef-building corals, coralline algae, bivalves, and gastropods, reducing the competitiveness with non-calcifiers. The combined effects of ocean warming and acidification have resulted and will further result in changing interactions between species, including competition, predation and pathogen dynamics.

A considerable number of biological, chemical, and physical processes act at enormous ranges of space and time scales to control ecosystem properties. Few of these processes and interactions are understood because most studies are short-term, organism-centric and examined just one driver at a time. Gaps in our understanding and uncertainty in future projections therefore remain. Coral reefs are the main ecosystem which already exhibits prominent signs of the impact of climate-related variables but it must be pointed out that seemingly stable ecosystems maintained by feedback mechanisms can be subject to abrupt ecological shifts. Taken together, these observations as well as the fossil record confirm links between ocean warming and acidification and responses of ocean ecosystems. There are no plausible alternatives to immediate, deep reduction of greenhouse gases emissions for limiting future ecological challenges and maintaining ocean services. It should be emphasised that reducing CO2 emissions to address ocean acidification will simultaneously address climate change but reducing emissions of other greenhouse gases to limit warming will not necessarily address ocean acidification.

Climate change and the Ocean: regional challenges and opportunities

O. Hoegh-Guldberg (1) ; T. Ocean 2015 Initiative (2)
(1) University of Queensland, Global Change Institute, Brisbane, Australia; (2) Institut du développement durable et des relations internationales, Paris, France

Earth's ocean plays a central role in its climate, absorbing 93% of the extra heat from the enhanced greenhouse effect, and approximately 30% of the CO2 emitted by the burning of fossil fuels and landuse change. While these contributions play an important role in reducing the rate of change in the average global temperature, they have come at a price in terms of shifts in ocean temperature and chemistry, and consequently a wide range of other key variables such as surface salinity, wind, pH, carbonate chemistry, stratification, ocean currents, nutrient availability, and oxygen content. According to AR5 of the IPCC we are now seeing changes in ocean conditions that are unprecedented, which in the case of ocean acidification, are "unprecedented within the last 65 Ma (high confidence) if not the last 300 Ma (medium confidence)."

These rapid changes within the Ocean are affecting the distribution and abundance of organisms and ecosystems, with important consequences for the goods and services that the Ocean provides to communities and nations worldwide. Fisheries and ocean-related livelihoods play important role in the lives of at least 3 billion people globally, with many nations receiving more than half of the protein requirements from the Ocean. While often overlooked in terms of national accounts, contributions by the ocean to key issues such as food security, employment, health, and coastal protection are large and are only likely to become more important over coming decades. Consequently, understanding the regional challenges posed by a changing ocean is critically important in terms of adaptation challenges and opportunities.

A regional analysis of climate change reveals a range of responses by ocean ecosystems. Recent changes to wind and ocean mixing are influencing the transfer of organic carbon to deep regions, which has had knock-on effect of stimulating microbial respiration and reducing oxygen levels. There is considerable evidence and agreement that fisheries in regions such as the High Latitude Spring Bloom Systems (HLSBS) in the North-Eastern Atlantic are changing in response to warming and ice retreat, with both positive and/or negative implications depending on the particular HLSBS fishery. Other fisheries are relocating at a high rate, placing stress on regional management.

Equatorial upwelling systems (EUS) which support highly productive fisheries off Equatorial Africa and South America, have warmed significantly over the past 60 years. While warming is consistent with changes in upwelling intensity, more work is needed to understand how EUS will change in response to warming over time. The risks, however, a significant given the importance of these changes for ecosystems, fisheries and communities. Coastal ecosystems such as coral reefs mangroves are under significant pressure from climate change, along with local stresses. Elevated sea temperatures are driving impacts such as mass coral bleaching and mortality, with models projecting that coral-dominated reef systems will have disappeared from most regions by 2050. Given that an estimated 500 million people depend on coral reefs for food and livelihoods, addressing this growing source of exposure for some of the least resourced nations must be a priority going forward.

The regional analysis of climate change for ocean systems reveals an important yet poorly understood source of risk and vulnerability for the world's nations. As a consequence, there is a major need to address these information gaps, and pursue otherwise poorly developed adaptation options, especially in terms of building socio-ecological resilience for the large number of exposed nations. Establishing communities of practice, knowledge and solutions platforms, as well as creating an alliance of nations around the challenges posed by a rapidly changing ocean will only grow in importance over the coming decades and century.

The Oceans 2015 Initiative comprises 17 experts (D. Allemand, R. Billé, L. Bopp, W. Cheung, M. Colombier, S. R. Cooley, J.-P. Gattuso, O. Hoegh-Guldberg, F. Joos, R. Kelly, D. Laffoley, A. Magnan, H.-O. Pörtner, A. Rogers, T. Spencer, C. Turley and S. Treyer). It is supported by the Prince Albert II of Monaco Fondation, Ocean Acidification International Coordination Centre, and BNP Paribas Foundation.

O-2207-01

Climate sensitivity across marine domains of life: limits to evolutionary adaptation shape species interactions

D. Storch (1) ; L. Menzel, (1) ; S. Frieckenhaus (2) ; HO. Pörtner (3)
(1) Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Integrative Ecophysiology, Bremerhaven, Germany; (2) Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, Scientific computing, Bremerhaven, Germany; (3) Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

Organisms in all domains, Archaea, Bacteria, and Eukarya will respond to climate change with differential vulnerabilities resulting in shifts in species distribution, coexistence, and interactions. The identification of unifying principles of organism functioning across all domains would facilitate a cause and effect understanding of such changes and their implications for ecosystem shifts. For example, the functional specialization of all organisms in limited temperature ranges leads us to ask for unifying functional reasons. Organisms also specialize in either anoxic or various oxygen ranges, with animals and

plants depending on high oxygen levels. Here, we identify thermal ranges, heat limits of growth, and critically low (hypoxic) oxygen concentrations as proxies of tolerance in a meta-analysis of data available for marine organisms, with special reference to domain-specific limits. For an explanation of the patterns and differences observed, we define and quantify a proxy for organismic complexity across species from all domains. Rising complexity causes heat (and hypoxia) tolerances to decrease from Archaea to Bacteria to uni- and then multicellular Eukarya. Within and across domains, taxon-specific tolerance limits likely reflect ultimate evolutionary limits of its species to acclimatization and adaptation. We hypothesize that rising taxon-specific complexities in structure and function constrain organisms to narrower environmental ranges. Low complexity as in Archaea and some Bacteria provide life options in extreme environments. In the warmest oceans, temperature maxima reach and will surpass the permanent limits to the existence of multicellular animals, plants and unicellular phytoplankter. Smaller, less complex unicellular Eukarya, Bacteria, and Archaea will thus benefit and predominate even more in a future, warmer, and hypoxic ocean.

(1) Centro Fermi and University of Bologna, Department of Physics and Astronomy, Bologna, Italy; (2) University of Bologna, Marine science group, dep of biological, geol and environmental sciences, section of biology, Bologna, Italy; (3) University of Bologna, Department of biological, geological and environmental sciences, section of geology, Bologna, Italy; (4) University of Bologna, Department of management, Bologna, Italy; (5) University of Bologna, Department of physics and astronomy, Bologna, Italy; (6) Bar-Ilan University, The mina and everard goodman faculty of life sciences, Ramat-Gan, Israel; (7) Harvard University, Wyss institute for biologically inspired engineering, Cambridge, United States of America; (8) Australian Institute of Marine Science, Pmb 3, Townsville, Australia; (9) University of Bologna, Department of chemistry "g. ciamician", Bologna, Italy

Global climate change is predicted to affect marine organisms and ecosystems reliant on the accumulation of calcium carbonate structures, as coral reefs, potentially reducing the socioeconomic benefits these habitats provide. In the marine realm, two of the main stressors causing significant changes are ocean warming and ocean acidification.

Projections of future climatic change estimate a 0.6–2.0°C average increase in surface ocean temperature by the end of 2100, posing a major threat for marine organisms. In temperate areas, the effect of warming is expected to be even greater. The Mediterranean Sea is already showing warming rates three times higher than the global ocean. Increased seawater temperature in the Mediterranean Sea has determined longer stratification periods associated with mass mortality events. The first well-documented Mediterranean multispecies mass mortality events were during the summers 1999 and 2003. In both years, a positive correlation was observed between mortality rates and exposure to heat stress, indicating that shallow water corals are living, at least in the North Mediterranean, near their upper thermal limits during summer. Since the frequency of abnormally warm summers is expected to increase in the next century, as a result of climate change, such mortality events in summer may also become more frequent as a direct response to elevated temperatures.

Also ocean acidification is a global phenomenon which impact varies locally. The Mediterranean Sea has experienced a pH decrease of up to 0.14 units since the pre-industrial era, larger than the global average surface ocean pH decrease. Hence, understanding how enhanced acidity has already affected and how it will likely affect Mediterranean Sea ecosystems and their key taxa is urgent and crucial.

Given the projected decrease of seawater pH, the mass mortality events could be exacerbated by the combination of high temperatures and low pH. Studies like this one, assessing the synergistic interaction between low pH and elevated temperatures, are essential to detect possible interactions between multiple stressors and establish to which extent corals inhabiting shallower ranges will be threatened by climate change.

Here we assessed the combined effects of in situ exposure to different acidity and seasonal temperatures on the mortality and growth rates of three Mediterranean scleractinian corals; the solitary zooxanthellate Balanophyllia europaea, the solitary azooxanthellate Leptopsammia pruvoti and the colonial azooxanthellate Astroides calycularis. The corals were transplanted and observed in different seasonal conditions in proximity to a volcanic vent where water is naturally acidified to levels matching different future Intergovernmental Panel on Climate Change scenarios.

The results suggest differential synergistic adverse effects of increased sea temperature and acidity and different levels of resilience/resistance to climate change among temperate coral species, probably related to different modes of nutrition and/or biomineralization processes, making symbiotic species relatively less sensitive due to the increased photosynthesis at high CO2.

Acknowledgements: The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013)/ERC grant agreement n° 249930 - CoralWarm: Corals and global warming: the Mediterranean versus the Red Sea.

(1) UPMC, Ipsl-locean, Paris, France; (2) IRD, Ipsl-locean, Paris, France; (3) Université de la Réunion, Entropie, Saint Denis, La Réunion, France; (4) UPMC, Borea, Paris, France; (5) HIBM, Kaneohe, United States of America

Since the industrial era, the atmospheric partial pressure of CO2 (pCO2) has been rising. Consequently, the world's ocean is getting warmer and acidified. By the end of the century, IPCC models in the worst case scenario predict an increase of sea surface temperature of 4°C and a decrease of seawater pH estimated at 0.3-0.4 pH-units. As a consequence, the saturation state of surface seawater (Ω) with respect to calcium carbonate minerals (CaCO3) will also decrease. All these climatic factors are expected to affect calcification and dissolution processes, putting for instance in jeopardy coral reef ecosystems which are entirely made of carbonates. Among those processes, biogenic dissolution of carbonates due to bioeroding microflora (or euendoliths), which comprise cyanobacteria, algae and fungi, has been the most overlooked process and is currently not taken into account in biogeochemical models. So far, rates of biogenic dissolution were estimated by quantifying the volume of calcium carbonate removed by bioeroding filaments using microscopy observations. Although those rates are significant (up to 1.1 kg CaCO3 dissolved per m^2 per year in coral reefs), the question is how much alkalinity bioeroding microflora are able to release in the ocean, and how they are influenced by climate change (pH and temperature). In addition, all experiments recently carried out which highlighted the positive effects of ocean warming and acidification on biogenic dissolution, were realized under controlled conditions (mesocosms) in tropical regions over short periods of time (2-3 months). The long term dynamics of the process of biogenic dissolution under natural conditions remains poorly known. Here we present results of five experiments carried out in tropical (Hawaii, New Caledonia reefs) and temperate regions (Ischia in Italy) at different time scales (a few hours up to 4 years), to show that (1) the amount of alkalinity produced by bioeroding microflora is significant (as high as 71 mequiv m^{-2} d^{-1} which converts to a CaCO3 dissolution rate of 1.3 kg m^{-2} y^{-1} under constant light conditions in tropical regions), (2) biogenic dissolution can occur under various saturation states ($0.8 < \Omega \leq 5$ both in temperate and tropical regions) and increases under rising pCO2 (by 50% to 250% depending on conditions) as long as the saturation state is above 1 (otherwise carbonate dissolution due to chemical conditions limits euendolith development and thus, biogenic dissolution), and (3)

biogenic dissolution is more efficient (x2.7) when new carbonate substrates become available for colonization by microboring communities in the summer season (higher temperature, light intensities, etc…) than in the winter season in tropical regions as colonization by the main agents of biogenic dissolution is faster in summer than in winter. These results suggest that at least in coral reef systems, global warming and ocean acidification will most probably stimulate the process of carbonate bioegenic dissolution due to microboring flora, accelerating the transition from a net coral reef accretion towards net coral reef dissolution. We estimate that today, at ambient temperature and pH in coral reef ecosystems, at most 20% of produced carbonates are dissolved by bioeroding microflora. By 2100, these organisms may be responsible for the dissolution of up to 70% of reef carbonates that are expected to be produced. If all dissolution processes are taken into account, i.e. chemical dissolution driven by water chemistry and bacteria metabolic activity, biogenic dissolution by bioeroding flora and biogenic dissolution by macroborers (such as boring sponges), reef carbonate budget may become negative much earlier than 2100. The capacity of carbonate biogenic dissolution due to bioeroding flora in buffering seawater remains however, unknown and needs to be investigated in order to better understand carbon biogeochemical cycles and to improve predictions of the fate of carbonate coastal systems.

O-2207-04

From natural science to management: Pteropods as sentinel species for OA waters status assessments

N. Bednarsek (1) ; T. Klinger, (2) ; R. Feely, (3)
(1) University of Washington, School of marine and environmental affairs, Seattle, WA, 98105, United States of America; (2) Universtiy of Washington, School of marine and environmental affairs, Seattle, WA, 98105, United States of America; (3) Pacific Marine Environmental Laboratory, Noaa, Seattle, WA, 98115, United States of America

Pteropods are ubiquitously distributed pelagic marine zooplankton of importance in productive upwelling and high-latitude systems, where they represent an important prey item for variety of economically, ecologically, and culturally important fish species. Because of their extreme sensitivity to ocean acidification (OA) conditions, pteropods can be used to establish cause and effect relationships between OA status and biological condition. As a result, pteropods can be used as a robust bioindicator for use in OA assessment. To demonstrate this utility, newly developed methods were used to determine and quantify pteropod responses in the natural environment. Biological responses, such as shell dissolution, shell calcification, changes in vertical distribution, and survival success were assessed to establish pteropod condition under a variety of OA conditions. We used modelling to estimate population survival rates based on future regional ocean acidification scenarios and to determine the level of sampling required to make confident predictions. We found that pteropods provide a repeatedly quantifiable measure that can be used as a rapid and cost-effective biomarker to monitor biological response to ocean acidification conditions across scales of time and space of relevance to managers.

O-2207-05

Ocean acidification and its relevance to the United Nations Framework Convention on Climate Change in Paris in December 2015

C. Turley (1) ; P. Williamson (2) ; D. Herr, (3) ; K. Isensee (4) ; E. Harrould-Kolieb (5)
(1) Plymouth Marine Laboratory, Plymouth, United Kingdom; (2) University of East Anglia, School of Environmental Sciences, Norwich, United Kingdom; (3) International Union for Conservation of Nature, Bonn, Germany; (4) IOC-UNESCO, Ocean Science Section, Paris, France; (5) University of Melbourne, School of Geography, Melbourne, VIC, Australia

Ocean acidification is a relatively recently recognised phenomenon, with recognition of its importance growing rapidly over the last few years. It is caused by anthropogenic carbon dioxide emissions and it has the potential for widespread, damaging effects on marine ecosystems that will also impact human society. It therefore must be part of the debate on emissions reduction at the United Nations Framework Convention on Climate Change Conference of the Parties (COP-21) in Paris in December 2015. Ocean acidification brings additional arguments for encouraging national governments to rapidly reduce CO2 emissions and accelerate the transformation to a carbon-free economy, thereby reducing the impact of both climate change and ocean acidification. Emission pathways to stay within the 2oC global warming target are under discussion by nations. However, ocean acidification impacts at the CO2 equivalent of a mean global temperature increase of 2oC would already be substantial for some regions and ecosystems. To bring this important issue fully into the discussion, recognizing that ocean acidification is a major threat to societies worldwide, there would be considerable merit in the UNFCCC process formally embracing the ocean acidification issue in its COP-21 text and post 2015 agenda. Thus the UNFCCC could promote the mitigation of ocean acidification, and adaptation to its impacts, in all relevant policy documents and regulation instruments.

MEAs, Mandates and More – A coordinated regime complex for ocean acidification

E. Harrould-Kolieb (1)
(1) The University of Melbourne, School of Geography, Melbourne, VIC, Australia

Ocean acidification, a complex global issue, results from the emission of anthropogenic carbon dioxide (CO2) and is exacerbated by a myriad of local stressors. Its consequences are not limited by geography and largely occur in an area of the global commons. It has uneven impacts, results in both ecological winners and losers and has implications for biodiversity, economic stability and sustainable development, with its solutions intimately tied with other global problems. As a result, it is of relevance to many treaties and yet, does not fall neatly within the mandate of any.

It has been suggested that ocean acidification appears to exist in somewhat of a legal twilight zone (Baird et.al. 2009), with no treaty body seemingly willing and able to take on the issue. Kim (2012, p.257) observes that ocean acidification "sits within a very complex institutional landscape, at a rather cracked interface between the climate, biodiversity and oceans regimes." This ambiguity and lack of clarity around the responsibility for addressing ocean acidification within the international policy space is likely to be a contributing factor in the apparent lack of action to mitigate and further respond to ocean acidification (Kim 2012, Herr et.al. 2014). As it currently stands, no single treaty or international instrument has been established to address ocean acidification as a stand-alone issue.

In response to the apparent lack of policy action on ocean acidification, the development of a completely new comprehensive treaty to respond to ocean acidification has been proposed. However, this is unrealistic, as there is likely to be little interest among states to do so. In light of this, this paper offers an alternative path forward by proposing the parsing out of activities needed to respond to ocean acidification across a range of existing multilateral environmental agreements (MEAs), overseen by an umbrella body and thereby forming a coordinated ocean acidification regime complex.

A variety of applicable treaties already exist that could take on elements of a broader coordinated response to ocean acidification. Indeed, a number are already taking action to address ocean acidification within their own institutional capacity. For instance, the Convention on Biological Diversity is well placed to expand monitoring and assessment as well as address issues of biological adaptation; and MARPOL, concerned with issues of ocean dumping, has taken steps to regulate iron fertilisation and other geoengineering schemes. Despite clear concern about ocean acidification these treaty bodies are unable to act further to mitigate OA due to their inability to regulate carbon dioxide emissions. Conversely, the UN Framework Convention on Climate Change (UNFCCC) – the treaty deemed responsible for the regulation of CO2 emissions – is seemingly hamstrung by the lack of mandate to incorporate ocean acidification into its activities. This paper concludes with an examination of the UNFCCC

mandate, and finds that ocean acidification falls within its purview, and hence proposes ways to better incorporate OA across its workings.

« Bridging the Gap between Ocean Acidification Impacts and Economic Valuation »

N. Hilmi (1) ; S. Reynaud (1) ; M. Marc (2) ; L. Hansson (3) ; P. Batra (3) ; D. Osborn (4) ; D. Allemand (5)

(1) Centre Scientifique de Monaco, Environmental Economics, Monte-Carlo, France; (2) IAEA, Radioecology, Monte-Carlo, Monaco; (3) IAEA, Iocc, Monte-Carlo, Monaco; (4) IAEA, Director, Monte-Carlo, Monaco; (5) Centre Scientifique de Monaco, Director, Monte-Carlo, France

Ocean acidification, is a growing environmental concern. The chemistry and therefore biology of world oceans will be impacted to varying degrees depending on region and type of ecosystem. Ocean acidification, through impacts on marine organisms and ecosystems, has the potential to seriously impact coastal communities and their economies. Communities ranging from mega-cities to subsistence fishing villages differ significantly in population, maritime activity, reliance on marine natural resources and therefore their respective adaptability. Identifying the magnitude and types of impacts ocean acidification will have on communities will become a concern of governments of coastal countries seeking to maintain current marine activities and benefits.

In 2008, the Monaco Declaration (requested by HSH Prince Albert II) advocated for the development of links between economists and scientists in order to better evaluate the socioeconomic impacts of ocean acidification. In line with the Monaco Declaration and in accordance with the wishes of Prince Albert II, an International workshop series – « Bridging the Gap between Ocean Acidification Impacts and Economic Valuation » – was launched by the 'Centre Scientifique de Monaco' and the Environment Laboratories of the IAEA. Three workshops have been organized since 2010 all gathering multidisciplinary international experts, to work on providing recommendations and an appropriate methodology for considering different policy or management options. These workshops resulted in clear conclusions and recommendations for policy makers.

The first workshop (2010) focused on the impacts of ocean acidification on the global economy. For the first time, economists and scientists came together to open the lines of communication and foster cooperation and coordination. The second workshop (2012) focused on impacts of ocean acidification on fisheries and aquaculture in different regions of the world. Social and economic impacts of ocean acidification on livelihoods, commerce and food security were discussed. What are the socio-economic impacts of ocean acidification on coastal communities? The third workshop (2015) discussed impacts on major coastal fisheries and tourism activities, and considered ways to model the cascade of potential impacts of ocean acidification on human activities. The workshop also discussed potential adaptation and capacity-building options and policy responses available to these various sectors and governments. Each of the workshops provided a set of specific recommendations for policy makers on possible mitigation and adaptation measures, and research priorities.

One of the fastest global changes caused by human activity is the continuing increase in carbon dioxide (CO2) levels in the atmosphere which have now reached over 400 ppm (http://www.esrl.noaa.gov/gmd/ccgg/trends/). Rising atmospheric CO2 is causing global warming and ocean acidification which can independently affect many marine organisms in a variety of marine habitats from tropical to high-latitude ecosystems.

Both acidification and warming are expected to alter the ecology of the Mediterranean Sea, although the evidence to date is sparse. A large scale mesocosm experiment focusing on the study of the simultaneous impact of warming and acidification on the planktonic ecosystem of the Eastern Mediterranean took place from August 30th to September 14th 2013 at the mesocosm facilities of HCMR in Crete, in the framework of the EU funded MedSeA project (www.medsea-project.eu). Natural plankton assemblages were incubated in 3 m3 mesocosms to examine the impact of changes in carbonate chemistry and temperature on biogeochemical variables and processes.

Two different pCO2 levels (present day and predicted for year 2100) were applied in the mesocosms for 2 weeks and tested in two large concrete tanks with different temperatures (ambient seawater: 25°C, ambient+3°C : 28°C). Four triplicates of mesocosms were deployed simulating the conditions of: current temperature and pCO2 (served as Control; C), Ocean Acidification (OA), Warming (W) and Greenhouse (GH).

The control of temperature in the two large tanks was made by means of a heating and cooling system connected to a control unit. Temperature was successfully controlled, exhibiting a nycthemeral variation of less than ± 0.5oC of the target temperature throughout the experimental period. The 'acidified' conditions were achieved by additions of CO2 saturated seawater during three consecutive days at the start of the experiment and then were let to evolve due to biological activity and air/sea exchanges of CO2 till the end of the experiment.

The effect of acidification was evident in the Chla concentration (highly dominated by the pico-sized fraction) and also in the pico-eukaryote density; Chla and pico-eukaryotes increased in both acidified treatments, whereas primary production was likely more dependent on temperature than OA. Bacterial abundance and production were not or only slightly affected by OA. There was also no effect of warming (even combined with acidification) on bacterial abundance; however a slight effect of temperature on bacterial production was observed. Alkaline phosphatase activity showed higher values under warm conditions, while it remained suppressed at lower levels in the GH mesocosms. No significant differences were measured for the phosphate turnover time between treatments, while the turnover times suggest P deficiency in all treatments for the duration of the experiment. P-uptake from different size fractions also showed no notable changes between treatments and experimental days. However, there was some indication of enhanced nitrogen fixation under warming conditions. Copepod (eggs & Nauplii) production (CP) varied significantly with time during the experiment. Acidification had no clear effect on CP, whereas acidification and warming resulted in a significant decline of CP and this decrease was higher than that observed at the warming conditions only.

The overall mesocosm experiment results showed that, for CO2 conditions forecasted for the end of this century, the pelagic ecosystem in the eastern Mediterranean Sea will prove resilient to increases in the ocean acidification. However, the warming will have a more important effect than acidification; and will enhance the effect of acidification on pelagic ecosystem functioning. The results obtained will help to gain insight on the dynamics and trophic efficiency of the food web under increased CO2 levels and temperature and may allow better predictions of the overall effect of ocean acidification and warming on the functioning of marine ecosystems.

Ocean Acidification: Global Issue, Local Effects

J. Newton (1) ; L. Jewett (2) ; P. Williamson (3) ; Z. Willis (4) ; T. Klinger, (5) ; R. Feely, (6) ; N. Bednarsek (7)

(1) University of Washington, Applied Physics Laboratory, Seattle, WA, United States of America; (2) NOAA , Washington DC, United States of America; (3) University of East Anglia, School of Environmental Sciences, Norwich, United Kingdom; (4) US IOOS, Washington DC, United States of America; (5) University of Washington, School of marine and environmental affairs, Seattle, United States of America; (6) Pacific Marine Environmental Laboratory, Noaa, Seattle, WA, 98115, United States of America; (7) University of Washington, School of Marine Affairs, Seattle, United States of America

Ocean acidification is a global problem already impacting our coasts and oceans at scales that span from individual species to ecosystems to indigenous communities to human industry such as aquaculture. Efforts are underway at several scales to observe ocean acidification and its effects on biological organisms. In this talk we present the Global Ocean Acidification Observing Network (GOA-ON), as well as how national, regional and local networks can integrate within GOA-ON. The major characteristics of GOA-ON will be presented, including how this international network is interoperable with observing networks on smaller scales. As an example, we present data from the Pacific Northwest United States and observed impacts on shellfish growth and pteropods. Programs from the states of Washington and Oregon and from the United States are being synergized to afford better observing and communication of these data in near real-time. This effort seeks to optimize interoperability and sharing of data. These contributions nest within GOA-ON and help to define our global status based on the mosaic of local views.

P-2207-05

Projected changes, climate change signal, and uncertainties in the CMIP5-based projections of ocean surface wave heights

X. Wang (1) ; Y. Feng, (1) ; VR. Swail, (1)

(1) Environment Canada, Climate Research Division, Science & Techonology Branch, Toronto, Ontario, Canada

Ocean surface waves can be major hazards in coastal and offshore activities. However, wave observations are available only at limited locations and cover only the recent few decades. Also, there exists very limited information on ocean wave behavior in response to climate change, because such information is not simulated in current global climate models.

In a recent study, we used a multivariate regression model with lagged dependent variable to make statistical global projections of changes in significant wave heights (Hs) using mean sea level pressure (SLP) information from 20 CMIP5 climate models for the twenty-first century. The statistical model was calibrated and validated using the ERA-Interim reanalysis of Hs and SLP for the period 1981-2010. The results show Hs increases in the tropics (especially in the eastern tropical Pacific) and in southern hemisphere high-latitudes. Under the projected 2070-2099 climate condition of the RCP8.5 scenario, the occurrence frequency of the present-day one-in-10-year extreme wave heights is likely to double or triple in several coastal regions around the world (e.g., the Chilean coast, Gulf of Oman, Gulf of Bengal, Gulf of Mexico).

More recently, we used the analysis of variance approaches to quantify the climate change signal and uncertainty in multi-model ensembles of statistical Hs simulations globally, which are based on the CMIP5 historical, RCP4.5 and RCP8.5 forcing scenario simulations of SLP. In a 4-model 3-run ensemble, the 4-model common signal of climate change is found to strengthen over time, as would be expected. For the historical followed by RCP8.5 scenario, the common signal in annual mean Hs is found to be significant over 16.6%, 55.0% and 82.2% of the area by year 2005, 2050 and 2099, respectively. For the annual maximum, the signal is much weaker. The signal is strongest in the eastern tropical Pacific, featuring significant increases in both the annual mean and maximum of Hs in this region. The climate model uncertainty (i.e., inter-model variability) is significant over 99.9% of the area; its magnitude is comparable to or greater than the climate change signal by 2099 over most areas, except in the eastern tropical Pacific where the signal is much larger. In a 20-model 2-scenario single-run ensemble of statistical Hs simulations for the period 2006-2099, the model uncertainty is found to be significant globally; it is about 10 times as large as the scenario uncertainty between RCP4.5 and RCP8.5 scenarios.

Climate Change Challenges Ecological Functions of the Deep Half of the Planet

L. Levin (1)

(1) Scripps Institution of Oceanography, UC San Diego, Integrative Oceanography Division and Center for Marine Biodiversity and Conservation, La Jolla, United States of America

Half of the planet's surface, and over 90% of its volume is covered by deep ocean below 200 m. We now know this realm hosts a wealth of different species and ecosystems that provide services critical to the health of the planet. Nutrient recycling, carbon sequestration, habitat and food web support of biodiversity occur on vast scales. The deep sea also contains fish, shellfish, hydrocarbons, mineral and genetic resources subject to growing demand from human society. The deep ocean is highly connected to the surface ocean and accordingly experiences both natural and anthropogenically induced climate variation. Ocean warming, ocean acidification, ocean deoxygenation and altered organic matter fluxes to the seabed are among the major deep-water manifestations of rising CO2 in the atmosphere. We are just beginning to document these changes and understand the implications for ecological function and resilience in the traditionally stable deep sea. Deep waters have absorbed significant heat from the atmosphere, with potential effects on species metabolic rates, distributions, and interactions. Warming margins will experience gas hydrate dissociation, releasing methane, a potent greenhouse gas. Increasing CO2 and carbonate undersaturation threatens the process of calcification and the resilience of deep-water coral reefs in the face of disturbance, particularly in the North Atlantic. Ocean deoxygenation and expanding oxygen minimum zones at upper bathyal depths can lead to biodiversity loss, habitat compression, and changes in food webs – all of which affect fisheries and livelihoods. Interactions among stressors are likely. Warming will interact with oxygen and the carbonate system (pH, carbonate saturation) to cross tipping points and shift ecological functions. Changing ocean conditions will alter fluxes of particulate organic carbon to the deep sea, influencing energy budgets and organism abilities to cope with climate stressors. Insights into potential future changes can be drawn from the study of deep-sea faunal responses to environmental gradients in space and to changes over time. By combining information from the paleo record and from patterns in the modern ocean, and by conducting experiments we can begin to assess how climate change might be manifested in the future deep sea. There remains an urgent need however, for a network that measures essential climate-change variables in the deep ocean over time and documents biological responses from the molecular and genetic to the population and ecosystem level. The influence of climate change on the function, resilience and recovery of deep-sea ecosystems and on the services they provide takes on added significance as societal exploitation of the deep sea introduces novel forms of disturbance and stress.

K-2208-02

Evidence of change in deep-sea ecosystems: a societal concern?

A. Glover (1)
(1) Natural History Museum, Life Sciences Department, London, United Kingdom

Concerns over the potential impacts of recent global change have prompted renewed interest in the long-term ecological monitoring of large ecosystems. The deep sea is the largest ecosystem on the planet, the least accessible, and perhaps the least understood. Nevertheless, deep-sea data collected over the last few decades are now being synthesised with a view to both measuring global change and predicting the future impacts of further rises in atmospheric carbon dioxide concentrations. For many years, it was assumed by many that the deep sea is a stable habitat, buffered from short-term changes in the atmosphere or upper ocean. However, recent studies suggest that deep-seafloor ecosystems may respond relatively quickly to seasonal, inter-annual and decadal-scale shifts in upper-ocean variables. At some deep-sea sites, progressive changes can be detected that could be linked to recent climatic change.

Why should society be concerned about changes in the deep sea when it is so apparently remote from most humans economic, social, cultural, aesthetic and ethical world? One answer is that it is one of our last great wilderness regions, filled with an astonishing reservoir of mostly undocumented biodiversity. Where it is documented, we have found examples of remarkable evolutionary and ecological novelty that have challenged the notions of where life may exist, or have existed, in elsewhere in the solar system and beyond. The deep-sea, less constrained by time, has become a vast evolutionary experiment across one of the great ecological gradients on the planet, that of depth. Knowledge of this diversity, how it has formed and what role it plays in the global ecosystem should not be a hobby for enthusiasts, but a key tranche of the scientific and public understanding of our planet and how we attempt to manage it.

K-2208-03

Marine cabled observatories as a new technology for the highly integrated environmental and biological monitoring

J. Aguzzi (1) ; A. Purser (2) ; L. Thomsen (2) ; JB. Company (3)
(1) Instituto de Ciencías del Mar (ICM-CSIC) (www.icm.csic.es), Recursos marinos Renovables, Barcelona, Spain; (2) Jacobs University, Ocean lab. earth and space sciences, Bremen, Germany; (3) CSIC, Institut de ciències del mar, Barcelona, Spain

Marine depths below 1000 m represent approximately the 65% of the planet surface, making of the deep-sea the largest biome on Earth. Presently, there is a lack of capability in fostering high-frequency sampling in deep-sea areas, which is limiting our understanding of oceanographic processes and their influence on continental margin and deep-sea life. Additionally, this constraint is hindering development of the marine ecological framework. In this context, marine species show rhythmic and massive population movements synchronous with geophysical cycles (light intensity, hydrodynamic tidal and inertial variations), over timescales not comparable with the frequencies of trawling surveys. As a result, significant errors in population/stock and biodiversity assessments occur over 24-h and seasons as a result of use of this "classic" sampling method. Also for more advanced ROV surveys a time-consuming and costly vessel support can be required, limiting the sampling repetition. A new technology should therefore be implemented in order to establish reliable: i. Faunal lists, key in deep-water ecosystems exploration; ii. Cause-effect principles, which link animal behavior to environmental changes; and finally, iii. Population assessments, with sampling stations coordinated into geographic networks. Cabled seafloor observatories allow the continuous and real-time video-counting of animals, and allow these counts to be related to the oceanographic, chemical, and geologic multiparameters, as measured by sensor systems mounted alongside the imaging equipment. Video cameras may be the first true "intelligent" ecological sensors operating at high level of ecological complexity (i.e. ecosystems fauna), as these can capture species rhythms and resulting overall community dynamism in an automated fashion. Automation may transform cameras into sensors delivering numeric outputs (i.e. visual count time series for the different species). Presently, networks of fixed monitoring stations, which include cabled seafloor and water column observatories, are being deployed to provide scientists and generic users with relevant data for the environmental research and sustainable management of marine ecosystems at all depths, considering the geosphere, hydrosphere, and biosphere as integrated components. These observatories are "historicizing" data acquisition, delivering multiannual time series (i.e. into decades) of physical, chemical, and geological parameters. International networks include the European Multidisciplinary Seafloor and water-column Observatory (EMSO; www.emso-eu.org) as a Research Infrastructure of the European Strategy Forum on Research Infrastructures (ESFRI; ec.europa.eu/research/esfri/). At this stage of technological development, cabled observatories may be used forreliable ecosystem monitoring at discreet locations, i.e. the sensor platforms. In order to expand their field of coverage, crawlers (Univ. of Bremen; http://www.jacobs-university.de/ses/research/oceanlab/crawler; L. Thomsen IP) are a promising tool for extending the reach of the observatory to the surrounding area. Crawlers connected to benthic observatory nodes by umbilical, are movable multiparametric and multisensor expandable platforms. They can monitor the marine environment around the node with nested transect procedures which may be modified according to required changes in sampling strategies. Presently, crawler technology is in use at the largest infrastructural observatory network in the planet, the Ocean Network Canada (ONC; http://www.oceannetworks.ca/). A unit (named Wally) has been in operation for 5 years in Barkley Canyon (~890 m depth), video-surveying fauna in a geomorphologically active, hydrocarbon cold seep region of Pacific margin. In the future, crawlers could be standard equipment deployed with benthic platforms. Current developments are underway to automate crawler movements, with umbilical cables being superseded by submarine wifi communications, wireless power transfer and automated docking procedures similar to those developed for Space robotics (ROBEX; http://www.robex-allianz.de/en/).

Habitats characterization of the New Caledonia deep sea ecosystems

J. Delavenne (1) ; P. Lozouet (2) ; L. Poncet (3) ; S. Samadi (1)
(1) museum national d'histoire naturelle, UMR ISYEB, PARIS, France; (2) museum national d'histoire naturelle, Service des collections, Paris, France; (3) museum national d'histoire naturelle, Service du patrimoine naturel, Paris, France

The impact of climate change on marine ecosystems at different levels is demonstrated by many studies focusing on various regions of the globe. New Caledonia and other south west Pacific islands are very vulnerable to these threats with sea level rise or ocean acidification which impacts coral reefs. New Caledonia Exclusive Economic Zone is 1.3 million km² and most of it belongs to the deep sea with ridges and seamounts which represent unique ecosystems not easily accessible. It has been shown that deep sea ecosystems can also be impacted by climate change and to evaluate these potential effects the considered ecosystems must be precisely described and characterized.

The exploration program "Tropical Deep Sea Benthos" launches sea surveys in the south west pacific for more than 30 years and 37 surveys (3800 stations) sampled the New Caledonian waters. This program gathers a worldwide taxonomist network and led to numerous new species descriptions. Here, we used this large taxonomic database to develop a multi taxa approach to describe species associations on the New Caledonia seamounts in relation to stable physical environment like depth or slope. Some of the studied species have really narrow distributions or are only know from one location; hence they can strongly depend on very local environmental conditions. The change in sea level or sea surface temperature and their consequences on the deep sea habitats could have a strong influence on these organisms.

This study represents a first attempt at the habitats characterization and species associations' description of the deep sea ecosystems of New Caledonia and will be used to implement conservation and management plans of the area.

P-2208-02

Impact of climatic events on deep-sea ecosystems: the response of cold-water corals to dense water shelf cascades

F. Lartaud (1) ; E. Peru, (2) ; N. Le Bris (1)
(1) UPMC, Cnrs umr8222, Banyuls-sur-mer, France; (2) CNRS, Cnrs umr8222, Banyuls-sur-mer, France

The cold-water scleractinian corals (CWC) are the main ecosystem engineers in the deep-sea, and thus play a key role in deep-ecosystems. They form reef structures that provide niches and nursery grounds for a variety of species, including commercial an patrimonial species, making these reefs significant centers of biodiversity in deep water shelf settings. In submarine canyons, these habitats depend on the exportation of organic matter from the shelf to the deep-sea, and thus are closely related to climatic conditions. Particularly in the Mediterranean Sea, in the Gulf of Lion canyons, which is characterized by seasonal meteorologically-driven hydrological events, resulting from severe coastal storms or from the formation and sinking of dense water masses (i.e., cascading). The dense water formation occurs as a result of wind-induced cooling and evaporation of surface waters during winters. This annual pulsed phenomenon last several weeks, with strong inter-annual variation in intensity. The effects of the dense water shelf cascades on cold-water coral reefs are however poorly known. High densities of organic particles associated to the cascading events should constitute an energy supply but the strong currents result in major disturbance in the ecosystem functioning, with breaking of coral fragments.

Therefore, studying the response of cold-water corals to these cascading events is essential (1) to better assess the resilience of present reefs to the environmental dynamics, particularly in Mediterranean where the range and frequency of cascading events will change with in the next future with the global warming, and (2) to determine the growth dynamic of fossil reefs, probably linked to past climate conditions.

The development of mark and recapture techniques, coupled with sclerochronological analysis, allows growth rate estimations at the polyp scale based on the identification of staining as a time marker in the skeleton (Lartaud et al., 2013), whereas the use of support cuttings of coral fragments give growth rate information at the colony scale (Lartaud et al., 2014). In situ growth experiments were conducted in the Lacaze-Duthiers canyon (between 340 and 520 m depth) on two reef-building cold-water coral species (Lophelia pertusa and Madrepora oculata). The results show temporal changes in the growth dynamics, with a seasonal response of M. oculata, whereas L. pertusa appear less sensitive, and inter-annual variability presumably relied to the cascading intensity. Nevertheless, the two species living in the same habitat exhibit distinct growth response both at temporal and spatial scales, which should be take into account for further management strategies in the conservation of these species.

The climate-sensitive deep-sea ecosystem of the Lacaze-Duthiers submarine canyon: first steps of a long-term study of ecosystem dynamics and functions

(1) Sorbonne-Universités UPMC CNRS LECOB-UMR8222, Observatoire océanologique, Banyuls-sur-mer, France; (2) CNRS UPMC UMR8222 LECOB, Observatoire océanologique de banyuls, Banyuls-sur-Mer, France

Submarine canyons are recognized as ecological hotspots on continental margins providing a number of services to ecosystems and humans. In the Mediterranean sea, these canyons are particularly threaten by cumulated anthropogenic impacts and climate change effects (including changes in deep water convection and extreme meteorological events). Several of these canyons host abundant populations of deep-sea corals and may display even higher vulnerability to climate change, as these ecosystem engineers are particularly sensible to warming and acidification of deep waters.

Despite recent efforts in seabed mapping and dedicated physical oceanography monitoring, constrained access to these marine habitats largely limited the capacity to acquire basic knowledge on ecosystem dynamics. The complex links between environmental fluctuations and ecosystem functions therefore remains largely unknown. There is a critical need to fill these gaps in order to understand how climate forcing may challenge ecosystem stability and functions.

In this perspective, we established a multiannual integrated ecological study in the Lacaze-Duthiers submarine canyon (western Mediterranean Sea), which aimed to investigate key ecological functions in naturally variable conditions. The integrated experimental approach combined in situ growth studies of dominant cold-water coral species with the multidisciplinary study of sediment biogeochemistry in relation to microbial and meiofaunal communities.

The strong temporal variability of ecosystem components and functional rates revealed by these pioneer works further documents the strong influence of atmospheric fluctuations on these deep-sea environments, while providing first insights to the mechanisms underlying these interactions. These results set the basis for a long-term ecological study of this climate-sensitive deep-sea ecosystem and supports the implementation of effective monitoring strategies of the Lacaze-Duthiers canyon in the frame of the Marine Protected Area of the Gulf of Lion (Parc Naturel Marin du Golfe du Lion).

State of the art in oceans and climate change research: Synthesis of the 3rd International Symposium on the Effects of Climate Change on the World's Oceans (Santos, Brazil; March 2015)

M. Barange (1) ; JL. Valdes (2)
(1) Plymouth Marine Laboratory, Plymouth, United Kingdom; (2) Unesco , Oceanography, Paris , France

There are global concerns over the potential impacts of global environmental change on marine ecosystems and the services they provide. Initial assessments indicate geographically diverse impacts (Cheung et al. 2010), with significant consequences for the wellbeing of dependent communities (Barange et al. 2014). In March 2015, the IOC-ICES-PICES 3rd International Symposium on the Effects of Climate Change on the World's Oceans was held in Santos (Brazil). This symposium followed the recent IPCC 5th

Assessment Report, which included a number of dedicated ocean chapters. The symposium was a significant event in the challenge to provide evidences and project impacts of climate change on ocean physics and biogeochemistry, ecology, phenology and biodiversity, fisheries and foodwebs, as well as on the use and communication of uncertainties in projection methodologies. In this presentation, the convenors of the IOC-ICES-PICES 3rd International Symposium on the Effects of Climate Change on the World's Oceans, will summarise the main results and highlights of the conference, to update the research and user community on the rapidly developing research field of oceans and climate change.

Seafood is an important source of livelihood, nutrition and culture to many people, in particular, those in coastal communities. The Fifth Assessment Report of Intergovernmental Panel on Climate Change (IPCC AR5) highlights that climate change (CC) is challenging sustainable management of fisheries by redistributing fish stocks and therefore catches, particularly with many tropical regions suffering decreases in fisheries production. Overfishing further exacerbates climate risks on fisheries by depleting fish stocks while stock rebuilding is expected to help improve climate-resilience. However, quantitative assessment of the contribution of stock rebuilding in reducing the vulnerability of global marine fisheries to CC, with considerations of projection uncertainties, is not included in IPCC AR5. Using multiple climate-living marine resources models driven by a range of emission and fisheries scenarios, we examine the scope of vulnerability reduction of fisheries under CC and different pathways to stock rebuilding. We show that both CC and fishing scenarios contribute significantly to changes in global fisheries yields in 2050. Overall, stock rebuilding increases climate-resilience of the fishing sectors and marine ecosystems. However, even with stock rebuilding, substantial climate risks, particularly in sensitive ecosystems such as tropical oceans, may not be avoided without substantial reduction in greenhouse gas emission. Our results highlight the need for implementing integrated mitigation-adaptation approaches to improve climate-resilience for the fisheries sectors.

Challenges and advances in climate projection methodology and their use in projecting oceans futures

Sl. Ito (1) ; C. Enrique (2) ; J. Chan Joo (3) ; W. Muyin (4)

(1) The University of Tokyo, Atmosphere and Ocean Research Institute, Kashiwa, Chiba, Japan; (2) Rutgers University, Department of environmental sciences, New Brunswick, United States of America; (3) Korea Institute of Ocean Science and Technology, Ansan, Republic of Korea; (4) University of Washington, Joint institute for the study of atmosphere and ocean, Seattle, United States of America

Increasing computational power, improved fidelity of climate models and data obtained by global observing networks have advanced our understanding of both climate change and climate model evaluation. In addition, Coupled Model Intercomparison Projects (CMIPs) have contributed to improving climate model ability to reproduce past climates as well as climate variability through the use of ensemble modeling approaches. Nevertheless, typical model resolution is a half to one degree in latitude/longitude in the ocean model component, which makes it difficult to represent many ocean structures and phenomena important to marine ecosystems (e.g. upwelling, western boundary currents, eddies). Coastal areas are some of the most productive and biodiverse regions, and are dominated by mesoscale phenomena, which cannot be properly resolved by the climate models. One approach that is being used to achieve regional high-resolution climate-scale simulations is by nesting of a high-resolution limited-area model within a lower resolution large-scale model. Typically, information is downscaled from the coarse- to the fine-resolution region through an overlap in the domains. The high-resolution nest can explicitly resolve features missing from the large-scale model. However, when making a future projection, regional changes may also possibly affect the global climate (i.e. upscaling effects). Furthermore, model requirements are often different when considering ecosystems. For example, phenology is one of the most important items for marine ecosystems; a slight difference in the start of the spring stratification may result in a quite different marine ecosystem response.

Earth system models (ESMs), which include the carbon cycle, couple physics to lower-trophic-level marine ecosystem models. A common major weakness of ESMs lower-trophic-level models is the coarse functional group representation of zooplankton and lack of calibration with zooplankton abundances. This is partly because of the lack of a global database for zooplankton and partly because ESMs lower-trophic-level models have been designed to obtain accurate simulations of nutrient cycling and primary production but not necessarily for zooplankton dynamics. Nevertheless, zooplankton is a key component of marine ecosystems and it is our challenge to improve their representation, as well as the full marine ecosystem in climate models.

Socio-governance considerations and the impact of climate change on oceans and fisheries

Y. Ota (1) ; R. Caddell (2) ; R. Sumaila (1) ; CM. Andres (1)

(1) University of British Columbia, Fisheries Centre, Vancouver, Canada; (2) University of Utrecht, Department of law, Utrecht, Netherlands

Climate change represents a host of challenges and opportunities for the regulation of fishing effort. Stock displacement may lead to new and improved fishing opportunities in certain locations in a short time, while for other species climate change may truncate their natural ranges and biological processes. Fisheries management bodies will face difficult and often highly politicised choices in addressing the future regulation of fishing effort. These developments will clearly have a considerable impact both on fishing economy, society and the legal norms governing fisheries management and allocations. This paper accordingly examines the implications for international oceans governance raised by the impact of climate change on global fisheries, from both a societal and regulatory standpoint.

This paper will first examine the fundamental challenges posed to legal and societal governance by global climate change in the context of fisheries, identifying faultlines within the current regulatory regime advanced under the law of the sea that will be most affected by shifts in fish populations. This paper then moves to examine a case-study of how RFMOs and other regulators have responded to population shifts and climate-induced reductions in fish stocks in the emergent regulation of new and exploratory fisheries. To this end, it will be demonstrated that RFMOs exhibit strong potential to regulate new fishing effort in a precautionary manner and in accordance with ecosystem-based management, perhaps in contrast to the way in which many current stocks are being managed, although the process remains nascent and iterative.

This paper also acknowledges that stock mobility and regime changes could result in immediate stresses to those are considered to be vulnerable socially and economically. Accordingly, this paper will examine

the response of small-scale fisheries (with a particular emphasis on indigenous groups) to climate-induced changes to populations, noting the potential implications to these communities. These elements will accordingly frame an appraisal of current and emerging demands upon fisheries governance and evaluate the ability of the present system to address human dimensional impacts of climate change on fisheries across global and local scales.

The industrial development of High Seas pelagic fisheries targetting tuna and associated (billfishes) species since the 1950s has taken place in a warming Ocean. The short-living skipjack tuna is the most tropical and productive species while bluefin tuna is the most temperate and long living species, providing small but extremely valuable levels of catch. Rather than a single oceanic habitat, these species have overlapping vertical and horizontal habitats defined by their preferences and tolerances developed over the evolution for several key physical and biological variables. Though some tuna and billfishes can move far in high latitudes searching for rich foraging grounds they all return to warm waters (roughly >24°C) for spawning, leading to seasonal migrations and complex population dynamics mechanisms interacting with several environmental variables. Therefore, characterizing habitats and projecting them in the future using IPCC scenarios is a useful but incomplete approach when investigating the impact of climate change on these species. The progress in the study of climate change impacts on tuna and associated species is reviewed with highlights on recent results based on a modeling framework developed to simulate the spatial dynamics of fish with mechanisms constrained by relationships based on the bio-physical environment predicted from coupled 3D models of ocean physics and biogeochemistry. This framework includes a Maximum likelihood Estimation approach allowing reconstructing past history of fish population, to dissociate fishing impacts from natural variability, and to forecast population dynamics under climate change scenarios.

Ocean dynamical-biological models are required tools to address consequences of climate change upon marine biogeochemistry and halieutic resources in the future. For the Intergovernmental Panel of Climate Change (IPCC) report, the Coupled Model Intercomparison Project (CMIP5) gathers results of simulations computed from several Coupled Global Climate Models (CGCM, with different physical/biogeochemical Oceanic and/or Atmospheric components). Despite their ability in producing a consistent global warming trend for the future, they are known to display significant biases in the mean state as well as in the variability of the ocean for the historical and present periods along with tremendous regional discrepancies for the future climate variability and marine ecosystems. The discrepancies between the biogeochemical response in these coupled models may arise from the very different biogeochemical components used, whose complexity varies from simple nutrient restoring schemes to the explicit representation of several plankton functional types based on very different physiological assumptions. As a consequence, the comparison of the predictions of these different coupled models, crucial to assess how biogeochemistry may vary in the future, has proven to be very challenging. However the tremendous consequences on higher trophic level predicted by models that use future climate scenarios advocate more than ever for a better understanding and quantification of the predictions uncertainties.

To pin point the most robust changes in response to future climates, we propose an innovative method using a single physical/biogeochemical ocean model (NEMO/PISCES) forced with a mix of more realistic atmospheric forcing fields (improved ERA-interim reanalysis) and atmospheric trends extracted from the coupled climate models for the RCP8.5 scenario. With this method, we produce «state-of-the-art» simulations of the dynamic and biogeochemical state of the ocean which span over the historical (1979-2010) and the future (2011-2100) periods using different climates from different climate coupled models but with common ocean/biogeochemical model. The advantage of this method is to constrain the mean spatial patterns of the ocean forcing fields to remain close to the observations, to retain the desired observed modes of variability while having the changes induced by the anthropogenic perturbations. Using outputs from six CMIP5 coupled models, this method has been successfully applied and the produced forcing datasets have been used to force our dynamical/biogeochemical model for the future period.

These forced simulations exhibit spatial pattern of the Sea Surface Temperature (SST) warming similar to the one seen in the corresponding coupled climate models. However, a noticeable difference between the forced and the coupled models can be seen in the equatorial Pacific, and is related to a well known bias of the coupled models (i.e. too weak equatorial upwelling) mostly attenuated with our method. The different forced model simulations exhibit either contrasting or similar patterns between what is produced by our simulations and what is produced by the corresponding climate coupled models. They also exhibit a weaker spread in their biogeochemical projections as compared to the original coupled solutions. It suggests that discrepancies in the modeling of biogeochemical processes in the coupled climate models play a crucial role in the projections spread. However those projections produced by our forced strategy do still show significant differences. As an example, our forced simulations predict a decrease at the end of the century between 5% and more than 10% of the global Primary Production. The volume of the oxygen minimum zone ($O2 < 5 mmol.m^{-3}$) is also increasing with values bracketed between 10% and 50%. Those changes depend only on the diverse climates used to build our forcing sets. This allows understanding which of the biological patterns are robust across the diverse climates but also which of the biogeochemical models have a functioning different from ours, under a similar climate.

In a companion abstract, our simulations of future biogeochemical states of the ocean are used to force a model of tuna stocks (SEAPODYM) to characterize the potential for future tuna stock changes.

Evidence for trophic amplification and attenuation of climate change impacts on groundfish species productivity in the Bering Sea, AK

K. Holsman (1) ; A. Hollowed (2) ; K. Aydin, (2) ; J. Ianelli, (2) ; A. Punt, (3) ; A. Hermann, (4)

(1) NOAA Fisheries, Alaska Fisheries Science Center, Seattle, Washington, United States of America; (2) NOAA, Alaska fisheries science centre, Seattle, United States of America; (3) University of Washington, School of aquatic and fishery sciences, Seattle, United States of America; (4) University of Washington, Joint institute for the study of the atmosphere and ocean, Seattle, United States of America

Climate change is expected to impact marine ecosystems globally, with largest changes anticipated for arctic and

sub-arctic ecosystems. We used multi-species stock-assessment models to link climate-driven changes in physical and trophodynamic conditions to recruitment and mortality of three Eastern Bering Sea groundfish species (Gadus chalcogrammus, G. macrocephalus, and Atheresthes stomias, herafter pollock, P. cod, and arrowtooth, respectively) in order to distinguish harvest impacts on fish populations from large-scale climate pressures. When we compared model projections under climate scenarios to those under mean historical conditions, we generally found declines in estimated acceptable biological catch (ABC) for pollock and declines in recruitment for both pollock and P. cod. However, projected declines in ABC were sensitive to model specifications of trophic interactions, specifically the strength of bottom-up or top-down controls. Stock assessment models with predation had the largest projected declines in ABC, whereas single-species models without bottom-up controls on recruitment had the lowest projected changes in ABC. Inclusion of trophic interactions amplified climate-driven declines or increases in fish abundances, implying that fisheries models that do not include trophic interactions or climate effects might over-estimate sustainable harvest rates for fish species negatively impacted by climate change (e.g., pollock), and under-estimate harvest rates for predator species positively impacted by climate change (e.g., arrowtooth). Our work emphasizes the need to evaluate multiple future scenarios and model structures when projecting climate effects on fishery species.

P-2209-03

Climate Change Affects Marine Fish Distribution: Temporal and Latitudinal Evolution. Approach using GIS Technique and Satellite Data for Data-poor Areas

A. Kaimuddin (1) ; R. Laë (2) ; L. Tito De Morais (3)
(1) Institut Universitaire Européen de la Mer (IUEM), Laboratoire des sciences de l'Environnement MARin (LEMAR), Plouzané, France; (2) IRD, UMR LEMAR (CNRS/UBO/IRD/IFREMER), INRH, Casablanca, Morocco; (3) IRD, UMR LEMAR (CNRS/UBO/IRD/Ifremer), IUEM, Plouzané, France

Accurate knowledge of physical ocean conditions, i.e. sea surface temperature distribution and temporal variation is needed as a key input in many modeling types that are widely used for various applications. Climate varies naturally across a range of temporal and regional scales reflected by the change in pattern of marine species. Currently, global studies on how temperature changes have been performed in several articles, while studies in smaller region are still few. Besides, collecting the necessary quantitative data on a smaller region is costly.

The most powerful way to collect such comprehensive data is through the use of satellite sensors that measure different types of energy coming from the Earth. Using 30 years recent version of AVHRR SST dataset Pathfinder 5.2 from NOAA polar-orbiting satellite, we observed change of sea surface temperature and its effect in marine species distribution in three marine regions defined in LME (Large Marine Ecosystems) and ICES (International Council for the Exploration of the Sea): Canary current, the South European Atlantic Shelf and the Celtic Seas. Species richness in the middle region is generally higher because many species have their southern or northern distribution limits. The zoogeographic importance of this latitudinal area has long been recognised, representing the transition between north-eastern Atlantic warm-temperate and cold-temperate regions, which makes the zone an area of great sensitivity to the detection of climate change. The magnitude and variation change are differences among the ecosystems. We modeled the potential distribution of three fish species living in different environments: pelagic (Pomatomus saltatrix), benthopelagic (Balistes capriscus), and demersal (Solea senegalensis) to demonstrate the effect of climate change in marine fish distribution. The ability of GIS technique with the integration of Python programming language and the use of global marine environmental raster data from satellite remote sensing, such as sea surface temperature from AVHRR over the past three decades and other oceanic parameters from MODIS and the incorporation of world bathymetric data from GEBCO along with its derivates, we were able to demonstrate the potential distribution of marine fish species in space and time and to capture their northern and/or southern limits as well as to follow the evolution of their suitable area from 1981 to 2013. All species showed a northbound trend. This confirms a clear evidence of ocean warming effect in shifting marine fish distribution.

The models of species potential distribution were built by projecting the species environmental envelope on the environmental raster time series data. Species environmental envelope or the species realized niche were calculated by estimating the relationship between species records at given sites and the environmental characteristics of those sites with respect to the time of observation. The species records came from various databases. The use of Python programming language for GIS under ArcGISTM environment, allows us to extract the environmental raster values at the locations of species records at the time of observation. This new approach minimizes the biases from different sampling techniques among data sources as well as issues of small sample data size. When cross-checked with the species' environmental envelope defined in experimental or observational studies, the result yields coherent results for all species observed. Presentations in the form of animated maps, tables and graphics show the evolution of species' suitable area over time. This approach can be used to generate environmental envelope for a wide range of organisms as well as their potential distribution in data-poor areas and bring a better understanding of climate change effects in the ecosystems. The model will enhance the prediction models available today and will provide valuable information for conservation planning, fisheries, and climate change studies and furthermore contribute in the comprehension of species distribution study as well as management and conservation strategies.

P-2209-04

Slight impacts of marine animals on ocean biogeochemistry under global climate change

S. Lefort (1) ; O. Aumont (2) ; O. Maury, (3) ; L. Bopp (4)
(1) CNRS, Paris, France; (2) IRD, Paris, France; (3) IRD, Sète, France; (4) CNRS, Gif-sur-Yvette, France

We compared two transient climate change simulations of a global coupled biogeochemical-ecosystem model with and without feedbacks of marine animals on biogeochemistry. We found that marine animals have little effect on the biogeochemistry of carbon, but they modify the Net Primary Production (NPP) and oceanic oxygen content. These results imply that marine animals take no significant part in the oceanic storage of carbon under climate change. However, as a link of the food chain, they may attenuate the decrease of NPP under climate change through top down effect, favoring their food supply. On the other hand, as aerobic species, marine animals contribute to decrease the oxygen concentration in the ocean subsurface and increase the volume of hypoxic/anoxic water in the ocean, reducing their habitats.

P-2209-05

Effect of rising sea surface temperatures on the extension rates of the massive coral Porites spp from the Philippines

M. Manglicmot (1) ; C. Ringor, (2) ; FP. Siringan (3)
(1) UP Institute of Environmental Science and Meteorology and UP Marine Science Institute, University of the Philippines, Quezon City, Philippines; (2) UP Institute of Environmental Science and Meteorology, Quezon City, Philippines; (3) University of the Philippines Marine Science Institute, Quezon City, MM, Philippines

The integrity of coastal ecosystems is threatened by the effects of warming ocean waters brought about by global climate change. Thermally-sensitive species such as zooxanthellate corals and the reef structures they form are to suffer as they operate at optimal temperatures between 25 to 28°C. Long term coral growth band data provide a continuous record of the responses to increasing sea surface temperatures (SST). Extension and calcification rates of massive corals were enhanced at the onset of warming in the twentieth century but recent studies on the Great Barrier Reef, the Red Sea and the Thai-Malay peninsula reported declines with the further increase in SSTs after the 1990s. Other reefs however showed contrasting results with extension and calcification rates higher at present. The variable results of the studies highlight the need to investigate local responses to increasing SSTs. Philippine reefs comprise 8% of the world's total, following Indonesia

and Australia and is part of the Coral Triangle, described to be centre of marine biodiversity. The impacts of climate change to the country's reefs cannot be understated. In this study coral growth band data was used to establish the responses of Porites spp from reefs in the Philippines to changes in sea surface temperature over a period of 48 years (1956 to 2004). The linear extension rates (LERs) of Porites spp coral cores from the Calaguas Islands (north Philippine Sea), Parola Island, Kalayaan Island Group/ Spratlys (West Philippine Sea), Pamilacan Island (Bohol Sea) and Ayuki and General Islands, Surigao (south Philippine Sea) were measured from the density banding patterns of the coral skeleton revealed through x-radiography. Linear regression and time series analyses were performed to determine interannual and long-term changes in the extension rates. Time series of standardized anomalies of annual LERs of the Porites spp corals from the Philippines all show high interannual variability but the long-term trend displayed a decline in extension rates. The LERs of Porites spp are highly correlated to calcification rates and this decline in extension consequently reflect a decline in the calcification rates of Philippine corals. Different responses at the local level are also evident: the Porites spp from the Calaguas and Surigao reefs the LERs declined significantly at ca 0.38 mm per year and ca 0.16 mm per year respectively. Pamilacan Island showed a significant increase in extension of 0.22 mm per year however a sharp decline in the extension rates of the Pamilacan colony after 2000 is evident. The LERs of the Spratlys colony also decreased but the trend was not significant. The variable results even at the local level indicate complex responses of corals to warming ocean waters. Local factors such as wave energy exposure and interannual climate oscillations such as ENSO may enhance or counteract the effects of higher SSTs. Nevertheless, an overall decrease in the mean extension rates of the Porites corals on a national scale (0.097 mm per year) with an increase of mean annual SSTs of ~0.6°C from 1956 to 2004 was determined and is a cause for alarm as the decline in extension rates and calcification rates of a major reef builder coral, the Porites spp, maybe widespread throughout the Indo-Pacific region.

Will atmospheric changes impact bioluminescent organisms in the abyss?

S. Martini (1) ; C. Tamburini (2) ; S. Escoffier (3) ; D. Nerini (2)
(1) IRD, perpignan, France; (2) MIO, Marseille, France; (3) In2p3, Marseille, France

The sampling and understanding of complex environmental systems over long time scales aims at the detection of potential disturbances as a shift from the intrinsic variability of these systems. Marine systems are variable at all time and space scales and their variability is still poorly understood due to sampling strategy, instrumentation and spatio-temporal heterogeneity challenges. In response to this lack of knowledge, there is an international effort to capitalize oceanographic data and costs of autonomous and for mobile infrastructures that enables the detection of long term environmental context as well as episodic events or perturbations.

The deep-sea ecosystem is unique because of its permanent darkness, coldness, high pressure and scarcity of carbon and energy to sustain life. Most of its biological activity relies on the arrival of carbon in the form of organic matter from surface waters. Ninety percent of the numerous pelagic organisms that inhabit the deep ocean are capable of emitting light through the chemical process of bioluminescence. In this context, the ANTARES* neutrino telescope is a deep-sea cabled observatory situated in the north-occidental Mediterranean sea, close to the French coast. An unanticipated application is to provide a direct method to detect in situ bioluminescence from deep marine organisms, between 2200m and 2500m depth.

Our two recent studies show that high bioluminescence intensity periods have been detected since 2006 and are attributed to major water-mass changes due to winter convection. Dense deep water formation occurs during late winter and early spring due to cold, strong and persistent northern winds (Mistral and Tramontane) causing surface cooling of the Modified Atlantic Water both on the shelf and over the deep basin. When the cooled shallow waters on the shelf become denser than the ambient waters, they start sinking, overflow the shelf edge, and cascade downslope until they reach their density equilibrium depth, which may vary from 150 m to more than 2,000 m. These open-sea convections represent a major vector in fueling the deep-sea ecosystem with nutrients, carbon, oxygen and potentially organisms. Such water mass changes have been shown to induce higher bioluminescence emission. Indeed, the input of organic matter into the deep water has the potential to fuel the deep-sea biological activity. Bioluminescent bacteria are potential contributors to high bioluminescent events affected by environmental growth conditions.

Dense water formation is likely to be altered by the on-going global warming. Recent models based on the A2 IPCC scenario indicate a strong reduction in the convection intensity in the Mediterranean Sea for the end of the 21st century. This will induces a massive reduction in organic matter supply and ventilation by oxygen input of the deep basin with clear impact on deep organisms that could be detected by bioluminescence survey.

National ocean modeling for Philippine coral reef connectivity

MM. Noblezada (1) ; C. Villanoy, (1) ; D. Manalaysay (1) ; KM. Yatco (1) ; PL. Cadelina (1) ; P. Pata (1) ; C. Benjamin (1) ; A. Yniguez (1)
(1) Marine Science Institute, University of the philippines, Diliman, Quezon City, Philippines

The Philippines being an island nation of 7,100 islands, has one of the longest (34,000 km) coastline in the world characterized by highly complex bathymetry and hydrography. The country's reef system is extensive (25,000 km2) and its rich marine life is world acknowledge. Coral reefs are critically important ecosystems, as they provide valuable services including resources for coastal communities, buffer vulnerable coastlines from storm surges and habitat to various marine organisms. However, the country's coral reef system is in a degraded status attributed to various factors including unsustainable exploitation, sedimentation, and more recently events related to climate change such as extreme storms and coral bleaching which have led to declines in the function and resilience of these important ecosystem. Furthermore, Philippines is among the ten most vulnerable nations in the world affected by the impacts of climate change such as sea-level rise and severely damaging typhoons. Key capabilities such as numerical and biophysical modeling and their visualize outputs are valuable due to their capacity to provide a broad overview of connectivity patterns by tracking population sources and sinks as well as predictions of past and future hydrodynamic events. There is a growing evidence and efforts acknowledging connectivity and tracking population sources and sinks play an integral role to bolster resilience and ability of the reef populations to survive disturbances particularly related to climatic change such as typhoons, bleaching events, crown-of-thorns predation and diseases, any of which may increase and severity with changes in climate. This information as well can assist in the identification and monitoring of important or vulnerable habitats and designing management and conservation strategies. Here we present and describe the application of these approaches in determining pattern of reef connectivity in the Philippines. Philippine scale HYCOM model nested to the global HYCOM model runs for both real-time and hind cast mode and Lagrangian particle tracking model driven by the HYCOM hydrodynamic model to estimate coral reef connectivity patterns and matrices will be implemented. Model output will be offered for access near real-time via an OPENDAP server to be setup for disseminating model results. Ongoing model simulations and preliminary results are presented.

P-2209-08

The High-latitude Coral reefs of South Africa: A Canary in the Coral Coal Mine?

M. Schleyer (1)
(1) Oceanographic Research Institute, PO Box 10712, Durban, South Africa

Coral reefs are amongst the ecosystems most vulnerable to climate change. They occur at high-latitude in South Africa where they are at the southernmost limit of their

African distribution and are not accretive. While aragonite saturation and temperature are at levels that limit their growth, other factors including turbulence also play a role in their attenuation. The reefs are nevertheless rich in biodiversity, having 90 scleractinian and 40 alcyonacean species. Temperature and community monitoring commenced on the reefs in the early '90s and subtle shifts in coral community structure have been recorded, shifting from a tendency toward soft coral dominance to that of hard corals. Significant coral bleaching occurred in the austral summer of 2000/2001 when sea temperatures exceeded 28°C during a period of high insolation. Molecular work has shown that the corals are regionally rather isolated and ecologically independent of gene flow from northern reefs along East Africa. There even is a measure of spatial genetic structure in the corals studied at the reefal scale; the populations appear to be largely self-seeding. Furthermore, some of the more northern South African reefs seem to act as landing sites for putatively recruited migrants and have high levels of unique or private alleles. This degree of isolation and the stress to which these high-latitude corals are naturally subjected make them an excellent laboratory to examine the effects of climate change, viz. increasing temperatures and ocean acidification (OA). They may well manifest some of these effects in advance of the global future of corals. Representative coral species are thus under intensive study in the face of these stressors, in terms of their reproduction, recruitment, the incidence and progress of disease, and genetic adaptation. This is being accomplished in the field and a research aquarium equipped to manipulate temperature and OA. Results will be presented of completed and current work, showing the responses of the corals to these stressors, as well as observations on range shifts in their distribution. However, all the South African coral reefs are well conserved in a marine protected area and reef health appears to mitigate against some of the effects of global change.

P-2209-09

Projecting the state of the Mediterranean Sea Ecosystem under contemporary and future climate

C. Solidoro (1) ; P. Lazzari, (1) ; G. Galli, (1) ; MC. Donata (1) ; G. Cossarini, (1) ; T. Lovato, (2) ; M. Vichi, (3) ; C. Martin, (4) ; M. Giannoulaki, (5) ; M. Scardi, (6)

(1) Istituto nazionale di Oceanografia e di Geofisica Sperimentale OGS, oceanography, Trieste, Italy; (2) centro mediterraneo cambiamenti climatici , bologna, Italy; (3) university of cape town, cape town, South Africa; (4) united nation environmental program world conservation, Marine assessment and decision support, cambridge, United Kingdom; (5) hellenic centre for marine research, iraklion, Greece; (6) università tor vergata, roma, Italy

A suite of validated three-dimensional physical-biogeochemical-ecological models is used to assess the impact of future climatic and management scenarios on biogeochemical and ecological properties of the Mediterranean Sea. Results are discussed in term of temporal and spatial distributions of variables and indicators related to physical fields, carbonate system, cycles of carbon and inorganic nutrients, potential changes in higher trophic level organisms dynamics and in the distributions of critical habitats such as Posidonia oceanica and coralligenous formations.

The models properly describe available experimental information on contemporary seasonal dynamic and spatial distributions at the basin and sub-basin scales of the major biogeochemical parameters, as well as of primary production, carbon fluxes at the air-ocean interface and spatial distribution of critical habitats.

Model projections suggest that the future Mediterranean Sea will be globally warmer and more acidic, but with significant space variability. Plankton productivity and marine carbon sequestration would increase, even if the net primary production will remain at present level. Model results also indicate that changes in environmental parameters will alter the suitabilities of Poseidonia and Coralligenous over large areas, likely causing a reduction of those habitats. Intensification of extreme events occurence will impair the survival of red coral banks, decrease marine carbon sequestration, negatively impact aquaculture production. Simulations also highlight the possibility to compensate for adverse effects of climate changes on economic activities by relocating them or by changing management policies.

P-2209-10

Economic valuation and ecological status of coralligenous habitats under climate change

L. Thierry De Ville D'avray (1) ; JP. Féral, (1) ; D. Ami, (2) ; A. Chenuil, (1) ; R. David (3)

(1) IMBE, Marseille, France; (2) GREQAM, Marseille, France; (3) CNRS, IMBE, MARSEILLE, France

Climate change first impacts are on ocean temperature, acidification, nutrient content. In this context marine ecosystems may evoluate in a «no return state». How will be this state ? Study are on progress on marine living beings, but many incertitude remains.

Coralligenous habitats are typical Mediterranean marine coastal habitats identified on most Mediterranean coast at depths between 20 and 120 m. These biogenic hard bottoms, mainly formed by calcareous rhodophytes develop in conditions of reduced light, and at temperature of 13-20°C. With about 1670 species recordedThey are among the most important sources of marine biodiversity in the Mediterranean with Posidonia meadows (UNEP, 2007). This rich biodiversity and ecological functions inherent to the ecosystem are the source of a set of ecosystem services or «biological processes which man can benefit» (Bouvron, 2009). Their use or their perception by Human gives amenities that can lead to an economic evaluation. Current knowledge on coralligenous allows to affirm their contribution to (i) the production of food resources and raw materials, (ii) the regulation of coastal ecosystems, and (iii) the realization of recreation diving fishing thanks to their attractive landscape and abundance of «gourmet» species.

Are the "right" to access to this ressource around Mediterranean sea equal? What are the differents factors that influence the repartition of valuable species, for food security and food "confort"? The study will demonstrate that ecosystem services from coralligenous habitats and economic value of some of these services are impacted by climate change. The impact in quantity and quality of services, may affect the access to differents services, and thus their value.

Towards a coastal vulnerability typology for small islands: Assessing diversity and similarity via a common framework

R. Mclean (1)

(1) University of New South Wales, School of physical, environmental and mathematical sciences, Canberra, BC ACT, Australia

The Small Islands chapter of the IPCC AR5 reaffirmed the vulnerability of small islands to climate change threats due to their inherent physical and human characteristics, high exposiure to extreme events, and to the high dependence of island communities and economies on threatened ecosystems such as coral reefs and mangrove forests. It also emphasized that small islands present diverse risk profiles – a point that has not been sufficiently recognized in the literature. The chapter invited the scientific community to include island diversity in future V & A assessments within a consistent methodology approriate at regional, archipelagic and island scales.

Envisaged was the design of a new island typology reflecting both the heterogeneity and homogeneity of islands and island coasts that also included a range of climate-ocean processes and not just sea-level rise.

Over the past three decades many coastal vulnerability assessments have been undertaken in the Caribbean, Mediterranean, Indian and Pacific Oceans most of which have applied a predetermined methodology with an emphasis on sectors, e.g. water, human health and agriculture, on certain coastal types, e.g. deltas, mangrove shores and sany beaches, and with an almost singular focus on sea-level rise. None of the assessments have: (1) covered whole regions; (2) dealt with the full range of coastal types on islands; or (3) considered the entire suite of climate-change drivers.

A protoype of a new typology that satisfies these criteria has been developed in the Pacific covering 15 countries and 1532 islands. The objective was to produce a regional coastal vulnerability typology based on the inherent geomorphological characteristics of islands and all relevant climate-ocean processes that drive coastal change. Development of the typology comprised a series of nested scales with increasing spatial and temporal resolution at each step from all islands to a coastal segemnt of a single island. Initially islands were classified into 8 types based on two simple characteristics: lithology (rock type) and maximum elevation. To these attributes were added island area and shape to develop an 'indicative susceptibility'. This index recognized that certain island types are inherently more susceptible (less resistant) to change than others, for example a low elevation sedimentary reef island is more susceptible than a high elevation volcanic rock island. A five-point susceptibility rating was derived for all 1532 islands that included all island types within each country in the region, e.g. the 431 islands in the Solomon Islands.

The second step was to refine the scale from whole-island to coastal-margin with more variables added to the diagnostic criteria, including measures of insularity and proximity to other islands. Further downscaling to coastal compartments with more diagnostic criteria enabled development of higher resolution susceptibility measures. The third step was to identify the key climate and oceanographic drivers of coastal change together with their projected future changes through 2100 based on AR5 and recent Pacific-wide projections of tides, wind and waves, distant-source swell, ENSO, tropical cyclones and sea-level change. Finally, how these processes interact with different island and coastal types in different regions of the Pacific was documented through a 'coastal sensitivity' measure based on island location and projected changes in that part of the Pacific. Sensitivities were calculated for the 1532 islands. Some surprising patterns emerged from these data including the fact that atoll islands do not all fit into the very high sensitivity class but range over moderate, high and very high on a five-point sensitivity scale.

This coastal vulnerability typology developed for small islands in the Pacific provides a consistent and defensible methodology that should: (1) enhance the capacity of decision-makers to take climate risk into coastal adaptation planning and management; (2) enable agencies to invest in targeted and transferable adaptation projects with island partners; and (3) be applicable at all scales from global to local including other small island regions.

K-2210-02

Benefits of mitigation of climate change for coastal areas

R. Nicholls (1)
(1) Tyndall Centre for Climate Change Research, Southampton, United Kingdom

This presentation will review the possible benefits of mitigation of climate change for coastal areas with a strong emphasis on sea-level rise. This is one of the most certain consequences of human-induced global warming and has significant impacts. Importantly, there is a long-term 'commitment to sea-level rise' due to the long thermal lags of the ocean system and hence the response of sea-level rise to mitigation is slower than for other climate factors. Therefore, while climate stabilisation reduces coastal impacts during the 21st century, compared to unmitigated emissions, the largest benefits may occur in the 22nd century (and beyond). While we cannot avoid some global rise in sea level, we can still avoid significant losses of the Greenland and Antarctic ice sheets, with significant long-term benefits to coastal inhabitants. The available results suggest that a mixture of adaptation and mitigation policies need to be considered for coastal areas, as this will provide a more robust response to human-induced climate change than either policy in isolation. This point has been clearly articulated in coastal impact chapters of the Fourth and Fifth IPCC Assessments. This approach requires the joint evaluation of mitigation and adaptation in coastal areas which has not been systematically considered to date. Because of the long time constants involved such assessments need to continue beyond 2100 to provide the full implications of the different policy choices. While the basic science of the commitment was available and presented in the First IPCC Assessment, the policy implications are less appreciated and need wider discussion.

K-2210-03

Marine and Coastal Ecosystems: what are the impacts?

LM. Piedra Castro (1)
(1) Universidad Nacional, Escuela de Ciencias Biológicas, Cartago, Costa Rica

Coastal areas have traditionally been important to the development of human communities. Those who have exploited ecosystemic resources they provide them. These systems have been overexploited and polluted modified by human activities. Associated with these pressures, climate change may be impacting these ecosystems. The objective of this study was to analyze the factors affecting coastal and marine ecosystems and their conservation. For this analysis, the province of Limon was selected on the Caribbean coast of Costa Rica, including the southern sector. The evaluation was conducted in the communities of Wesfalia, Vizcaya, Cahuita, Puerto Viejo, Manzanillo and Gandoca. For the analysis of the beaches, the width of the beach, vegetation cover, type of dominant roots of vegetation, plant species composition, average height of vegetation and substrate type were evaluated. For evaluation of the reef and seagrass beds community, we use the methodology AGRRA 2.2 modified for depths between 1 and 6 m. In the mangrove, we applied the methodology of using Murdiyarso et al. (2009). NOAA satellite data for sea surface temperature, chlorophyll, precipitation and atmospheric CO2 were used. In the analysis, the Integrated Health Index Reef showed Isla Uvita, Cahuita, Puerto Viejo and Manzanillo have values of 3.7; 2.6; 3.45 and 2.86 respectively. The first and third places have good condition. Meanwhile, the second and fourth showed regular condition. Seagrass beds coverage showed 71.67 ± 10.4, number of offshoots 39.00 ± 77.93 and average heights of 7.00 ± 1.0 for Thalassia testudinium in Uvita Island. In Cahuita and Manzanillo, 2 species were observed (Syringodium filiforme and Thalassia testudinium) with coverage (%), number of offshoots and average heights with lower values than those reported in Uvita Island. In Puerto Viejo, the coverage was negligible. In all areas, small patches were observed connected reefs. For beaches, quality indicators showed that Gandoca and Manzanillo are the most impacted areas. Erosion was 91% and 56% respectively. As for coverage was 95 ± 8.13 and 65 ± 6.6 respectively. The other localities showed regular conditions. Cahuita mangroves and Gandoca were analyzed. The area was 2.85 and 13, 58 ha respectively. The number of species was 7 and 12 respectively. The dominant species Pterocarpus officinalis (16.78%) and Rhizophora mangle (29.45%) respectively. The number of dead trees was 15 and 26 individuals per ha respectively. The densities were of 53 ± 3.26 and 77 ± 9.87 individuals per ha respectively. There is significant difference between the temperature of a surface of the sea between 2001 and 2013 ($W = 1.14284E7$; $p = 0$). According to the comparison of medians (Mann-Whitney test) there is a significant difference in the concentration of chlorophyll «a» between 2003 and 2013 ($W = 0.86652E7$; $p < 0.05$). Increased wave and tide, caused by the increase in sea level and global climate change to produce more intense hurricanes and Norths winds, affecting upper parts of the beach that normally were not affected, being more vulnerable low slope beaches. It is concluded that the composition and structure of the shallow coral community in the 4 locations were evaluated regularly, in the case of Puerto Viejo, right on the Isla Uvita. The most important sites in both species Rhizophora mangle was also found Laguncularia and Avicennia germinans with other associated species. Riverine mangroves are two types during the dry season but a sand bar that prevents water flow is established. For Gandoca is stable as a coastal lagoon and in the case of Cahuita, like a swamp. The conservation status of these systems as ocean acidification that seems to reduce the number of sperm released by corals and agrees that

recruitment of larvae and the effect may start slowly or perceived, can be mitigated by the resilience of whose mechanisms of macroevolution system could not hope to provide answers to climate change. The strategies by reduce pressures on the species referred must be reduced the pressure in this ecosystem. In that sense, they must have the flexibility to confront climate change and that seems to be the most recommended practice in marine and coastal areas due to the difficulties of direct management in these areas. Some actions to mitigate climate variability are rehabilitating habitat mitigation program of coastal erosion control plan and mitigate the impact of lionfish and adaptation measures in management plans for marine turtles.

O-2210-01

Assessing the vulnerability of Air and Sea Ports in Small Islands: Risk Factors and Adaptation Guidance

L. Nurse (1)
(1) University of the West Indies, CERMES, Faculty of Science and Technology, Bridgetown, Barbados

Since publication of the IPCC First Assessment in 1990, all subsequent reports have identified key reasons for and drawn global attention to, the vulnerability of small islands to the adverse consequences of climate change, particularly sea level rise. The Summary for Policymakers of the recently released Working Group II Contribution to the Fifth Assessment Report (AR5-SPM-WGII), notes that various forms of disruption in islands and low-lying coastal states due to storm surges, flooding and sea level rise can be expected, with high confidence. Specifically, the AR5 emphasizes the risk of loss and damage to vital living and non-living coastal and marine resources in islands (e.g. beaches, coral reefs, seagrasess, mangrove wetlands) and their associated goods and services. While impact severity will vary within and among regions, the AR5- SPM-WGII projects that some small island states could suffer damages and adaptation costs of 'several percentage points of GDP' over the 21st Century and beyond.

By virtue of the 'openness' of their economies and the consequential reliance on imports and exports to sustain livelihoods, small islands are heavily dependent on the functionality and efficiency of their air and seaports. Unlike many larger continental-scale countries, international trade in SIDS is not facilitated by other transportation media such as road and rail. Between fifty and ninety percent of all food and beverages consumed in SIDS come from external sources, and more than ninety percent of all energy products used in SIDS, including hydrocarbon fuels, are handled through air and sea ports. On average, in excess of seventy-five percent of the consumables that support other sectors pass through these ports of entry. In addition, SIDS earn considerable local and foreign revenues from various port-related activities, including berthing and bunkering, airport landing and maintenance, containerized and other storage charges, waste reception fees and cruise passenger imposts, inter alia. As in other countries, considerable direct and indirect employment is also generated by air and sea ports in SIDS.

The climate-related risks posed to ports must therefore be of considerable concern to small islands and low-lying coastal states. While an increasing number of vulnerability assessments conducted on islands have evaluated the impacts of climate change and climate variability on coastal infrastructure, few have specifically examined the implications of the threat for ports in these regions. Hence, this work attempts to contribute to filling that gap by focusing on the vulnerability of air and sea ports in SIDS to climate change related impacts. More specifically, the risks posed to port infrastructure by sea level rise and projected changes in the behavior of some hydro-meteorological events will be examined. Equally, the potential for disruption to critical port-related functions as a consequence of climate change, will also be explored.

Some guidance on the selection of criteria for evaluating the appropriateness of adaptation responses is offered, which it is hoped would be helpful to port managers and planners in the SIDS regions. In this regard, while the similarities among small islands will help to form a basis for identification of some criteria, the guidance emphasizes that island diversity in its many forms - biogeophysical, economic, socio-cultural and political - helps to shape the risk profile of each country, and should therefore be an important consideration when making adaptation choices, including in the air and sea port sub-sector.

Finally, it is cautioned that notwithstanding the uncertainties, delaying adaptation in this crucial sub-sector, the lynch-pin of many island economies, may not be prudent, given the conclusions of the IPCC-AR5. It is suggested that an approach to adaptation which judiciously integrates what is known about the present-day vulnerability of ports with our 'best understanding' of future climate risks, would constitute a meaningful risk management strategy for air and sea ports in SIDS.

O-2210-02

Managing increasing risks in coastal cities

S. Hallegatte (1) ; R. Nicholls (2) ; J. Corfee-Morlot (3) ; C. Green (4)
(1) Climate Change Group , Washington , United States of America; (2) Tyndall Centre for Climate Change Research, Southampton, United Kingdom; (3) OECD, Paris, France; (4) None, London, United Kingdom

Coastal areas are particularly exposed to climate change and sea level rise, and large coastal cities represent hotspots of vulnerability and risk. In particular, coastal protections calibrated for current hazards and environmental conditions can quickly become inappropriate, leading to major increases in risk level: with rapid climate and economic trends, good protections can be more dangerous than helpful, in the absence of continuous adaptation. This presentation illustrates on major coastal cities how risk responds to change in sea level with and without adaptation, and discusses policy implications regarding coastal protection, risk management, and investment needs. A specific focus will be given to the need for comprehensive risk management packages that combine ex ante prevention actions with ex post actions that enhance the ability of the affected cities and people to recover and reconstruct. Finally, implications on poverty and inequality will be discussed, as protection choices will have large distribution and wealth impacts.

O-2210-03

Coastal forested wetlands as affected by sea-level rise and land-use in Caribbean islands: lessons from the past

D. Imbert (1) ; D. Galop (2) ; A. Lenoble (3) ; C. Stouvenot (4)
(1) UMR ECOFOG/Universty of Antilles, Pointe-à-Pitre, Guadeloupe, France; (2) UMR GEODE, Cnrs, Toulouse, France; (3) UMR PACEA, Cnrs, Pessac, France; (4) UMR ArchAm, Service régional de l'archéologie, Basse-Terre, France

Tropical coastal plains and estuaries have developed large forested wetlands during the present postglacial transgression. In the Caribbean islands, such wetlands are subjected to specific hydrological characteristics due to small tidal range, seasonal rainfall, low mineral siltation, and frequent powerful hurricanes. In this context, a large amount of the atmospheric carbon fixed annually by the vegetation is stored underwater and form peat deposits several meters depth. As a result, these autochthonous organic sediments act as invaluable paleoecological archives of past climatic changes and catastrophic events that have affected coastal ecosystems over times. Recent and ongoing research conducted in the Lesser Antilles is presented to document this issue and put into a broader perspective the expected changes for the near future. In Guadeloupe, peat sediments over 10 meters depth have accumulated at an average rate of 1 mm/year during the last 3000 years, with no significant variation of the coastline. However, recent data indicate that before 4000 years B.P. faster sea-level rise (≥ 1,5 mm/year) may have cause dramatic coastline retreat. In the meantime, periodic climatic changes (dryer/wetter) have caused functional and structural changes whereas human activities inside these wetlands contributed to reduce forested areas (especially swamp forests) and, comparatively, promote herbaceous vegetation. Current trends in sea-level rise indicate that compensatory threshold of soil-level rise is being exceeded; as a result, landward intrusion of saltwater wedge is expected to occur farther and more frequently, especially under a forecasted dryer climate. Conversely, endangered freshwater ecosystems like the Pterocarpus swamp forest could be at risk of extinction because of the limited possibilities of upward migration, due to land use and inland steep topography.

P-2210-01

Short- and long-term impacts on coastal power plants under sea level rise

R. Bierkandt (1) ; M. Auffhammer (2) ; A. Levermann (1) ; B. Marzeion, (3)
(1) Potsdam Institute for Climate Impact Research, Research domain sustainable solutions, Potsdam, Germany; (2) University of California, Berkeley CA, United States of America; (3) University of Innsbruck, Institute for geophysics and meteorology, Innsbruck, Austria

Unmitigated greenhouse gas emissions may increase global mean sea-level by up to 1m during this century. Such elevation of the mean sea-level enhances the risk of flooding of coastal areas. Assuming, that existing power plants are protected against a 100-year flood risk, we compute the additional risk of flooding by the end of the century for different US states, if no adaptation measures are taken. The additionally exposed capacity varies strongly between states. For Delaware it is 80% of the currently generated power. For New York this number becomes 63% and for Florida 43%. The capacity that needs additional protection compared to today's status increases by more than 250% for Texas, 90% for Florida and 70% for New York. Current development in power plant building points towards a reduced future exposure to sea-level rise: Currently operating power plants are less exposed than those who have been retired or canceled and currently planned plants will be less exposed than those operating at present. If sea-level rise is properly accounted for in future planning, an adaptation to sea-level rise appears to be possible.

A complete melting of the Antarctic ice-sheets leads to a long-term sea-level rise by up to 65 meters over a time period of several thousand years depending on the amount of carbon emissions within the next decades to centuries. Decommissioned nuclear reactors that will be entombed but not dismantled may represent a long-term risk under sea-level rise. Since potential unstable socio-economic situations or other circumstances may prevent premediated dismantling intentions, it is necessary to know which sites will be affected by future sea-level rise. We computed the available dismantling-time for all nuclear reactors in the world. Operating, planned and nuclear units under permanent shutdown were considered. Our results show that, for example, for a 5120 Gt CO2 emission scenario more than 50% of all nuclear reactors in the world are exposed to sea-level rise within the next 5000 years. Of those exposed, 90% already within the next 2000 years.

P-2210-02

Climate change impacts on mangrove ecosystem

F. Fromard (1) ; A. Gardel (2) ; C. Proisy (3) ; E. Anthony (4)
(1) University of Toulouse-CNRS, Laboratory of functional ecology and environment (ecolab), Toulouse, France; (2) CNRS, Cayenne, France; (3) IRD, Amap, Montpellier, France; (4) University, Cerege, Aix-en-Provence, France

Mangrove forests are a major ecosystem of tropical coasts that support a wide range of ecosystem services, including protection against coastal erosion, a significant carbon storage capacity, nursery sites for marine species, and retention of terrigenous pollutants. Over the last few decade, mangroves have, however, been significantly decimated by direct human activities with the development of shrimp farming, urban expansion and agricultural practices.

Mangroves are also particularly sensitive to climate change, with different impacts on ecosystem structuring, functioning and dynamics. Sea level rise could promote landward mangrove migration, while high levels of atmospheric CO2 could enhance mangrove tree growth. A lower frequency of extreme low temperatures should facilitate a poleward expansion of mangroves, whereas extreme events such as cyclones and tsunamis should lead to mangrove retreat or demise. These processes are recognized variably worldwide. In particular, climate change impacts associated with direct, growing anthropogenic disturbances should drastically alter mangrove ecosystem services.

In this presentation, specific impacts and adaptive strategies of mangroves in the face of climate change will be addressed, with a specific emphasis on the mangroves of the French tropical overseas territories, and in the framework of the CNRS/IRD's 2015 Year of the Mangrove initiative.

P-2210-03

Islets of New-Caledonia lagoons in the perspective of Climate change and sea level rise

M. Garcin (1) ; M. Vendé-Leclerc (2) ; B. Robineau (2) ; P. Maurizot (2) ; G. Le Cozannet (3) ; A. Nicolae-Lerma (1)
(1) BRGM, DRP/R3C, Orléans, France; (2) DIMENC, Sgnc, Nouméa, New Caledonia; (3) BRGM / CNRS, BRGM-DRP-R3C / CNRS-LGP (UMR-8591), Orleans, France

Context and problematic: On July 7th 2008, UNESCO included parts of Lagoons of New Caledonia in the list of the Reef Diversity and Associated Ecosystems. Sandy islets from New Caledonian lagoons lie on lagoonal reef platforms or on the reef barrier.They have a major role in these specific and rich ecosystems, being the seat of nesting for turtles, seabirds, sea kraits etc. In addition, islets have a high importance in the Caledonian culture and way of life; economy of the islands has been developed around tourism and services with specific activities such as sports and relaxation. One of the recurrent issues for people and governmental agencies concerns the islets's future in the perspective of Climate Change and Sea Level Rise. In this context, the Coastal Observatory of New Caledonia (OBLIC) has initiated research about the recent and present evolution of islets in order to predict their "behavior".

Method: Around twenty islets from the southwestern and eastern lagoons of Grande-Terre (New Caledonia main island) and one from Nokanhui atoll (Ile des Pins) have been studied. Such studies integrate field work and observations (erosion scars, accretion area, sedimentology, etc.) and analysis of historical photographs and satellites images. Geomorphological and sedimentological data have been collected during 2013 and 2014 field surveys. Past extensions of each islet have been interpreted using available aerial views and satellite sensing. Old aerial photographs are rather rare because islets being sometimes quite away from the shore, they were not covered by aerial survey of the main island. All available data have been integrated in a GIS. Thus, islets's reconstitution extends from one decade to 70 years. Time evolutions of shape and surface of each islet have been mapped in order to compute surface changes and the present percentage of coast's lengths in erosion, in accretion or stable. Moreover, the forcing factors such as winds, wave, tropical storms or cyclone, and the ENSO have been analyzed, in order to understand potential links with the islet behavior.

Results: In terms of size and shape, a high diversity and a variety of evolution trends of islets during the past decades can be noticed. Actually, processes affecting the coast of each islet (erosion, accretion, stability) are highly variable. All islets have at least 50% of their coasts affected by erosion and for four this rate is close to 100%. Islets showing increasing surface during the past years are very rare. Analysis and observations show that five main stages constitute the life-cycle of Caledonian islets, namely: nucleation, growing, maturity, decay, relic or endangered. Changes of environmental parameters and forcing factors as well as the inherited geomorphology lead the islets from one stage to another. The becoming of each islet is linked to its past evolution, its present state and future evolution of environmental parameters. Parameters are linked to the climate variability like ENSO or IPO which control the intensity and direction of trade winds and the average sea level in the SW Pacific. Forcing factors include also extreme events like cyclones, storms and austral swells which can trigger at very short term powerful erosion or accretion with high impact on the islet. Sea level rise induced by the anthropogenic climate change has also to be taken into account. Using our data and informations and postulating that the current situation remains identical, we consider that : 19% of the islets are in a critical state with a very likely disappearance in the next future (few years); 10% of the islets are in a critical situation with a likely disappearance in the next future

and very likely disappearance in the middle term (next decades); 19% of the islets show a rapid evolution which can lead to their disappearance in the middle term but not in the next future; 10% of the islets are not endangered at short and middle time scale and 43% of the islets are not endangered at all (stable or accreting, large surface, relatively high altitude). Our results show that situations are contrasted from one islet to another. We have also to emphasize that uncertainties are higher for middle and long term future due to uncertainties about the sea level. Uncertainties are also linked to the potential reaching of a thresholds value (value and rates) which would lead to a modification of the resilience capacity of each islet. Thus, a coastal observatory will be of first importance in monitoring the impact of climate change and sea level rise on such systems.

P-2210-04

Sea-level rise impact on European shelf tide dynamics

D. Idier (1) ; F. Paris (1) ; G. Le Cozannet (2) ; F. Boulahya (1)
(1) BRGM, Orléans, France; (2) BRGM / CNRS, BRGM-DRP-R3C / CNRS-LGP (UMR-8591), Orleans, France

Sea-level rise (SLR) affects not only the total water level, but can also modify the tidal dynamics. Several studies investigated the SLR effect on the tide of the Western European continental shelf, analysing the tidal dynamics (mainly the M2 component) for various SLR scenarios or coastal defence schemes.

The present study aims at completing existing knowledge, using a modelling based approach, investigating 11 uniform SLR scenarios from -0.25 to +10m, and analysing the effect on high/low tide water level as well as the amplitude and phase tidal components. Sea-level rise scenarios include the present sea-level, as well as several idealized scenarios that correspond to plausible sea-levels for more or less distant past or future. On the one hand, the -0.25m scenario can be considered as a low bound for the preindustrial sea-level. On the other hand, positive SLR scenarios correspond to more or less plausible sea-levels in the future: according to IPCC, a rise of sea-level of +25cm is likely by 2046-2065 whatever the climate change scenario, and the likely range for high emissions scenarios reaches 0.5 to 1m by 2100. While higher SLR scenarios are not excluded by 2100, sea-level will continue to rise beyond 2100, and it is likely to reach values of several meters by 2200 and beyond. Finally, the +10m SLR scenario corresponds to a situation where most Greenland and west-Antarctic ice-sheets have melted.

Assuming that coastal defences along the present day shoreline are maintained and upgraded, the patterns of increase / decrease of high tide level (annual maximum water level) are almost stationary in most of the area (70%), with an increase in most of the domain and a decrease mainly in the Western English Channel. These changes are globally varying linearly with the SLR, till the +2m SLR scenario, with rate ranging between -15% and +15% of SLR. The main patterns are: (1) a decrease in the Western English Channel, (2) an increase in the Irish Sea, Southern North Sea and German Bight. The analysis of tidal component contributions shows that high tide level changes patterns are not exactly similar to M2 pattern changes (e.g. along the French Atlantic coast, high tide level increases whereas M2 amplitude decreases). This highlights the need to take into account all the components when analysing SLR effect on the tide. The main changes in the maximum water level result from the changes of the M2, S2, N2, M4 and MS4 components. Sea-level rise pushes several areas (e.g. Atlantic coast, Irish Sea) closer to resonance, leading to the increase of the resonant tidal components (especially semi-diurnal or quart-diurnal, depending on the area).

The linear behaviour of tide dynamics with the SLR is highly sensitive to the coastal defence strategy (i.e. let flood or not), the high tide level varying much less linearly with SLR when flooding is allowed, like for instance in the German Bight. However, several areas appear not sensitive to this choice, such that the estimated trends there are highly probable: an increase of ~6% SLR (resp. decrease of ~15% SLR) in the North of Irish Sea (resp. in the Western English Channel).

Finally, preliminary investigations show that, at least, for the non-uniform SLR scenario we computed, the high water level is very weakly sensitive to the (non)-uniformity, local rates of increase/decrease (relative to local SLR) being similar to the ones obtained from uniform SLR scenarios.

P-2210-05

Vulnerability of Coastal Crop Land to Climate Change in the Northern Part of Bay of Bengal: Issues, Challenges and Future Prospects

AHM. Kamal (1) ; MH. Nesarul (2)
(1) Universiti Putra Malaysia Bintulu Sarawak Campus, Animal Science and Fishery, Bintulu, Sarawak, Malaysia; (2) University of Chittagong, Institute of marine sciences and fisheries, Chittagong, Bangladesh

The coastal communities of northeastern part of Bay of Bengal are used to live and survive through facing different types of natural disasters since primitive time. Among the natural disasters, salinity intrusion due to climate change and sea level rise in the coastal agriculture land is the major unpleasant incident now days. Because of that wide area of the coastal agricultural land, coastal forest, drinking water facilities and fresh water availability are in critical condition which may cause 40 million people of 147 coastal districts covering 47201 km area are placed in danger. The nation wide assessment on the detected of coastal soil and water salinity is not conducted since 9 years. The survey on the coastal soil salinity on 1973 and 2000 found that the saline effected land is increased from 0.83 million ha to 1.20 million ha within 27 years. It is assumed that at present the rate of salinity intrusion in the coastal agriculture land will be higher than those of 1973 and 2000. The soil salinity was recorded 18-20 ppt after AILA in the south-eastern coast of Bangladesh and increased further 2-4 ppt due to low precipitation which causes crop burning. This paper aims to know the salinity intrusion in the coastal soil and water of Bangladesh, which would help to plan and improvement of the sustainable agriculture production. Study revealed that to face any extra stresses on the coastal agriculture land due to climate change requires extensive inventory, awareness activities, mitigation measures, adaptation techniques and extension of indigenous technology.

P-2210-06

Impact of climate change on estuarine ecogeomorphology, and application to the Loire estuary

P. Le Hir (1) ; R. Walther (2) ; F. Cayocca (1) ; J. Sawtschuk (3) ; F. Bioret (3) ; P. Bona (4)
(1) IFREMER, Dynamiques de l'Environnement Côtier (ODE/DYNECO), PLOUZANE, France; (2) ARTELIA, Grenoble, France; (3) Université de Bretagne Occidentale, Institut de géoarchitecture, Brest, France; (4) GIP Loire Estuaire, Nantes, France

Besides temperature increase, the main expressions of climate change in estuarine environments are sea level rise and possible change in storm regimes downstream, variations of river flow and solid fluxes upstream. For instance, in northern Europe, lengthening of the low river discharge duration is often predicted, leading to salinity intrusion and upwards shift of turbidity maximum in estuaries, with possible effects on water quality.

Previous modelling work on the Loire and the Seine estuaries (France) suggested that sea level rise (SLR) would only induce a moderate upstream shift of saline waters and turbidity maximum. These computations assumed no morphological coupling. However, expected changes in erosion/deposition patterns due to modified forcing conditions are likely to modify the estuarine morphology. These morphological processes have the same time scale as climate change, so that SLR consequences are likely to depend on the rate of climate change. Supported by the French Ministry of Environment (project GICC/C3E2), the present study aims to answer these questions, with a focus on the impact on tidal marshes frequently located on estuarine banks. Because these areas have the same elevation as spring tide high water, they are occasionally flooded and even a slight SLR is likely to dramatically alter their inundation frequency. A main question is to know whether the marsh elevation is likely to increase at the same rate as the sea level, or flooding will become more frequent.

Two models have been developed to address these

questions. A first one accounts for morphological coupling and deals with schematized and simplified morphologies. The study aims at classifying the estuarine systems response to climate change according to various types of hydrodynamic forcing (tidal amplitude, river flow), bed sediment nature and sediment inputs, and morphological configurations. The model is fully process-based, with a sediment module that accounts for sand and mud behaviour. Long term simulations (typically 100-200 years) are achieved thanks to the use of a morphological factor.

A second model is a similar process-based model with muddy mobile sediment, applied to the Loire estuary. The computation grid is refined in intertidal areas, allowing accurate simulation of specific hydrodynamics in a realistic and complex network of creeks and vegetated areas. This model is used to predict sediment deposition on lateral marshes, and its variation according to the location of the turbidity maximum which is related to the river flow. The model has been validated against field measurements, in terms of inundation heights, flow structure and intensity, suspended sediment concentration and sedimentation rate.

Tests on schematic geometries show that (1) SLR increases the tidal oscillating volume and consequently the hydraulic energy within the estuary, which results in channel widening or the development of creeks in elevated marshes; and (2) a strong dependence on the upstream sediment input : high sediment fluxes increase the sedimentation on the intertidal flats, while these flats are likely to be eroded in case of sediment deficit.

In cases of reasonable sediment input, a 1 cm/year SLR is never compensated by sedimentation, and flooding rate increases. When the SLR stops, lateral sedimentation is likely to continue, inducing a following reduction in the inundation rate. All these features are strongly dependent on the initial configuration, in particular the cross profile of the alluvial plain which allows or not any lateral extension of the flood. Surprisingly, vegetation on marshes does not seem to impact these processes much.

Simulations on the Loire estuary were run for the coming 30 years, and based on a 34cm SLR and longer low river regime duration, as predicted by hydrological regional models (project ICC Hydroqual). Results show that the turbidity maximum would slightly increase (despite a reduction of upstream sediment input) and would shift 5 km upstream, like salinity intrusion. Only a small fraction (5-10%) of the mobile sediment stock would supply lateral sedimentation, not enough to compensate SLR. Based on recent observations and comparison with 30 years old data, the potential effect on vegetation was assessed : upstream shift of halophytes and development of helophytes on marshes.

P-2210-07

Coastal erosion and Shoreline Changes assessment in different climatic periods in Kalpitiya Peninsula, Sri Lanka

RU. Piyadasa (1) ; MA. Samanmali (2) ; W. Deepthi (3)
(1) University of Colombo Sri Lanka, Geography Department, Colombo, Sri Lanka; (2) Colombo University, Department of geography, Colombo, Sri Lanka; (3) Colombo University, Zoology department, Colombo, Sri Lanka

Sri Lanka is an island located in Indian Ocean with a total coastline of length approximately 1600km. Western part of Sri Lankan coastal zones are facing shoreline retreat problems, losing territory due to monsoon wind sea actions, negative sediment transport balances and climate change phenomena. To deal with this problem, efficient tools are necessary to help decision-makers choose the right procedures to follow. These tools should assess, estimate and project scenarios of coastal evolution in a medium-to-long-term perspective. To perform reliable projections, as many variables as possible should be analyzed, and the impact of each of these variables on the shoreline evolution should be understood. The study has been conducted to evaluate and identify the Shoreline changes during the past 15 years in Kalpitiya peninsula. Both Remote Sensing and Image processing techniques were used to extract Shoreline. Shoreline vector data method was used in Digital Shoreline Analysis System (DSAS) of ArcGIS10.1 to estimate the change in shoreline (positive or negative). R 2.14.0 was used to calculate relationship between time and sand deposition/erosion in Kalpitiya Peninsula. In this ongoing study, temporally shoreline changes of Kalpitiya peninsula to be investigate on ArcGIS 10.1 with DSAS tool. It was find out maximum and minimum Shoreline Change rete as well as Shoreline erosion rete in Kalpitiya Area. The Multiple R-squared of time and Shoreline change distance was recorded positive relationship such as 0.97, at the confidence level of 0.05. These results shows North Western part coast area in Sri Lanka. The study defined a methodology for classification of risk areas in Kalpitiya coast, considering the uncertainty associated with erosion and wave climate sequences. The study help to identify and prepare different risk maps according to considered climate change effects were obtained, defining areas of high, medium and low risk of territory loss due to erosion.

P-2210-08

Urban Landscape Remodeling for Climate Resilient Neighborhoods in Coastal Mega-cities of India Using Integral Geographic Information System: A Participatory Urban Climate Change Risk Reduction Framework for Greater Mumbai Metropolitan

A. Tiwari (1)
(1) National Institute Of Technology, NITB, India

Indian coastal metropolitans represent the most densely populated and highly congested urban areas and rank among some the largest urban settlements of the planet in terms of population. However these mega-cities are characterized by inadequate infrastructure, lack of civic amenities and constraints of access undermining carrying capacity and resilience of urban ecosystems. Climate change has increased vulnerability of large population, particularly poor and marginalized, living in rapidly growing coastal mega-cities to increased frequency, severity and intensity of extreme weather events, particularly high intensity rainfall, floods and cyclone. Moreover, long-term impact of climate change is expected to result in uncertainty pertaining to energy consumption, and thereby reducing efficiency of urban energy systems and pushing carbon footprint further. Furthermore, temperature extremes are likely to adversely affect the accessibility to green and open spaces, and community services, particularly water, sanitation, health, public transport, markets and community centers posing serious threat to live-ability and resilient lifestyles. These changes are offsetting the interconnected network of urban infrastructure and services in sprawling coastal cities. Study aims at evolving participatory climate resilient urban neighborhoods through urban-surface 'remodeling' approach in 'Integral Geographic Information System' (GIS) environment for coastal megacities with the illustration of Mumbai.

The paper uses terrain analysis tools in integral geographical information system platform to identify and map the climate susceptible urban fabric and check its scope for urban landscape remodeling without adding to its (often) complex fragmentation. Harmonizing with people's perception and adaptation knowledge, and incorporating options and priorities of city administration and other stakeholders, the urban surface remodeling through integral GIS ensures inclusive solutions with reduced vulnerability and increased resilience. The application of integral GIS resolves conflicting perspectives, interests, and approaches of the multiplicity of stakeholders involved at various levels in climate smart urban planning. It ensures barrier-free climate communication process for decision making while looking for long term feasible outcome of remodeled surfaces. Surfaces available for remodeling include paved ground, streetscapes, commercial facades, rooftops, open areas, public spaces as well as dark corners (such as under flyovers). Remodeling alters certain characteristics in the intrinsic or extrinsic cross-section profile or in both (if suitable) with blue and green infrastructure measures that collectively involve ecosystem services for greater hydrological connection. The method fairly reduces exposure of vulnerable surface and minimizes risk to achieve an extremity-neutral state, forming the key to urban resilience.

The outcomes of this paper included measures for prevention of choking of drainage system during high intensity rainfall, therefore minimizing the risk from extreme weather events. Remodeling looked for efficient

heat transfer without contribution to urban heat island during upper extremes of temperature. The blue and green infrastructure measures enhanced natural services namely: temperature regulation and maintenance of humidity, which are otherwise lost during climate-extremes, through cooling via evapo-transpiration. Experience gained through study is likely to help individuals, stakeholders, and organizations involved in the process of urban climate change adaptation governance in coastal megacities all across the developing countries.

P-2210-09

Control of mangrove abundance by decadal changes in oceanic wave fields

R. Walcker (1)
(1) Université Paul Sabatier - CNRS, Umr 5245 ecolab, Toulouse, France

The ocean surface is crossed by fields of wind-generated waves. These can travel over basin-wide distances and drive a large portion of coastal sediment transport when they reach continent margins. The variability of wave fields is thus of crucial importance to understand observed natural changes of coastal areas such as tidal wetlands. However, to date, no studies have tackled this issue at regional scale and over the course of several decades. Here, we provide a 64-year analysis of coastal changes on the open-coast mangrove shoreline situated downdrift of the mouth of the Amazon River. We show that over 1950-2014, changes in North tropical Atlantic wave heights have primarily affected sediment dynamics leading to important natural variations observed in mangrove surface area. We show that mangroves mostly respond to low frequency fluctuations of wave fields mainly associated with the decadal variability of the wintertime North Atlantic Oscillation. Our results emphasize the need for a better understanding and quantification of the role of natural climate variability on coastal dynamics. This can be crucial in anticipating the near future evolution of tidal wetlands and their Carbon stock in the context of anthropogenically climate change.

2211 - Climate change in mountains: from impacts to resilience

ORAL PRESENTATIONS

K-2211-01

Impacts on society and economy of a changing climate and climate-generated hazards on mountain water resources

M. Beniston (1) ; C. Tucker (2) ; G. Grandjean (3)
(1) University of Geneva, Institute for Environmental Sciences, CAROUGE / GENEVA, Switzerland; (2) Indiana University, Anthropology, Bloomington, IN, United States of America; (3) BRGM, Risk and Prevention, Orleans, France

Mountains represent significant features covering nearly one-quarter of the world's terrestrial surface. Mountains support a range of socioeconomic sectors (e.g., tourism, forest production, ecosystem resources) that have experienced considerable change in the last two centuries, resulting from pressures on natural resources and traditions imposed by increasingly-industrialized societies. Development trajectories of these high-value environments vary considerably across the globe, but certain mountain regions have been extensively transformed, converting them from inaccessible and relatively poor hinterlands into attractive destinations for the wealthy, sometimes excluding longtime inhabitants from economic benefits. In certain cases, outmigration and an aging population have led to economic declines in agro-pastoral and forestry production. Across the world, such transformative processes in mountain social-ecological systems have been accompanied by profound social, institutional, and environmental changes. As a major supplier of resources, mountains collectively represent in particular the source region for more than 60% of surface waters. A significant fraction of world's population in lowland regions depends on mountain water resources for agriculture, industry, energy, and domestic water supply.

Rapid climate change occurring in mountains carries broad implications, given that such regions have long been a source of valued ecosystem services and natural resources. For example, future shifts in temperature and precipitation patterns, and changes in the behavior of snow and ice in many mountains may ultimately change the quantity, seasonality, and possibly also the quality of water originating in mountains and uplands. Natural processes controlled by hydro-meteorological triggers (e.g. floods, landslides, debris-flows, earthflows and rockfalls, glacier melt, river erosion) will in a future climate add further environmental pressures on both social and natural systems, thereby highlighting the need to promptly conduct proactive adaptation plans.

The challenge for both mountain societies and those located downstream but dependent on mountain water resources in particular is thus to estimate as accurately as possible future changes in water availability. This will help to prepare the way for appropriate adaptation strategies and improved water governance. Enhanced awareness and appropriate policies aimed at alleviating the more adverse climate impacts would help indigenous populations to better adapt to rapid change, and for water-dependent economic sectors to pursue their activities with lower risks of economic rivalries or conflicts.

Challenges and Possibilities for Sustainability in Mountain Social-Ecological Systems: Results from a Global Analysis

J. Klein (1) ; A. Nolin (2) ; C. Tucker (3) ; K. Hopping, (1) ; A. Grêt-Regamey (4) ; S. Lavorel (5) ; B. Müller (6) ; P. Bourgeron, (7) ; V. Bustic (8) ; E. Castellanos (9)
(1) Colorado State University, Fort Collins, United States of America; (2) Oregon State University, College of Earth, Ocean, and Atmospheric Sciences, Corvallis, OR, United States of America; (3) Indiana University, Anthropology, Bloomington, IN, United States of America; (4) ETH, Zurich, Switzerland; (5) CNRS, Laboratoire d'Ecologie Alpine, Grenoble, France; (6) Helmholtz-Zentrum für Umweltforschung GmbH - UFZ, Leipzig, Germany; (7) University of Colorado, Boulder, United States of America; (8) University of California, Berkely, United States of America; (9) Universidad del Valle de Guatemala, Centro de Estudios Ambientales y de Biodiversidad, Guatemala, Guatemala

Mountain regions provide critical hydrological and diverse ecosystem services to over half the planet's human population, most of whom live in the lowlands. At the same time, mountain systems face mounting pressures from climate, policy and economic change. Based on 48 mountain case studies from around the world, we describe the suite of characteristics and incongruities that create particular challenges for mountain sustainability, and also present a conceptual model of mountain social-ecological systems (MtSES) that highlights the broad processes driving mountain system dynamics and their ecosystem services from local to global scales. We focus our analyses across all of the mountain case studies, between subsistence and non-subsistence based mountain regions, and among land use groups that are dominated by tourism, pastoralism and crop agriculture. We then explore the use of coupled models explaining social behavior, policy and management, and economics with models simulating biophysical processes as a potential tool for identifying sustainable trajectories in mountains, particularly when used within a transdisciplinary framework. We present an analysis of existing coupled social-ecological models in mountains and examine how these models are currently employed to address critical mountain sustainability issues.

Our analyses reveal patterns in mountain characteristics, livelihood strategies and associated challenges for sustainability. Mountains are geographically and culturally complex systems that deliver ecosystem services from local to global scales and are prone to hazards and extreme events. Particularly among the subsistence-based sites, mountains continue to be physically remote and distant from centers of power and decision-making. These

features, combined with high representation of indigenous peoples and cultures, result in social, economic and political isolation and marginalization. Stemming from the dynamic and non-linear interactions of the mountain characteristics are mountain-specific problems that are multidimensional, often lacking clear definition and optimal solutions, so-called "wicked problems", which we identify as incongruities. The most ubiquitous incongruity across all of our mountain case studies is that 'policies affecting mountain systems are made by outsiders', a phenomenon that results in perverse policies and present barriers to climate change coping mechanisms and adaptations.

Climate change, extreme weather events, markets, policy, and land use change are key drivers across all case study sites, while phenomena such as land tenure change, resource extraction, and land cover change are more important within subsistence-based mountain sites. We explore the primary scales at which these drivers occur and how they interact with mountain land use and livelihood groups, and with the delivery of mountain ecosystem services across scales.

Based on our analysis of social-ecological modeling studies in mountains, we suggest that a coupled model involving multiple levels of participation, such as local resource users and policymakers, could be a powerful tool for engaging stakeholders and decision-makers about future trajectories of MtSES. We also conclude that while modeling efforts are currently focused on system understanding and prediction, there is great potential to also employ models that foster social learning and communication.

We conclude by identifying knowledge gaps and challenges regarding mountain sustainability. For a next step, we propose to use transdisciplinary modeling approaches in mountains, including co-creation of knowledge, participatory approaches, and coordinated practices, all of which are essential for sound decision-making and building resilient futures.

O-2211-02

Facing climate change in the Peruvian Andes: implications of shifts in precipitation patterns, river discharge and the availability of water resources for local communities and options for adaptation

N. Andres (1) ; P. Calanca (2) ; N. Salzmann (3) ; V. Bustinza (4) ; C. Huggel (5) ; M. Rohrer (6) ; R. Neukom (5)

(1) Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Mountain Hydrology and Mass Movements, Birmensdorf, Switzerland; (2) Agroscope, Institute for Sustainability Sciences (ISS), Department of natural resources and agriculture, Zürich, Switzerland; (3) University of Fribourg, Department of Geosciences, Fribourg, Switzerland; (4) Programa de Adaptación al Cambio Climático-PACC, MINAM-COSUDE-Helvetas Swiss Intercooperation, Cusco, Peru; (5) University of Zürich, Department of geography, Zürich, Switzerland; (6) Meteodat GmbH, Zürich, Switzerland

Communities in the high Andes are considered among the most vulnerable to climate change for various reasons. For instance, they rely on an agriculture that is largely practiced at a subsistence level and exposed to droughts, frosts, late season warm spells, pests and diseases. Also human settlements are often endangered by floods and landslides, which have not only been the cause of damages to buildings and infrastructure but also responsible for numerous casualties in the recent past. In view of a possible decrease in seasonal precipitation amounts but a more frequent occurrence of intense rainfall events, this situation is likely to worsen in the future as a consequence of climate change. This calls for cross- and interdisciplinary programmes that can help improving the resilience of Andean communities.

In response to this call, the Peruvian Ministry of the Environment, in collaboration with the Swiss Agency for Development and Cooperation (SDC) under the Global Programme Climate Change (GPCC), initiated in 2009 the "Programa de Adaptación al Cambio Climático en el Perú" (PACC), a programme that is now in its second phase. Involving practitioners and scientists from various disciplines, the specific goal is to build awareness, improve preparedness, and support and promote the process of adaptation. Its implementation includes the scientific assessment of climate impacts, vulnerabilities and risks, and the practical evaluation of adaptation options. This can be considered as a minimum framework to move from impacts to resilience.

With a focus on the implications of seasonal shifts in the precipitation regime for water availability and river discharge, in this contribution we present a few examples that illustrate the two steps involved in the implementation process. We first report on a modelling study of the impacts of climate change on the water resources in the Vilcanota river basin. The results indicate an increase in river runoff during the rainy season, but an overall decrease in water storage. The former is expected to lead to higher flood peaks, whereas the latter is expected to entail water shortage, in particular during the dry season. This is of concern because communities have already to face loss of glacier ice in the Cordillera Vilcanota, a process that is already changing the seasonality of water availability.

The second example is drawn from studies aiming at assessing the potential impacts of changes in temperature and precipitation on rainfed annual crops in the Central Andes of Peru. While in the near future not all crops would suffer from the projected decrease in water availability, it is shown that adaptation of the agricultural practices are necessary in the mid and long term to sustain production and improve the livelihood of the local population. Suggested adaptation measures include the adjustment of cropping calendars, the introduction of more robust crop varieties and alternative cropping systems and reconsideration of land use.

The third example shows how the rediscovery of low-cost, traditional technologies can contribute to improve the resilience of rural communities facing a decreasing availability of water resources. Specifically, we report on the outcomes of an effort to promote rustic micro-reservoirs called qochas. These were already used in ancient Peru but had largely fallen in disuse until recently. As a test, about 150 qochas were built between 2012 and 2013 in two small watersheds of the Peruvian Altiplano with the help of farmers and their families. Benefits from their establishment have included the recovery of downstream springs, the recovery of vegetation in the surroundings of the reservoirs and an overall easier access to water during the dry season.

O-2211-03

Impact analysis of Climate Change on Glacier and Water Potentiality in High Altitude Region of Western Himalaya

BW. Pandey (1)

(1) University of Delhi, Department of Geography, Delhi, India

Present research aims to investigate the issues concerning ecohydrology and potentiality of water in high mountain areas of Western Himalaya. Hindukush-Himalaya (HKH) region are the source of perennial rivers of South and East Asia which feed almost half of the world population. For the climate, people, economy and ecology, Hindukush-Himalaya region are known as "Human Equator" as drinking water for humans and animals; water for irrigation of food other agronomic practices; and, a very mountain-specific use: hydropower depend on water of the HKH Mountains. Increasing populations and economic transformations have exerted considerable pressure on land and water resources in Western Himalaya. Such changes have brought modifications in water flows, nutrients, sediments and pollutants as well as loss of biodiversity. Hence, the ecohydrological processes in headwater regions of western Himalaya, especially the role of natural processes, impact of human interference and climate change on the availability of water, highland-lowland interactive linkages, and sustainable use of water require attention for planning and conservation. Therefore, there is an urgent need for a better understanding of the vulnerability of the land-water system to human activities and climate change impacts in high mountain region of Western Himalaya.

O-2211-04

Past and future changes in seasonal snow in the French Alps : implications for water resources, mountain tourism and avalanche hazard

S. Morin (1) ; M. Déqué (2) ; H. Castebrunet (3) ; Y. Durand, (1) ; N. Eckert (4) ; H. François (5) ; E. George-Marcelpoil (5) ; G. Giraud (1) ; B. Hingray (6) ; M. Lafaysse (1) ; E. Martin (7) ; M. Rousselot (1) ; P. Spandre (1) ; D. Verfaillie (1)

(1) Météo-France – CNRS, CNRM-GAME/CEN, St Martin d'Heres, France; (2) Météo-France – CNRS, Cnrm-game, Toulouse, France; (3) INSA Lyon, Lgcie-deep, Villeurbanne, France; (4) Irstea, Etna, Grenoble, France; (5) Irstea, Dtm, Grenoble, France; (6) LTHE, Grenoble, France; (7) Météo France, Cnrm-game, Toulouse, France

Snow on the ground is a key environmental and socio-economic component of mountain regions. Storage of water in the form of snow during the winter period provides freshwater input to ecosystems, agriculture and human consumption. Natural hazards such as snow avalanches and snowmelt floods cause loss of lives and disruption of human activities. Snow plays a pivotal role for numerous socio-economic activities such as hydropower (electricity generation and industry) and winter tourism.

The French Alps have encountered significant changes of snow conditions over the past decades, which can be inferred at the massif scale using the dedicated meteorological analysis system SAFRAN feeding the detailed snowpack model Crocus. Superimposed over a large year-to-year variability, these changes are most pronounced in mid-altitude areas which are highly sensitive to the rain/snow partitioning of precipitation. Such an extensive reanalysis of meteorological and snow conditions has been further used to un-bias and downscale regional climate model projections spanning the XXIst century. The presentation will highlight key results at the scale of the entire French Alps obtained using CMIP3 projections and preliminary results using CMIP5/EUROCORDEX projections.

The interpretation of the numerical simulations spanning the observational era for the past decades and an ensemble of climate projections into the XXIst century not only addresses changes of snow conditions in terms of snow water equivalent, relevant for water resources, but also trends in the seasonality of discharge in selected catchments, avalanche hazard and resort-level snow viability. The latter is currently being developed accounting not only for meteorological drivers of snow on the ground but also socio-economic components of mountain tourism including snow management practices and the spatial organization of ski resorts. This approach seeks at contributing to an integrated representation of the impact of climate change in mountain areas thereby helping to quantitatively assess the resilience of these sensitive environmental and socio-economic systems.

O-2211-05

Challenges and needs for interdisciplinary studies on mountain water resources: curent issues and perspectives

JP. Dedieu (1) ; I. Zin (2) ; T. Condom (3) ; JE. Sicard (3) ; Y. Arnaud (3) ; A. Rabatel (4) ; D. Six (4) ; C. Obled (5)

(1) CNRS, LTHE, Grenoble, France; (2) Grenoble INP, Lthe, Grenoble, France; (3) IRD, Lthe, Grenoble, France; (4) UJF, Lgge, Grenoble, France; (5) Lthe, Grenoble, France

Hydro-meteorological observations coupled with snow and ice measurements are the basic material for a number of scientific and operational issues linked to socio-environmental needs. They are required for studies aiming at understanding and/or modeling climate-environment-society interactions along with their spatial and temporal variations. They constitute also the basic information for estimating hydrological resources and risks, real time operations or prospective studies for water management. The aim is to foresee adaptations strategies required by societies to face changes in resource and risks induced by ongoing global change. In mountainous areas, such observations are even more pronounced and variable than anywhere else, as hydro-meteorological events are more pronounced and variable than anywhere else. Major difficulties due to topographic constraints as elevation and slopes, added to strong local weather conditions, reduce the capabilities of long-term observation networks in regard of lowlands observing systems.

Supported by the Laboratory of Hydrology and Environment (LTHE) and the Laboratory of Glaciology and Environmental Geophysics (LGGE), Grenoble (France), we focus here on some "Hot-Spot" application areas which federate cross-disciplinary approaches over several thematic fields (hydrology, glaciology, natural hazards versus socio-ecological systems), linked to national Programs (ANR, local stakeholders) and long term Observatory Programs (e.g. Glacioclim, Great Ice/IRD). Specific examples of case studies will be presented: the Chamonix-Mont Blanc area in the Alps (Europe), the Koshi river basin in the Himalayas (Nepal), and the Zongo glacierized catchment in the Andes (Bolivia). The interest of such federative application areas is highlighted by various key hydrological issues, taken from the operational research or environmental monitoring domains. Measurement networks and observatories developed to meet the corresponding objectives are presented. Limits of observations, associated to the measurements themselves, spatial representativeness and temporal coverage are discussed. Some perspectives for improving current observations systems are finally suggested.

Mountains represent an important part of the global earth system. Because of their vertical extent, climate varies drastically with elevation and thus differs from those in adjacent lowland areas. Natural processes controlled by hydro-meteorological triggers (e.g. floods, landslides, rockfalls) will add further environmental pressures on both social and natural systems, stressing the need to promptly conduct proactive adaptation plans. The relevance of mountain hazard and risk zonation for environmental policy and decision making is set forth in the European Thematic Strategy for Soil Protection and the associated proposal of a Framework Directive, in which hydro-meteorological hazards are considered as one of the soil threats for which it is necessary to identify risk areas where risk reduction measures have to be implemented. However, to implement risk mitigation strategies in an integrated way (e.g. including physical but also economic and social adaptation), additional research is needed on how climate controls mountain hazards occurrence. The influence of climate and climate change on slope stability and floods over various spatial and temporal scales has to be better understood and quantified; studies are also needed on how the main economic, social and political stakeholders interact for the definition of adaptation scenarios at the region scale.

The SAMCO (Society Adaptation for coping with Mountain risks in a global change Context) project aims to develop a proactive resilience framework enhancing the overall resilience of societies on the impacts of mountain risks. The project aims to elaborate methodological tools to characterize and measure ecosystem and societal resilience from an operative perspective on three mountain representative case studies.

To achieve this objective, the methodology is split in several points with (1) the definition of the potential impacts of global environmental changes (climate system, ecosystem e.g. land use, socio-economic system) on landslide hazards, (2) the analysis of these consequences in terms of vulnerability (e.g. changes in the location and characteristics of the impacted areas and level of their perturbation) and (3) the implementation of a methodology for quantitatively investigating and mapping indicators of mountain slope vulnerability exposed to several hazard

types, and the development of a GIS-based demonstration platform.

The strength and originality of the SAMCO project is to combine different techniques, methodologies and models (multi-hazard assessment, risk evolution in time, vulnerability functional analysis, and governance strategies) and to gather various interdisciplinary expertises in earth sciences, environmental sciences, and social sciences.

The climate change inputs of the project correspond to at least 2 scenarios of emission of greenhouse gases. The used simulations available on the portal DRIAS (http://www.drias-climat.fr) were performed with the GHG emissions scenarios (RCP: Representative concentration pathways, according to the standards defined by the GIEC) RCP 2.8, RCP 4.5 and RCP 8.5 for the ALADIN-Climate model of Météo-France, and RCP 4.5 and RCP 8.5 for the WRF model used by the IPSL. The impact of climate change is then firstly addressed through the use of these climate scenarios into hazards computations. In that way, future changes in temperature and precipitation volume and patterns are analyzed, permitting to address the direct and indirect impacts of climatic change on mountain societies and their vulnerability to change.

Secondly, the climate change is also considered in global scenarios, with taking into account political actions at local and global scale that might influence the climate change as well as the land use planning in the areas of interest. It is then possible to identify the most important factors of community resilience (e.g. coping capacity) and their dependence upon controlling factors in order to propose risk management strategies adapted to possible impacts of global changes.

P-2211-02

Hazard Assessment of Glacial Lake Outburst Flood and Potential of ICTs for Coping: A Case of Eastern Himalaya of Nepal

DR. Bhattarai (1)
(1) Tribhuvan University, Central Department of Environmental Science, Kathmandu, Nepal

Retreat of glaciers and formation of glacial lakes in Nepal Himalaya have been reported to be related with the temperature rise in the region. Glacier Lake Outburst Floods (GLOF) are the growing climate induced hazards in the Himalaya. GLOF has increased the vulnerability of community and fragile ecosystem in the mountain valleys. This study has analyzed the potential impacts from GLOF in the highland of eastern Nepal and the potential role of Information Communication Technologies (ICT) to cope with such impacts. I analyzed the trend of climatic pattern (temperature and precipitation) of the Eastern Himalaya Region of Nepal available from the Department of Hydrology and Meteorology, Government of Nepal, and prepared the latest location map of the glacial lakes using google earth and ArcGIS applications in the highland of the Kanchanjungha Conservation Area of the region. Tiptala glacial lake, located at an elevation of 4950 m, within the conservation area, was selected for the GLOF hazard assessment. I used semi-structured questionnaire survey and key informants' interviews in the community in order to assess the potential hazard of GLOF. With the varying sizes, 46 glacial lakes were located in the region, which covers over 2.57 sq. km in total. Though the larger portion of the downstream area of the Tiptala glacial lake fall in the remote location away from major residential area, few villages, major pasture lands for Yaks, foot trails, and several bridges across the Tamor River below the lake are in risk of GLOF. Poor access due to extreme geographical remoteness and capacity to afford the modern technologies in the community are the major limiting factor to the knowledge and information about the climate change and related impacts. Modern ICTs has high potential to reduce the risk of climate related hazards in the remote area by information dissemination and awareness.

P-2211-03

On the impacts of global warming on the deep peri-alpine Lake Geneva

S. Goyette (1) ; M. Perroud (1)
(1) Institute for Environmental Sciences, University of Geneva, Carouge, Switzerland

Observations over the period 1880 to 2012 indicate that the globally-averaged surface temperature data has increased from 0.65°C to 1.06°C IPCC (2013). During the 20th century, European climate experienced a surface air temperature warming of 0.9°C, resulting in a wide range of impacts that followed the first signs of change. Global-mean surface temperature exhibits temporal and spatial variability. According to projections made for future climate, southern and central Europe would experience the largest changes in mean air temperature during summer while the northern regions would be more strongly affected during winter. Higher inland freshwater temperatures have been reported in response to warmer conditions. In many western European lakes climate warming has resulted in increased water column stability, longer stratified periods, and warmer temperatures in the epilimnion. These findings are in agreement with the observations for other middle- and high-latitude lakes. Jeppesen et al. (2012) analysed the impacts of climate warming on the long-term dynamics of key fish species in 24 European lakes and found the mean water temperature of Lake Geneva increased by 0.17°C per decade since 1986, and lake stratification occurs "apparently" one month earlier than it did 30 years ago. This has impacted the fishery, with conditions favouring warmer water species and a dramatic reduction in some others. While the impacts of changes in climate in the Alps have been reported by many authors, very few studies have attempted to relate future climate projections to their potential impacts on peri-alpine lakes. This enhances the need to lead investigations on a variety of lakes, grabbing the opportunity to develop new methods. In order to avoiding the computational load of complex models such as Global or Regional Climate Models, the use of a Single-Column atmospheric Model (SCM) coupled to a lake model provides a practical and economical framework for assessing the sensitivity of water temperature profiles to current and perturbed climatic conditions. Lake Geneva is a 89 km3 body of water shared by Switzerland and France, and greatly exceeds in size and depth all others that are connected with the main valleys of the Alps. Analyses reported by Anneville et al. (2013) from long-term observations and findings of research projects both led to the conclusion that climate change has already impacted Lake Geneva ecosystems and these are likely to continue when considering the predictions based on complex climate models. In a recent study on Lake Geneva by Perroud and Goyette (2012) using a SCM coupled to a lake model, it has been shown that increasing the atmospheric greenhouse gas concentration impacted the lake's thermal structure, increasing the stability of the water column and extending the stratified period by 3 weeks. Epilimnetic temperatures were seen to increase by 2.6°C to 4.2°C, while hypolimnion temperatures increased by 2.2°C. Climate change modified components of the surface energy budget through changes in air temperature, moisture, and cloud cover. A strong rate of change in the epilimnion temperature found in Spring, would lead to an earlier onset of thermocline formation and this may explain the advance in spawning as reported by Gillet and Quetin (2006). At the same time, changes in plankton population dynamics with an advance of the spring bloom can be expected and may affect the timing of the clear-water phase of the lake. Climate, freshwater, biophysical and socio-economic systems are interconnected in complex ways (IPCC, 2008). Freshwater-related issues are critical in determining regional and sectoral vulnerabilities, as aquatic ecosystems provide a wide range of goods and services. Therefore, the relationship between climate change and freshwater resources is of primary concern to human society and also has implications for all living species.

Projected changes on the surface water resources of the Rherhaya basin (High Atlas, Morocco) by a set of Med-CORDEX models

L. Hanich (1) ; Y. Tramblay (2) ; A. Marchane (3) ; L. Jarlan (4) ; D. Ruelland (2)

(1) Faculté des Sciences et Techniques/Université Cadi Ayyad, Sciences de la Terre, Marrakech, Morocco; (2) IRD – HydroSciences Montpellier, Montpellier, France; (3) Faculté des Sciences et Techniques/Université Cadi Ayyad, Sciences de la Terre, Marrakech,, Sciences de la terre, Marrakech, Morocco; (4) IRD – Centre d'Etudes Spatiales de la Biosphère, Toulouse, France

To anticipate the potential changes in water quantity available within the Rherhaya mountainous watershed (near to Marrakech), it's important to know the evolution of this resource in relation with climate changes. In this study we use the GR4J model with a snow module with time series of precipitations and discharge (1989 – 2009). The model was calibrated and validated successfully over various periods. Then we used an ensemble of 5 regional climate models (RCM) provided by the Med-CORDEX program with a method of perturbation by quantiles to simulate future scenarios of flow predictions.

The evaluation of the precipitations simulated by the RCMs models (RCM) shows a strong underestimation of ~50% but a good reproduction of the cycle for the temperatures. The future changes according to two scenarios RCP4.5 and RCP8.5 show a rise of the temperatures (+1.4°, +2.6° respectively) in conjunction with a decrease in total precipitation (-19%,- 31%). Concerning the hydrological modeling with GR4J, stable results are obtained for calibration and validation whatever the chosen period, with maximum bias of 15% in validation on the monthly flows. Flow forecasts (2049-2065) present a strong projected decrease in surface runoff (-30%, -60%) and significant drops of the snow-covered reservoir levels, related to the precipitation decrease and the temperature increase.

P-2211-05

Debris flow in the French Alps in changing climate

V. Jomelli (1) ; N. Eckert (2) ; I. Pavlova (3) ; D. Brunstein (4)

(1) Cnrs, Physical geography, Meudon, France; (2) Irstea, Etna, Grenoble, France; (3) Unesco, Paris, France; (4) CNRS, Geography, Meudon, France

In the Alps, debris flows are a major threat as they periodically damage infrastructure, may even cause loss of life. The triggering process is definitely sensitive to climate change due to an interaction between meteorological and geomorphological factors, such as extreme precipitation, the local topography or the accumulation of rock debris. Evaluating the link between climate and debris flow activity is the necessary pre-request to estimate the impacts of future climate change.

Here we analyze the evolution of debris flow occurrence in the French Alps over the last four decades using an innovative probabilistic model which makes it possible to analyse the main environmental and climatic drivers of debris flow occurrence simultaneously, so as to quantify their respective influence at a regional scale.

As a case study, we extract 124 debris flow events triggered between 1970 and 2005 in 27 catchments located in the French Alps from the French national natural hazard survey and model their variability of occurrence considering environmental and climatic predictors at the same time. We document the environmental characteristics of each debris flow catchment (morphometry, lithology, land cover, and the presence of permafrost). We also compute 15 climate variables including mean temperature and precipitation between May and October and the number of rainy days with daily cumulative rainfall greater than 10/15/20/25/30/40 mm day-1. Application of our model shows that the combination of environmental and climatic predictors explained 77% of the overall variability of debris flow occurrences in this data set. We also note that the occurrence probabilities depend mainly on climatic variables, which mostly explain the variability through the number of rainy days and maximum daily temperature. This important time component in the variability of overall debris flow occurrence is shown to be responsible for a significant increase in debris flow activity between 1970 and 2005 at regional scale. Environmental variables, which accounts for 1/3 of the overall variability, includes mostly the morphometric variables of the debris flow catchments.

Diurnal cycle processes associated with precipitation in central Andes (Peru)

C. Junquas (1) ; K. Takahashi (2) ; S. Chavez Jara (2) ; T. Condom (3) ; JC. Espinoza (2)

(1) Instituto geofisico del Peru, Lima, Peru; (2) Instituto geofisico del Peru, Lima, France; (3) IRD, Lthe, Grenoble, France

The identification of regional atmospheric processes is important to understand how the greenhouse gases increase in the atmosphere could affect the precipitation and the water resources at a regional scale.

The atmospheric processes in the tropical Andes climate are of particular interest because in this region, mechanisms are associated with the interplay of complex orography and convective processes characterizing the tropical climate. In the central Andes, physical processes associated with the humidity transport between the wet Amazon on the east and the dry Pacific on the west, and the spatio-temporal distribution of the precipitation are little understood.

The Andes cordillera is extended over almost all South America, that are 7000km between 45°S and 7°N. Its maximum width is 1800km in its central part. This configuration is unique in the planet, and consequently the glaciers in the tropical Andes represent 99% of the world tropical glaciers. These glaciers show a retreat since the PIA with an unprecedent acceleration since 70's. The risks generated by such glacier retreat are here in terms of hydrological resources, agriculture, hydro-electricity, and turism. Tropical glaciers mass balance is strongly depending of humidity and precipitation, so it is important to study localized associated atmospheric processes. The identification of high-resolution horizontal scale climate mechanisms (some km) in terms of diurnal cycle could particularly help to understand how the atmospheric circulation influence the glaciers mass balance at diurnal time-scales. The characterization of humidity fluxes and of the associated spatial distribution of the precipitation in central Andes, with in addition the understanding of localized atmospheric processes in terms of diurnal cycle variability are the main objectives of this study.

Due to a poor number of in-situ meteorological stations in the region of the central Andes, we consider that a dynamical downscaling using a regional climate model is the most adequate methodology to improve the understanding of localized orographic processes in this region. The WRF (Weather Research and Forecasting) model is used to simulate the climatological diurnal cycle of the wet season (austral summer) in the Cuzco region (central Andes), at a 9-km horizontal resolution and 3-hourly time resolution. The precipitation model outputs are compared with radar products of TRMM-2A25 and in-situ observations. Results show that the model is able to reproduce the main diurnal precipitation features with rainfall maximum in the western cordillera during the afternoon, and in the eastern part of the cordillera during the night. The model also simulates both mechanical and thermo-dynamical orographic processes. For example, while some valleys are mainly affected by the well-known diurnal thermal valley/mountain circulation, others are more influenced by the large-scale moisture flow. This difference seems to be linked with the width and the orientation of the different valleys.

The Himalayan Cryosphere and Highlanders' Adaptability: A Case Study of the Miyar Valley of Himachal Pradesh and North Sikkim in the Indian Himalaya

U. Lal (1)

(1) Sikkim University, Geography, Gangtok, Sikkim, India

Rugged topography coupled with high altitudinal areas between the Great Himalayan Range and the southern flank of the Tibetan Plateau presented a stage where the elements of Nature has been more pronounced than normally they are at other places. Thus, the history of the highlanders of the area has been basically the history of their direct response to the vacillation in the various elements of the climate. The highlanders of 3000 meters and above in both the Himalayan and Trans-Himalayan mountain-scape responded directly to such changes which basically lead to changes in the Cryosphere.

Wandering of the Highlanders across rugged valleys and jagged pastures and passes in and across the Himalaya for trans-ecological exchanges. Initially, it was more of an ecological compulsion for a tenable survival amid harsh environmental conditions of higher altitudinal regions than for fortune or better resources. Thus, leading to making of the neighbouring highland societies both collaborator and competitor at the sometime.

With the basic premise that like any other place on the planet; Himalayan landscape did registered episodes of cooling and warming resulting into both glacial maximum and glacial minimum periods. Thus, resulting into advancement and retreat of permanent snowline in the area. This paper is an attempt to study the human inhabitation response to the cryospheric fluctuations based on the field investigation from Miyar Valley of Himachal Himalaya and North Sikkim in Sikkim Himalaya lying in Western and Eastern Himalaya respectively. This paper also underscores that remote Himalayan valleys have been inhabited since quite an early time rather than being colonised in the recent past.

The study combines the moraine sampling and Optically Stimulated Luminescence (OSL) analysis with simple random sampling and Focus Group Discussion to comprehend and capture the rough period of legends of rise and fall of remote Himalayan Villages which seems to be following the pattern of glacial maximum and minimum periods.

Impact of the Nurek Mountain Water Reservoirs in Tajikistan on Meteorological Conditions and Agriculture of Coastal Area

I. Normatov (1)

(1) Institute of Water problems,Hydropower and Ecology, Meteorology and Climatology, Dushanbe, Tajikistan

The purpose of the present research is the retrospective comparative analysis of statistical parameters of 60-year temporary ranks of temperature, atmospheric precipitation and humidity and monitoring of influence of the Nurek reservoir on a trend of change of these parameters. For establishment of influence of mountain reservoirs on possible changes of agroclimatic conditions we analyzed a trend of meteorological parameters of two regions of Dangara and Yavan of the Republic of Tajikistan with the developed agricultural branch coastal to the Nurek reservoir. Dynamics of change of humidity of Yavan district demonstrated that humidity of this area had everything the reducing character up to 1980 and was characterized by moderate increase of precipitation. After 1980 sharp increase and humidity and an atmospheric precipitation is observed. Calculations indicate about reduction of an atmospheric precipitation of Yavan for the periods 1950-1979 on 4.7 mm at their increase for the period 1980-2011 to 443 mm that in comparison with 1979 makes about 30%. Change of temperature of Yavan for the period 1980-2011 equals 1.1 C against his increase on 0.97 C for the period 1950-1979. Consequently, existence of the developed network of meteorological stations in mountain districts is pledge of receiving a real scenario of dynamics of meteorological parameters. It should be noted that continuous monitoring of meteorological parameters of large water reservoirs is important from the point of view of development of agriculture. Timely establishment of variations of weather conditions and development of technology of adaptation to the modern meteorological conditions and selection of agricultural grades steady against changes of climatic factors and stressful situations pledge of ensuring food security.

P-2211-09

Creation of modern approach adaptation of water consuming branches to climate changes and degradation of glaciers

P. Normatov (1)

(1) Tajik National University, Meteorology and Climatology, Dushanbe, Tajikistan

One is actual problems of modernity is Global Climate Change and adequate behavior of the each component of ecosystems to this change. For the Tajikistan 93% territory, which do mountains and which characterized by availability more 8500 glaciers by the total area of 8476.2 km2 occupy, or about 6% of all territory of the Republic of Tajikistan is very important. There is a large unit of conglomeration in mountains of Northwest Pamir with the center of Fedchenko glacier - the largest mountain glacier in the world. By 1988, the glacier has receded more than on 500 m and has decreased on the area for four square kilometers. Average speed of step of Fedchenko glacier for the last century made 10-12 meters one year. Average speed of movement of glacier in connection with loss of weight has decreased with 72 up to 69 sm daily. In total for 20th century the glacier has lost about 12-15 km3 ice. For last 16 years (1990 - 2006 years) a glacier of the Zeravshan River Basin has receded on 35-55 m annually the average its speed has made about 3 m per year though in the eightieth years of the last century it has made about 8 m annually. The created situation and prospect of development of the given trend of reduction of glaciers stimulates search of modern methods in preservation and an effective utilization of water resources. In this plan, building of reservoirs for water accumulation and corresponding corrective amendments in planning of the water use in agriculture is actual.

P-2211-10

Historical and future changes in precipitation and snow in the Hindu-Kush Karakoram Himalaya region as seen by CMIP5 models

E. Palazzi (1) ; S. Terzago (1) ; J. Von Hardenberg (1) ; A. Provenzale, (2)

(1) Institute of Atmospheric Sciences and Climate (ISAC), National Research Council (CNR), Torino, Italy; (2) Institute of Geosciences and Earth Resources (IGG), National research council (cnr), Pisa, Italy

The Hindu-Kush Karakoram Himalaya (HKKH) mountains and the Tibetan plateau are the world's largest snow and ice reservoir outside the polar regions and they are often referred to as the "Third Pole". These mountains feed the most important Asian river systems, and changes in snow and precipitation dynamics in this area could severely impact on water availability for downstream populations, agriculture and energy production, ecosystems and biodiversity.

Despite their importance, precipitation and snowpack characteristics in the HKKH region are still poorly known, owing to the limited availability of surface observations in this remote and high elevation area. Global Climate Models (GCMs) still have too coarse spatial resolution to reproduce the small scale variability of precipitation and snow in orographically complex environments. Nevertheless, they may be effective in providing, even at a regional scale, a smooth but coherent picture of the large scale temporal and spatial patterns of these two variables in these areas. The quantification of the uncertainties in GCM simulations is essential to define the models skills in reproducing climate variability and to critically analyze future climate change projections.

We investigate how the spatial and temporal variability of precipitation and snowpack in the HKKH region is represented in historical and future simulations of the state-of-the-art GCMs participating in the CMIP5 effort, and we investigate the role of elevation-dependent surface warming. The model outputs in the historical period are compared with the main, currently available, observational datasets including surface- and satellite-based observations and reanalysis data.

P-2211-11

Implications of Depleting Himalayan Cryosphere under Changing Climate

S. Romshoo (1)
(1) University of Kashmir, Earth Sciences, Srinagar, India

Lidder tributary in the Upper Indus Basin (UIB) of the Alpine Himalayas, India, an important source of surface and ground water, is experiencing clear indications of climate change. In the basin, minimum, maximum and average temperatures are showing a significant increasing trend in all the four seasons. Precipitation is showing insignificant decrease over time in the basin, however the proportion of the snow in precipitation has decreased and the proportion of the rain has correspondingly increased. The temperature projections also show increasing trends for the end of this century. The time series analysis of the Normalized Difference Snow Index (NDSI) from MODIS satellite shows a depletion of the snow-cover in the region. Furthermore, during the last 51 years, the glacier area in the basin has decreased from 46.09 km2 in 1962 to 33.43 km2 in 2013, a depletion of 27.47%. As a result of the glacier recession in the basin, the streamflow fed predominantly by snow- and glacier-melt, is overall showing a statistically significant decline. However, the spring disharge is showing an increase, might be due to the early melting of the snow due to warmer springs. The declining streamflows have potential to adversely affect agriculture, energy production, tourism and even domestic water supplies. In the Kashmir Himalayas, one of the major concerns about the climate change relates to its impact on streamflows in the Indus basin, whose waters are shared between India and Pakistan under the Indus Water Treaty. Snow and ice reserves of the Himalayan river basins, important in sustaining seasonal water availability over South Asia, are likely to be substantially affected by climate change, but to what extent is yet unclear. Therefore, it is of utmost importance to develop strategies for the conservatizing of the depleting water resources in the region. Accordingly, Snowmelt Runoff Model (SRM) was tested for estimating the runoff from this glaciated basin on an operational basis. The average simulated runoff at the outlet 11.94 m3/s is in concordance with the average measured runoff 13.51 m3/s showing R2 of 0.82. The model could thus be used for snowmelt runoff estimation, on an operational basis, for judicious utilization of the depleting water resources in the region.

P-2211-12

Climatic and Socioeconomic Drivers of Water-Related Changes in the Andes of Peru: Challenges and Future Implications

J. Seidel (1) ; F. Drenkhan (2) ; C. Huggel (2)
(1) University of Stuttgart, Institute for modelling hydraulic and environmental systems, Stuttgart, Germany; (2) University of Zürich, Department of geography, Zürich, Switzerland

One sixth of the world's population lives in river catchments supplied by snow and glacier melt, and is therefore considered to be affected by climate change impacts on the cryosphere and water resources. In the tropical Andes glaciers have been a crucial source for societies and livelihoods for thousands of years. Nonetheless, climatic and non-climatic stressors pose potential risks and challenges to the provision of water resources and linked ecosystem services, both in terms of quantity and quality. Mountain communities in Peru are considered to be highly vulnerable to changes in water availability due to a strong exposure to climate change impacts and limited adaptive capacity. However, comprehensive analyses of water-related risks considering multi-dimensional drivers across different scales in the framework of climate change are complex and barely addressed in climate-sensitive mountain regions with limited data availability.

Here we present a comprehensive data assessment study for two major catchments in the Andes of Peru: Santa River (Ancash region) and Vilcanota River (Cusco region). These river basins, which comprise various ecosystems, hold the largest tropical glacier mass worldwide and are particularly exposed to climate change impacts. In the upstream areas, snow and glaciers store fresh water and buffer low flows during the dry season. Decreasing ice volume and changes in climatic patterns will subsequently alter river runoff characteristics.

For these study areas, we analyze to what extent both water supply and demand of two mountain catchments can be assessed using multiple data sources such as ground-based (air temperature, precipitation and discharge records) and remote sensing (TRMM precipitation, MODIS evapotranspiration and snow cover) data. Furthermore, we include a first assessment of socioeconomic key drivers identified by expert interviews with local and international stakeholders, decision-makers and water users. We propose an integrative water balance model approach which combines the main key variables of water supply and demand under hydrological risks considering climate-related hazards, human and natural vulnerability and exposure assessments.

P-2211-13

The impact of climate change on mountain landscapes of the North Caucasus

V. Vinogradova (1)
(1) Institute of Geography, Russian Academy of Sciences, laboratory of Climatology, Moscow, Russia

Changes in the boundaries of high-altitude mountain belts can be treated as a proof of climate change. These changes were caused by termination of human activities. The presentation shows the role of climatic factors in changes of the boundaries and state of sub-alpine landscapes in the North Caucasus, where the transformation of land use system was observed. These are mainly mountain meadows, which were being shaped for centuries of grazing and are semi-natural formations. The system of mountain land use has been changing for the last decades: nowadays more than 60% of sub-alpine meadows are abandoned.

Heat and moisture are the limiting factors of vegetation existence. The estimate of changes in heat and humidity was made for the territory of 42-44N 42-44.5E using vegetation index (NDVI), the index of vegetation conditions (VCI), Satellite Climatic Extremes Index (SCEI) and the sum of active temperatures (air temperature above + 10 °C).

Analysis of index changes shows normal humidification on the slopes of the main Caucasian ridge throughout the more humid period (2000-2006). In the second - dry period (2007-2013) for most part of the southern European Russia, the situation is changing. In the foothills moisture decreases, whereas in the middle mountains the increase in moisture is seen. The estimate of the amount of active temperatures and precipitation for the period of modern warming (1981-2010) compared with the previous period (1951-1980) shows the increase of these parameters in the early twenty-first century in the foothills of the North Caucasus. These changes cause the increase in vegetation in the middle mountains of the North Caucasus. It is evidenced by the growth of vegetation index (NDVI) at the beginning of the twenty-first century in this area. And in the areas with low altitudes (500-1000 m) vegetation index decreased after 2006, reflecting degradation of vegetation state. In the middle mountains the increase of vegetation index is observed, showing the improvement on conditions of vegetation.

In the middle mountains of the North Caucasus regeneration of natural boundaries of altitude zones is observed: the expansion of mountain-forest belt and restoration of pine forests on the southern slopes; restoration of mountain meadow steppe and steppe sub-alpine meadows on former agricultural terraces; northern slopes overgrown with crooked birch. These processes occur in the context of climate change (rising temperatures, increasing moisture) and reduce of human impact. Thus, climate change and weakening economic activity on the territory lead to restoration of vegetation in the area of middle mountains.

Researches were supported by RFFI grant № 14-05 00233A.

K-2212a-01

Impacts of Climate Change on Freshwater Resources and Managing Global Risks

T. Oki (1)
(1) University of Tokyo, Tokyo, Japan

The real hydrological cycles on the Earth are not natural anymore. Humans are now driving changes in atmospheric processes through emission of green-house gases and land cover changes directly and indirectly. Global mean temperature is projected to rise approximately proportional to the cumulative total anthropogenic CO2 emissions from 1870 (AR5, IPCC WGI). Temperature rise itself will have direct impacts on the availability of water resources through changing flow regimes in snow-dominant or glacier-effluent river basins, and it will also be associated with sea level rise because thermal expansion is one of the major causes of observed and projected sea level rises. Further, climate change is projected to alter hydrological cycles: changing temporal and geographical patterns of hydrological components, such as precipitation, evapotranspiration, runoff, and ground water recharge, and particularly in their extremes. Consequently, the frequency of floods and/or droughts is projected to increase some parts of the world.

However, as articulated in the AR5 of IPCC WGII, "Risk of climate-related impacts results from the interaction of climate-related hazards (including hazardous events and trends) with the vulnerability and exposure of human and natural systems", increasing frequency of natural hazards, such as torrential rainfall or long-lasting heat wave, alone will not cause damages on human and natural systems, and both climate and social changes are relevant for planning sustainable development in the future.

AR5 (WGII) also says "Significant co-benefits, synergies, and tradeoffs exist between mitigation and adaptation and among different adaptation responses; interactions occur both within and across regions". Mitigation and/or adaptation actions should not be planned in an isolated manner, but should be integrated into wider frameworks, such as integrated water resources management and sustainable development. It would preferably be integrated into a risk management framework assessing and managing possible global risks, and ultimately pursue increasing human well-beings.

K-2212a-02

Hydrometeorological and hydroclimatic worldwide monitoring, data sharing, cooperation and services

B. Stewart (1) ; H. Lins (2)
(1) former Director, Department of climate and water, wmo, Croydon, Victoria, Australia; (2) President of WMO Commission for Hydrology, Washington, United States of America

Freshwater resources are essential to all forms of life and, in a changing environment, hydrometeorological and hydroclimatic information are critical to ensure that resources are managed sustainably. Our precious freshwater resources are under increasing stress due to a range of factors. These include, inter alia, growing populations, increasing food and industrial production and a changing and variable climate. Unless we improve the availability of, and access to, good quality hydrometeorological and hydroclimatic information, we will not be able to fully understand and manage our water resources in a sustainable manner and monitor the implications of future decisions.

In this regard, the current status of monitoring climatic change and its impacts, with an emphasis on global freshwater resources is reviewed. In particular, the value of comprehensive hydrometeorological and hydroclimatic monitoring is described, including international efforts to facilitate and improve data collection and accessibility. Benefits from monitoring include improved understanding of the state and variability of freshwater resources, as well as reduced uncertainty in resource management decision-making under climatic change. Additionally, the status of, and efforts associated with, the promotion of regional and international data sharing are described. The value associated with the combination of monitoring, data sharing and cooperation between relevant agencies are realized through the services that can be provided. Finally, the efforts of the hydrological community to provide hydrological services, the importance of a quality management framework for the collection and presentation of data, the development of associated information systems, data registries, and web services for data sharing are emphasized.

In order to manage our freshwater resources in a sustainable manner, we must learn from the mistakes of the past and support the collection of hydrometeorological and hydroclimatic data into future. This requires two actions: 1) reversing the current trend in declining monitoring stations and the data and information derived from them; and 2) improving the collection, processing, and presentation of these data through innovative new technologies.

Responding to the Challenges of Water Security: the Eighth Phase of the International Hydrological Programme 2014-2021

B. Jimenez-Cisneros (1)
(1) UNESCO, IHP, Paris, France

This paper presents the major water challenges at global, regional and local level, including adaptation to climate change, based on the AR5 IPCC findings. It relates how the International Hydrological Programme (IHP) will respond in its VIIIth Phase to water-related risks and seize opportunities to contribute to water security at all levels. Cooperation between science and innovation and policy lie at the core of this strategy.

Management of natural resources must draw on science and innovation to be sustainable. From this perspective, the UNESCO-IHP Member States periodically define priorities for research, technological development, innovation and education. To implement the priorities in a coordinated manner, Member States works with the IHP Secretariat based at UNESCO HQ, as well as the UNESCO "Water Family", consisting of UNESCO-IHE, a Category I Centre located in the Netherlands; the World Water Assessment Programme, based in Italy, which produces the UN World Water Development Report; thirty Category II Centres under the auspices of UNESCO; and thirty-five water Chairs around the globe.

IHP's role in this context is to put in place procedures for the use of knowledge and innovation to adapt to climate changes impacts in the water sector, and to increase resilience to water-related disasters.

O-2212a-01

River flood risk and climate change

Z. Kundzewicz (1)
(1) Institute for Agricultural and Forest Environment, Polish Academy of Sciences, Department of Climate and Water Resources, Poznan, Poland

River floods are an important problem area related to freshwater resources, at any spatial scale - from local to global. More than 10% of the global population are currently living in flood-prone areas and about 1% of the global population are, on average, exposed to floods each year. Average global flood damage reaches tens of billions of US$ and the number of fatalities amounts to thousands. Flood losses are higher in developed countries, while relative fatality rates and economic losses expressed as a proportion of GDP are higher in developing countries.

Observations of changes in climate, hydrological /

terrestrial, and socio-economic systems influencing flood risk are examined. Despite the diagnosed extreme-precipitation based signal, and its possible link to changes in flood patterns, no gauge-based evidence had been found for a climate-driven, globally widespread change in the magnitude/frequency of floods during the last decades. There are strong regional and sub-regional variations in the trends. Moreover, it has not been generally possible to attribute rain-generated peak streamflow trends to anthropogenic climate change. Indeed, economic losses from floods have greatly increased, but this has been primarily attributed to increasing exposure and damage potential and not to climate change.

Further, model-based projections for the future are critically discussed. Projected changes from both global and regional studies indicate that it is likely that the frequency and intensity of heavy precipitation, or the proportion of total rainfall from heavy falls, will increase. Physical reasoning suggests that projected increases in intense rainfall would contribute to increases in precipitation-generated flooding, while less snowmelt flooding and earlier spring peak flows in snowmelt-fed rivers are expected in the warmer climate. Increase of flood hazard is projected over many areas.

Studies that project future flood losses and casualties indicate that, when no adaptation is undertaken, future anthropogenic climate change is likely to lead to increasing flood losses, alongside the increase in exposure linked to ongoing economic development, and the total increase would depend on the degree of warming.

Finally, uncertainty in our understanding of past floods and projections for the future is reviewed, with identification of gaps in knowledge. The impacts of climate change on flood characteristics are highly sensitive to the detailed nature of those changes and presently we have only low confidence in numerical projections of changes in flood magnitude or frequency resulting from climate change. Attention is drawn to the fact that over less than a decade, projections of flood hazard in Europe have dramatically changed. This is of vast practical relevance, hence interpretation of such changes has to be sought, related to both different climate scenarios and different modeling approaches.

O-2212a-02

Adaptation to changing water demand and climates in Sub-Saharan Africa: the role of groundwater

R. Taylor (1)

(1) University College London, Geography, London, United Kingdom

Freshwater demand in Sub-Saharan Africa (SSA) is expected to increase substantially in coming decades with projected rises in land under irrigation and water volumes required for domestic and industrial purposes. Anthropogenic warming is projected to further amplify variability in rainfall and river discharge that is already the most extreme in the world. Current metrics of freshwater availability (e.g. water stress index, relative water demand) misrepresent the "water crisis" in SSA as they greatly exaggerate freshwater demand, define renewable freshwater resources in terms of mean river discharge and, critically, exclude groundwater storage. Total groundwater storage in Africa (~0.66 million km3) is more than 100 times annual renewable freshwater resources, and more than 20 times the volume of freshwater stored in African lakes. Although substantial quantities of fossil groundwater in Africa have long been known to exist and are heavily exploited in arid landscapes remote from people (e.g. Great Man-Made River Project), less well understood is the comparatively small (equivalent to water depth of 0.5m) but vital groundwater storage that underlies much of SSA where people live. The extent to which this estimated groundwater storage is both accessible and renewable remains unclear. Recent research based on ground-based observations in semi-arid and humid areas of Tanzania and Uganda reveals the strong dependence of groundwater recharge on heavy rainfall events (>10 mm per day) and extreme rain events associated with the El Niño Southern Oscillation (ENSO). Consequently, the shift to fewer but heavier rainfall events projected under climate change may enhance groundwater recharge while reducing rain-fed soil moisture and exacerbating flooding. Under such circumstances, increased use of groundwater resources not only to supplement soil moisture through irrigation but also to meet increased freshwater demand may prove a hydro-logical adaptation in SSA. Increased reliance upon groundwater resources has led to groundwater depletion of regional aquifer systems in the USA, China and India through competitive abstraction and aquifer mismanagement. In contrast, aquifer systems underlying much of SSA are localized and characterized by low transmissivities and low storage. 'Small is beautiful' since these systems greatly restrict the impact of competitive, unregulated abstraction witnessed in other groundwater-dependent countries and enable low-intensity abstraction for which the impacts of overuse are largely localized. Thus, the prevailing geology naturally resolves the 'Tragedy of the Commons' that complicates management of productive, regional aquifer systems. Indeed, the potential for distributed, low-intensity groundwater use strongly complements land tenure systems in SSA that are characterized by a large number of distributed, smallholder (< 1 hectare) plots. Groundwater in SSA therefore represents a low-cost, distributed and potentially renewable store of freshwater that can enable many communities to adapt to changing water demand and climates. Two key physical challenges that currently constrain the realization of this potential are: (1) reducing the prohibitively high cost of drilling that currently impedes the development of groundwater by small landholders; and (2) resolving the aggregated impact of multiple low-intensity groundwater users to ensure the continuity of groundwater supplies and groundwater-dependent ecosystems.

O-2212a-03

Groundwater on North Sea islands in a future climate – a geophysical approach

H. Wiederhold (1)

(1) Leibniz Institute for Applied Geophysics, Hannover, Germany

For the North Sea Region climate change scenarios predict a shift of precipitation to the winter season leading to an enhanced groundwater recharge and rising water table. Additionally a sea level rise is expected leading to a new balance of freshwater and groundwater in the subsurface with consequences for, e.g., water supply, wetland drainage, construction stability. In the EU Interreg project CLIWAT (climate and water) the consequences of climate change to the groundwater systems were investigated in seven project areas in Denmark, Germany, the Netherlands and Belgium (CLIWAT Working Group 2011, Hinsby et al. 2012). Here the approach is shown exemplarily for the German North Sea island Borkum (Sulzbacher et al. 2012, Wiederhold et al. 2013).

The main challenge in the study of coastal aquifers in Northern Germany is the freshwater/saltwater environment. The water supply of the North Sea offshore islands is in many cases restricted to a freshwater lens and intrusion of seawater is a major constraint on groundwater utilization. To study the impact of climate change on the freshwater lens of a barrier island, a density-dependent groundwater model was developed. The structure and parameters of this model were designed using information from boreholes and various geophysical and hydrogeological investigations. To characterize the hydrogeophysical setting of a freshwater/saltwater system, we need a description of the actual situation including temporal changes in the freshwater/saltwater transition zone. This concerns the study of water salinity and its changes. Due to the strong contrast in electrical conductivity between seawater and freshwater, resistivity and electromagnetic methods are most suitable to map salinity in the subsurface. To overcome ambiguity in interpretation, the combination with methods such as nuclear magnetic resonance or seismics turned out to be successful.

This data were used to generate a hydraulic model for density-dependent groundwater modelling that is able to predict the long-term behaviour of the system under changing climatic conditions. To monitor the temporal behaviour, permanent resistivity installations are a cost-efficient alternative to repetitive soundings. The data acquired in periods of years or decades can help to improve the groundwater model and its implications.

Nubian Sandstone Aquifer System

EHM. Ahmed (1)
(1) Lead Author, WG III, IPCC, climate change and sustainable development, Cairo, Egypt

The Nubian Sandstone Aquifer System (NSAS) is the world's largest known fossil water aquifer system. It is located underground in the Eastern end of the Sahara Desert and spans the political boundaries of four countries in north-eastern Africa, it covers a land area under boarders for Egypt, Libya, Sudan and Chad. The geographical position between latitude 14°-33° north; longitude 19°-34° east. It contains and stored water volume 150.000 km2.

Many studies were made looking for the hydro geological setting of the area's aquifer; its results indicated that litho logical characteristics and tectonic settings are having a substantial effect on groundwater flow patterns and the area's overall aquifer potentiality.

Many surface bodies and groundwater traverse boundaries with no restrictions; any action which may be caused by one country could affect the water resources, and also could vary in significant consequences to the quality or quantity of water in another country.

In sub-Saharan Africa, freshwater withdrawals for agriculture are less than in Asia, Europe and North America. Also, estimation of freshwater demand assume annual withdrawals for irrigate and industry which are 20 times that required for domestic water use. Groundwater in many parts of sub-Saharan Africa can play a strategic role in adapting to changing freshwater availability and improving food production and security through groundwater-fed irrigation.

The actual withdrawal rates as follows; Egypt draw 1029 Million m3/yr; Libya 851 Million m3/yr; Sudan 406 Million m3/yr and Chad Million m3/yr. There're two different systems because of different water bearing strata; The Nubian Aquifer System (NAS), the second system is the Post Nubian Aquifer System (PNAS).

One of the great project that consumption a huge amounts of Nubian Aquifer Groundwater that made by Libya and called "The Great River", which be constructed on 1980. Withdraw water for municipal, industrial and agricultural use should be enough to produce adequate water and food to meet the countries own needs, it reduces the dependency on imports from foreign market.

So, we have to manage and implement a good convention for states that sharing in the same aquifer to control their draw and to implement a good plan to recharge the same aquifer using floods and other resources.

P-2212a-02

Green and Blue Water Impact Assessment under AR5 Climate Change Scenarios in Asian Monsoon Region

D. Bae (1) ; M. Lee (2)
(1) Professor, Sejong University, Civil & Environmental Engrg., Director, center for climate change adaptation for water resources, Seoul, 143-747, Republic of Korea; (2) PhD candiate student, Sejong University,, Department of civil engineering, Seoul, 143-747, Republic of Korea

The evaluation of continental-scale water availability is an important issue for sharing and distribution of transboundary water resources. Water resources are abundant in some regions, but water scarcity has been a major disaster in many other regions. In particular, the water resources in Asia monsoon region are more important, because they provide many benefits but also cause serious drought problems. There are various reasons for these water-related disasters, but the current climate change will be one of the critical triggers for the upcoming water scarcity.

In this sense, the understanding of climate change impact on green and blue waters and the development of climate change adaptation framework for water resources over the region will be important and urgent issue. The objectives of this study are to investigate the future climate change impacts on green and blue waters in addition to the changes of temperature and precipitation and to delineate the highly variable regions under future AR5 climate change scenarios in the Asian Monsoon region. Several GCMs representing the better performance in this region were selected and used for climate change projections. The change factor method with bilinear interpolation method was used to project climate change at 0.5 degree horizontal grid resolution. The Variable Infiltration Capacity (VIC) macroscale hydrological model was employed to project runoff using future climate change scenarios. Average temperature, precipitation, green and blue waters were projected for all future periods i.e. 2020s, 2050s, and 2080s. These findings can be useful for the better implementation of climate change adaptation strategies and wise water resources management in this region.

Spatial distribution of the vegetation and rainfall over West Africa during the last three decades (1981-2012) and associated atmospheric patterns

A. Bamba (1) ; A. Diedhiou (2) ; B. Dieppois (3) ; P. Thierry (4) ; A. Konare (5) ; A. Diawara (6) ; B. Kamagate (7) ; S. Issiaka (8)
(1) Universite Nangui Abrogoua, SGE, Abidjan, Ivory Coast; (2) Institute of Research for Development (IRD), LTHE - University Grenoble Alpes, Grenoble Cedex 9, France; (3) Université de Rouen, Mont-Saint-Aignan, France; (4) University of Grenoble-Alpes, LTHE, Grenoble, France; (5) Universite Felix Houphouet Boigny, Cocody, Ufr sst, Abidjan, Ivory Coast; (6) University Felix Houphouet Boigny - Cocody Abidjan, Physic, Abidjan, Ivory Coast; (7) Université Nangui Abrogoua, Laboratoire de géosciences et environnement, Abidjan, Ivory Coast; (8) Université Nangui-Abrogoua, Ufr sge, Abidjan, Ivory Coast

Decadal variability of the rainfall and the vegetation over West Africa is revisited from 1981 to 2012 using Climate Research Unit (CRU) observation rainfall data and Normalizied Differentiel Vegetation Index (NDVI) from NOAA. From decade 80s to 90s, we observe a significant return to wetter conditions over West Africa confirmed during the decade 2000's (00's) except over Central Benin and all the western side of Nigeria where there are a decrease in annual rainfall magnitude. From decades 80s to 90s, we observe a regreening of the Central Sahel and Soudano-Sahel regions. From decade 90s to 00s, this regreening belt is observed toward the South and the Coastal areas, mainly over the Guinea Coast, Soudano-Guinean and Western Sahel regions. Factors of the atmosphere associated with the vegetation and rainfall changes over West Africa during the last three decades was investigated: During the last two decades, the West African monsoon (at 925hPa) and the Tropical Easterly Jet (at 200hPa) were stronger than in 80's, and the African Easterly Jet (at 700hPa) is weaker. This synoptic configuration is known to be favorable to wet conditions.

P-2212a-04

Synthesis Report on Climate Change Vulnerability Assessment over Niger River Basin

G. Bogale (1)
(1) ACMAD, Climate and environment, Niamey, Niger, Republic of

The Niger River Basin encompasses an area of 2.2 million square kilometer from this only 1.5 million square kilometer is hydrologically active. Development activities are going on along the basin such as mining, construction of dams for generating electricity and irrigation. The construction of dams is increasing across the Niger River basin by riparian countries. Most of the riparian countries recorded economical growth in recent years. The sustainability of the economical development and the achievement of million development goals are threatened by climate change.

In this paper, we tried to assess climate change vulnerability over the basin. The climate of the region varies from tropical humid climate to arid climate and one of the most vulnerable regions to climate change. The Basin suffered from desiccation in 1970s and 1980s and catastrophic recent flood events. The drought of 1984 reduced the GDP of Mali and Niger by 9% and 18% respectively. The inner delta is one of the most vulnerable parts of the river basin because of the dependency of millions of lives and livelihoods including the pastoralist on it.

Studies of National Adaptation Programme of Action of riparian countries indicated that the surface temperature increased by less than 10C in the second half of the 20th century. The surface temperature is expected to rise between 3-60C at the end of the 21st century under different socio-economic scenarios. The decadal and multi-decadal observed variability of the rainfall in the Niger River basin was clearly figured out in the national and international reports. The rainfall variability in the Niger River Basin is associated with the sea surface temperature of global oceans, ENSO and complex interacting processes including land surface and desert dust aerosols.

Among the hydro-meteorological disasters of sub-Sahara Africa, 25% of the disasters occurred in West Africa which is the second vulnerable region after East Africa in the period 1974-2003. The number of days with heavy rainfall is expected to increase in 21st century in West Africa. Furthermore, the projected mean sea level rise coupled with land subsidence due to the oil and gas extraction in the Niger delta will threaten the existing physical, biological and socioeconomic systems.

Rain-fed agriculture is dominated the Niger River Basin which is highly sensitive to climate variability and change. The population growth compounded with climate variability and change is a major challenge for agriculture sector to meet the demand. The major impacts of climate change for agricultural sector are a reduction in crop yield and total failure of the crops as well as the death of livestock and reduction of productivity.

The Niger River basin is considered as one of the basin which is affected by fresh water shortage in West Africa and the River itself influenced by the ground water base flow. Climate variability and change impacted the river basin in the past. A significant decrease in rainfall amount resulted in two fold decrease in the surface and sub-surface runoff. The projection of rainfall in West Africa is uncertain due to the disparity of climate models; however, the water sector will be under stress as result of population growth, urbanization, water for agricultural growth and land use change.

The basin is affected by climate sensitive diseases such as malaria, meningitis, cholera, dysentery and diarrhea. The expected increase in surface temperature will exacerbate the incidence of climate sensitive disease in the basin. The multi-model forecast which consider climate factor only as an outbreak of malaria revealed that the malaria belt zone will shift 10 to 20 south wards in West Africa.

P-2212a-05

Impacts of climate change on the performance indexes of a water resource system: A case study of Boura reservoir in Burkina Faso

T. Fowe (1) ; B. Ibrahim (2) ; JE. Paturel (3) ; H. Karambiri (1)
(1) International Institute for Water and Environmental Engineering, Hydraulic department, Kadiogo, Burkina Faso; (2) West African Science Service Center on Climate Change and Adapted Land Use (WASCAL), Competence Center, Ouagadougou, Burkina Faso; (3) IRD, HydroSciences Montpellier, Abdijan, Ivory Coast

In developing regions like Africa, availability and access to freshwater largely determines patterns of economic growth and social development. Burkina Faso, as others Sahelo-Sudanian countries pledged for some decades to control water resources after the severe droughts that occurred during the 1970s and 1980s through the construction of small reservoirs. Thus, thousands of small reservoirs dot the landscape and they are used for multiple purposes with especially irrigation in order to increase food production. The Boura reservoir, located in the southern of Burkina Faso, is a representative pilot site of many small reservoirs in the Volta Basin in West Africa. The ungauged catchment area upstream of the Boura dam of about 150 km2 is lying to the Centre West Region, Burkina Faso and Upper West Region, Ghana. This study aims to assess the performance indexes such as reliability, resilience and vulnerability of the Boura reservoir under the climate change conditions.

The methodology is organized in steps: (i) Firstly, climate change scenarios for the periods 2041-2070 and 2071-2100 relative to the reference period 1971-2000 were projected by using the outputs of regional climate model RCA4 (Rossby Centre Atmosphere model, version 4) under two emission scenarios (RCP4.5 and RCP8.5); (ii) Secondly, the impact of climate change was then investigated on the input runoff of the Boura reservoir by using the hydrological model GR4J (daily lumped four-parameter) for the future periods and also on the crop water requirement of the irrigation schemes downstream the Boura dam; (iii) Thirdly, the simulation of reservoir performance in the delivery of agricultural water demand was implemented by using the water evaluation and planning (WEAP) model.

The analysis of the inter-annual average changes in rainfall and potential evapotranspiration (PET) between the future two 30 year horizons (2041-2070 and 2071-2100) and the reference period (1971-2000) showed upward trends with increases up to +23% for rainfall and +9% for PET, dependent on the RCP emission scenario (RCP4.5 or RCP8.5).

These projected changes in rainfall and PET will cause higher inter-annual variability of future inflow to the Boura reservoir compared to the reference period, necessitating increased reservoir capacity to meet future irrigation water demands. However, the performance indexes of system revealed that failures in agricultural water demand satisfaction would be observed in the future periods. In terms of overall performance, the reliability and vulnerability indexes decreased in the future relative to the reference period, especially for the socio-economic development scenario with an increase in agricultural water demand under climate change conditions.

This approach enable a comprehensive understanding of the functioning of a water storage reservoir under future climate scenarios and can also be a robust tool to predict future challenges faced by water supply systems under climate change conditions.

P-2212a-06

Result of numerical modelling of groundwater resource in the Shiraki catchment

M. George (1) ; N. Zhukova (1) ; M. Todadze (1)
(1) Institute of Geophysics, Ivane Javakhishvili Tbilisi State University, Tbilisi, Georgia

Eastern Georgia encounters, due to its semiarid climate, a big deficit of 1040 million cubic meters of water for irrigation and domestic use. One of the most important examples is the agricultural area of Shiraki Plain, which occupies over 80.000 km2 on a large, partly artesian aquifer of the Alazani basin and on the upland synclines between the rivers Alazani and Iori (1). In order to assessment water resource, numerical model of groundwater hydrodynamics was elaborated for this area based on the conceptual model, which based on the provisional data (geological, geophysical, hydrogeological, hydrological, etc). Model of the aquifer have been processed by special software Visual Modflow Package. In order to assessment water resource, a numerical model of groundwater was elaborated for Shiraki area. It is consists of 3 layers. Each layer represents a porous material with different infiltration properties. The model was calibrated in transient transport mode to tritium concentration measured in boreholes and springs located in Shiraki area. Tritium was assigned as a single mobile species, not reacting with chemical elements and concentrated in water, what allowed determining the residence time of groundwater flow. The model estimated

discharge and recharge zones, groundwater flow directions and velocities as well as groundwater age for Shiraki area. It is recommended to enhance the use of waters from the karstic formations as alternative drinking water sources.

P-2212a-07

Flooded area characterization and loss estimates for improving the water balance of the niger inland delta, mali

M. Ibrahim (1) ; D. Wisser (2) ; A. Abel (3)
(1) University Abomey Calavi, WASCAL, GRP. Water Resources and Climate Change, Cotonou, Benin; (2) University of Bonn, Center for development research (zef), Bonn, Germany; (3) Universite d'Abomey-Calavi, Graduate research program on climate change and water resources, Abomey-Calavi, Benin

Water availability is an ongoing challenge for West African countries in general, and the Niger River basin in particular. The Niger Inland Delta (NID) has experienced annual flood events from the Niger and Bani Rivers. During such events, the flooded area can cover 40,000 km2, and extend to 350 km long and 100 km wide in Mali. While these NID events can have considerable influence on downstream flow regimes due to water loss significantly impacting water availability, the processes that occur in NID are not fully incorporated in the conceptual development of many hydrological models of Niger Basin runoff. Though several studies in this region have developed conceptual models to represent hydrological processes in the system, the models have been criticized for their limitations and unsophisticated concepts for explicitly representing all the hydrological processes. This paper discusses an attempt to better assess the NID hydrological processes by considering more physical information about the system, and incorporating wetland processes into an existing hydrological model to improve model simulations of the basin.

The approach illustrates how flooded surface area estimates from large amounts of remote sensing data can be used to monitor flood dynamics with adequate spatial and temporal resolution. Characteristics of the extent of the flooded area are determined from monthly scale inflow levels data, and flooded areas within a non-linear regression based model. Previous correlations between flow levels and flooded areas were refined to account for the hysteresis as flooding recedes, and the timing of the area expansion. The model of the spatiotemporal extent of the flooding over the NID shows that the flooded areas varied between 25,000km2 in wet periods and 2,000 km2 in dry periods, resulting in actual evapotranspiration loss of between 17 km3 and 10 km3. The contribution of water abstraction from irrigated fields and direct precipitation assessments of flooded areas refined the NID water balance and infiltration estimates. The results of the timing and extent of the flood and water loss across the NID helped determine both the development of storage in one year, and the year-to-year variations. Furthermore, information about the NID flood dynamics and water budget can be used to develop and calibrate a specific model of the NID, and thereby account for the loss in hydrological models.

P-2212a-08

Impact of Rapid Urbanization on Water Resources in the Context of Climate Change (A Case Study of Urban Area through Multi-Temporal Remotely Sensed Data and GIS)

KN. Joshi (1)
(1) Institute of Institute of Development Studies, Natural Resources Management and Environment (Remote Sensing), Jaipur, Rajasthan, India

One of the many environmental problems incurred by climate change is creating a negative impact on water resources in urban areas. The effects of climate change on water quality and availability are significant, including shortages and contamination that directly affect health of people and proper functioning of urban development and government. Unplanned growth of urban area further deteriorates the situation. The present paper provides an overview to some of the effects of rainfall variability due to climate change coupled with urbanization on water quality as well as quantity in Jaipur urban Agglomerates, the most populous area in the state of Rajasthan (India). The study has been carried out using Indian remote sensing data, Survey of India topographical sheets and GIS techniques.

During the course of study, a series of thematic maps covering climatic parameters and anthropogenic activities have been prepared to depict the changes in land use pattern, surface hydrology, geo-hydro-morphology, rainfall pattern and its impact on urban water resources. It was found that increasing pressure of population and unsystematic anthropogenic activities have made negative impact on water resources. It encroached upon lakes, rivers, streams, and ponds etc in the vicinity of urban area. As a result, out of total 518 rivulets in urban area and surrounding, 13 first order , 37 second order and 10 are of third order stream are completely blocked by settlements (Total 60). □Out of 2600 wells, 1116 well/tube wells have stopped recharging due to increase in pavement area between years 1986 to 2003. :• Seven fresh water reservoirs have dried-up which were supplying drinking water to Jaipur city •The surface drainage network of rain water has been converted into municipal sewerage :• Local source of water supply from surface as well as ground is closed due to scarcity of water •Recharge of ground water has stopped due to increased pavement area for urban development like infrastructure development, industrial development and other urban development activities.

Finally, it is suggested that by using remote sensing and GIS technique one can prepare an integrated plan for urban development in which surface water bodies can be protected which in turn would take care to recharge ground water and also provide the surface water in decentralized manner in the urban area.

P-2212a-09

Developing adaptation strategies to face the impact of climate change on the freshwater resources of India

SN. Krishnapillai (1)
(1) Nansen Environmental Research Centre (India), Kochi, Kerala, India

Major challenge associated with the management of freshwater resources in India is the abnormalities and uncertainties in climate. With changing climate, increasing water demands in the domestic, agricultural and industrial sectors, and fast deterioration of the water resources, India is heading towards a water crisis. Life of millions living in climate sensitive river basins and wetlands make India one among the countries highly vulnerable to the impacts of climate change. Drylands are potentially threatened by desertification. Indian economy and life of the majority has been traditionally linked to agriculture, the largest consumer of water. Abnormalities in rainfall seriously affect water availability and agricultural production. Extreme hydrological conditions affect hydropower generation and industrial development. Increasing rainfall seasonality in certain parts reduces groundwater recharge and summer water availability. Changes in the intensity, frequency and tracks of storms increasingly salinate coastal aquifers. In the Western Ghats Mountain area, increasing intensity of rainfall results in erosion and sedimentation, reducing reservoir capacity and summer flow in rivers. Retreat of Himalayan glaciers is likely to have large impact on water resources in entire north India. Water related health issues are worsening. Vector-borne and water-borne diseases extend into new areas. Even the heavy rainfall zones face serious water shortage as a result of drawbacks in water conservation and management. Most of the surface and groundwater resources are highly contaminated. Falling availability of reliable water leads to socio-economic issues such as water disputes, migration, pricing of water that is unaffordable to millions and large investments for the adaptation and mitigation. Present economic growth is likely to be haltered. India's preparedness for the effects of climate change is poor and India was too late to develop a climate policy. National polices including are only guidelines and they lack information on the effective implementation. Though several initiatives have been started in the water sector as part of adaptation such as cleaning of major rivers, protection of wetlands, groundwater recharge and introduction of water efficient technologies in agriculture and industries, the progress is slow because of issues like lack of coordination of departments, weak and corrupt administrative mechanism, social issues and vested political interests. Vulnerable groups are often neglected in decision making and policy development. Projects lack transparency and

accountability. India urgently needs appropriate policies and strategies and an efficient implementation mechanism to face the challenges in water sector. A mix of traditional, environment-friendly methods and modern technologies in water conservation and quality improvement could perform better. This paper assesses the impact of climate change on water resources of India and its reflections on different sectors. Changes in water availability in two decades from now under an altered climate have been estimated using hydrological model, based on the projections of climate models. Existing policies and adaptation strategies have been critically reviewed to suggest guidelines for adaptation and mitigation measures in the water sector to face the impending water crisis.

P-2212a-10

Key findings on groundwater and climate change from the UNESCO IHP GRAPHIC network

M. Leblanc (1) ; J. Gurdak, (2) ; A. Aureli, (3) ; T. Carvalho Resende (3) ; G. Faedo, (3) ; R. Taylor (4)
(1) University of Avignon, Department of hydrogeology, umr emmah, Avignon, France; (2) San Francisco State University, Department of earth and climate sciences, San Francisco, United States of America; (3) UNESCO, Division of water sciences, Paris, France; (4) University College London, Department of geography, London, United Kingdom

Groundwater is an essential resource. It provides baseflow to lakes and rivers and supports numerous terrestrial ecosystems during dry spells. Today groundwater is also paramount to freshwater and food supply. Globally it covers the demands for around 36% of domestic water and 40% of irrigation water requirements. Groundwater is often regarded as a key resource for adaptation strategies to climate change. Aquifers often represent large stores of slowly evolving water. Groundwater has generally a lower variability and vulnerability than surface water. Groundwater resources are consequently more resilient to drought and the impact of human activities than surface water.

Under the International Hydrological Program (IHP), the UNESCO is home to a scientific network examining the relationships between groundwater resources and global change, called GRAPHIC (Groundwater Resources Assessment under the Pressures of Humanity and Climate Change). The GRAPHIC community is composed of academics, researchers, government employees, and professionals from the water industry located across 34 countries. By encouraging and coordinating international collaboration, GRAPHIC aims to strengthen global research efforts on groundwater impacts from climate change and adaptation strategies. This presentation provides a geographic synopsis of progress made and lessons learnt to date by the GRAPHIC network.

Through a number of case studies in a variety of climatic and geologic settings, GRAPHIC has identified challenges that are important when considering the inclusion of groundwater in climate change adaptation strategies. Though generally less responsive than surface water, groundwater can still be substantially impacted by climate change. The magnitude of this impact can vary greatly from region to region. At the same time, compounding effects from other global anthropogenic changes also impact groundwater. It is possible to identify a number of hotspots where groundwater may be particularly vulnerable to climate change and will require careful sustainable management.

Key lessons learnt from GRAPHIC network include the need to account for groundwater in 1) monitoring of freshwater resources; 2) climate models; 3) land surface and water models; and 4) the management of transboundary basins. There is a great need to include and more carefully consider groundwater into climate change adaptation schemes and strategies.

Future activities will include, amongst others, applying satellite gravimetry for evaluating trends in groundwater storage across large transboundary aquifers (TBAs) in regions where data access is very limited either because of data scarcity or accessibility. Such activities will contribute to establishing water budgets at aquifer scale for better-informed water management decisions and policies.

Identifying Hydro-climatological Contributions to Hydrological Drought Formation with Uncertainty in Satellite Datasets: An Examination over the Poyang Lake Basin

Y. Liu (1)
(1) Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, Jiangsu Province, China

Hydrological droughts are generally the combined consequences of hydro-climatological influences. Identification of the individual influences on drought formation is essential to effective drought prevention. The identification with the principle of water balance requires all the major hydro-climatological measures. However, it is impractical to measure all the components from ground observations. While satellite remote sensing now provides spatio-temporally consistent retrievals of the components over large regions, its relevant uncertainty often remains undocumented. The uncertainty may propagate into total water deficit which is a residual of water balance. It casts a shadow on the reliability of drought analysis. This study addresses the uncertainty for drought analysis, and proposes to use a signal-to-noise ratio for quantifying the reliability. The approach is examined with satellite datasets of evapotranspiration and soil moisture, in addition to station data of precipitation and river discharge, for the Poyang Lake Basin with an area of 162,000 km2 for the periods of 2001-2010. Satellite datasets are processed for the cases with and without field validation. Hydrological drought events are identified with river discharge data for each of five sub-basins within the basin. The validated satellite datasets are used to quantify hydro-climatological contributions to individual drought events. The contributions are then compared to those from the datasets without validation. The results show that the difference in quantified contribution varies from 5~40% for the individual events in each sub-basins between the two cases. The signal-to-noise ratio is generally higher than 2.8, indicating the robustness and usefulness of the satellite datasets in water balance analysis for identifying hydro-climatological contributions to drought formation. The findings provide an approach to addressing hydrological droughts from water balance analysis, especially valuable for studying droughts under climate change with satellite datasets with limited accuracy.

P-2212a-12

Degradation of the Nyong River by the climate changes (Cameroon)

PM. Mani Essomba (1)
(1) International Relations Institute of Cameroon, International Cooperation, Humanitarian Action and Sustainable Development, Yaounde, Cameroon

Nyong is a river of the south- Cameroon, length of 640 km. It has its source 40 km in the east from the town of Abong- Mbang, in the large equatorial rainy forest. It runs parallel to the lower course of Sanaga's river, following an east-west direction. It crosses the towns of Mbalmayo and Ayos and flows into the gulf of Petit Batanga, Guinea village located at 65 kilometres in the south-south-west of Édéa. Rapids intersect its course with Mbalmayo and Déhané. In the city Ayos, one can fish fish called "Kanga".

The Nyong river flows through a good part of the south-Cameroonian tableland. It nourishes approximately 4 million individuals. With the varied and formerly abundant natural resources, the river Nyong is about today in the process of undergoing an ecological disaster without precedent. This river has been for several years, the seat of a series of aggressions (overfishing, bush fires, deforestation, erosion of the banks, silting, various pollution), which affects its medium of life and destroys its biodiversity. This constant rise of the dangers enabled possibly to conclude in an alarmist and pessimistic way that: if nothing is done in the twenty next years, the river could disappear.

The conditions of flow of the river are unfavourable with its blooming. Pollution, anthropic activities and the phenomena of eutrophication are hardly favourable to the survival of the hydrological rate of flow of the Centre and the South region. Lost in meanders of the forests of east-Cameroon at the Atlantic coast, this river is dying.

Because, attacked by the combined action of the man and the climate changes.

This river with almost still water on most of its course dies blackened by the drying of silts. The first drawback is the action of the human being, through his demographic pressure on the banks, the deforestation of the valley of the river for cultures, the discharge of waste by the sawmills and other abattoirs, the confluence of the Mfoundi river via the Mefou river, carting all kinds of pollution of the town of Yaoundé, in an absence of an environmental culture. The nature is also one of the causes. Climate changes alternating draining of affluent and devastated floods. We are not mentioning these unforeseen elements, concerning the invasion of part of the bed of the river by the hyacinth water and other luxuriant vegetations. And yet, the river Nyong brought satisfaction to the needs of its residents. Furthermore, his economy based on fishing; especially the fishing of the "kanga" and collects of other halieutical resources. It is also harnessing, the industrial treatment and the drain of its water to the taps of Yaoundé. Then, the question that brings up these findings is: What to do, to lend the river Nyong his patent letters of nobility?

P-2212a-13

L'eau virtuelle des produits agricoles d'importation : Un moyen de contrecarrer le problème du manque d'eau en Algérie

B. Mouhouche (1)
(1) Ecole Nationale Supérieure Agronomique (ENSA) ex INA, Génie Rural (Hydraulique Agricole), Alger, Algeria

Algeria is ranked among the 17 countries that suffer most from lack of water worldwide.Indeed, with less than 300 m3 / capita / year of renewable water, Algeria has less than 30% of the theoretical scarcity threshold set by the World Bank in 1000 m3 /hab./an.

Being unable to expand its agricultural land UAA and / or increase irrigated areas, to fill the food gap, Algeria resort to massive food imports, especially cereals and their derivatives.

Added to these non-food agricultural products.

These imports, although they represent a major financial drain for the country, they have at least one positive aspect represented by the virtual impressive amounts of water they provide to Algeria estimated at over 40 billions m3 2012.

It is in this framework that guides our study in which we try to quantify these virtual amounts of water that contribute greatly to temporarily relieve the country of its water shortage problem.

Keywords: Water scarcity, food security, water resources, virtual water, Algeria.

P-2212a-14

Climate Change and water resources in the Maghreb

B. Laignel (1) ; Z. Nouaceur (2) ; I. Turki (1)
(1) University of Rouen, UMR 6143 M2C, Mont Saint Aignan, France; (2) University of Rouen, Umr 6143 idees, Mont Saint Aignan, France

The Mediterranean area, known as hot spot area of Climate Change by IPCC, is expected to increase mean annual temperatures between +2,2°C and +5,1 °C, a decrease mean annual rainfall between -5 and -35 % and an increased of extreme events, in 2100. The combination of Climate Change and human impact could lead to water shortage for 290 million people (Plan Bleu of United Nations), particularly in North Africa.

The aim of this work is to provide an overview of the climate change and its effects on the water resources, at the Maghreb scale for the temperature and rain evolutions (30 synoptic stations located in the North and center of the 3 countries of the Maghreb, from 1970 to 2013) and 5 watersheds for the water resource (Soummam and Khébir Rhumel in Algeria, Tensift and Sebou in Morocco, Cap Bon en Tunisie). This study is performed in the framework of the 2 AUF and PHC Maghreb projects on the evolution of the water resource in Maghreb.

At the Maghreb scale and the studied watersheds, we observe an increase of minimum and maximum annual temperatures from the 80s. We observe 3 periods on the rainfall time series: a humid phase before the 80s, then several years of drought from 80s to the early 2000s, then a return of more humid phase with more of storm events.

However, it is difficult to dinstinguish and quatify the respective roles of the climate change and anthropogenic impact on the evolution of the water resources. The combined effects of these two factors led to a decline of the quantity and deterioration of the quality of water resources. Indeed, the groundwater, the main drinking water resource in the Maghreb, show a strong decrease, which can reach -50 cm to -1 m per year, and a deterioration of the water quality by infiltration of the anthropogenic pollutants from surface water (rivers) and by a water salinization in the coastal aquifer (related to the seawater intrusion), such as the examples of the Haouz and Sais aquifers in Morocco (Marrakech and Fès regions) and Cap Bon aquifer (North of Tunisia).

Nevertheless, a study of the hydrological variability carried out on 2 watersheds (Soummam and Tensift), by wavelet analysis, showed similar energy bands or variability modes (1, 2-3, 5-7, 15 years) in rainfall, streamflow and aquifer piezometry: 1, 2-3, 5-7 and 8-15 years. Moreover, 3 major temporal discontinuities are observed around 1970-1975, 1980-1985, 1990-1995 in all times series. The 1970-1975 and 1990-1995 discontinuities were also found in other hydrosystems on both sides of the of the Mediterranean Sea and the Atlantic Ocean, in various climatic and geomorphological contexts (USA, NW Europe, N Africa), in different hydrological compartments (surface and groundwater) and at various spatial scales (watersheds smaller than 1000 km2 and large rivers): the Seine watershed (streamflow and aquifer piezometry) and small high-Norman watersheds, Mississippi, Colorado and Texas small watersheds. Therefore, these discontinuities can be described as global disruptions. In addition, they are also present in climate indices NAO and SOI and can therefore be described as climatic discontinuities at the global scale. There is no satisfactory explanation of the phenomenon causing these discontinuities, although the first discontinuity coincides with the second phase of global warming (which also began in the early 1970s) and the second coincides with an apparent intensification of warming. However, the link between these phenomena is not yet established.

P-2212a-15

Impact of climate change and overexploitation in semi-arid areas on the water resources. Example of Essaouira Basin (Morocco)

S. Ouhamdouch (1) ; M. Bahir (2) ; A. Souhel (3) ; M. Paula (4)
(1) Cadi Ayyad University, Geology, Marrakech, Morocco; (2) ENS Marrakech, Geology, Marrakech, Morocco; (3) ENS Marrakech, Marrakech, Morocco; (4) Universidade de Lisboa, Lisboa, Portugal

The Maghreb countries Algeria, Morocco and Tunisia are affected by the climate change, which is manifested by the tendency to increased temperatures and decreased rainfall. This has several negative effects on natural resources such as water resources. Among them: (i) The scarcity of water resources. (ii) The increased salinization of soil and, consequently, the salinity of waters. (iii) The drought, which leads to soil erosion, which causes the silting of the dam and, consequently, the decrease in the rate of mobilization. Overexploitation of coastal aquifers and pollution vulnerability are among the main problems related to groundwater resources assessment and management in arid and semi-arid regions threatened by desertification being the only source for agricultural and public water supply. The behaviour study of the aquifer system in the Essaouira basin (the object of our study) in the face of climate change, based on the interpretation of hydrochemical data (major elements), piezometric and isotopic (18O, 2H, 3H and 14C) was used to determine the degree of impact of climate change on aquifer system. The follow-up of the quality evolution of groundwater in the Essaouira Basin through the electrical conductivity and the chlorides concentration showed that this quality is in close relationship with the vagaries of the weather.. Changes in groundwater levels in the study area, brings up these levels would decline over the years to rainfall deficit and would renew for excess. The use of the technique of

isotopic tools showed that the recharge of this aquifer system is recent and carried out by the direct infiltration of rainwater.

P-2212a-16

Salinisation: A social, ecological and health issue in the Bengal Delta

M. Rahman (1) ; PK. Streatfield (1) ; J. Levi (2)
(1) International Centre for Diarrhoeal Disease Research, Bangladesh , Center for population, urbanization and climate change, Dhaka, Bangladesh; (2) Institute of Global Health Innovation, Imperial college, London, United Kingdom

The Bengal Delta is formed by three major rivers; Ganges, Brahamaputra and Meghna. This region is particularly vulnerable to climate change and densely populated with 650 million inhabitants. Climate change causes a complex multitude of social, ecological and health problems. Salinisation (referring to the buildup of salts in both soil and water) may be exacerbated and amplified by climate change and is a growing threat to this delta.

Sea level rise, land subsidence, rapid transition from agricultural land use to shrimp cultivation, upstream fresh water extraction (which normally flushes out saline sea water), increasing cyclone and storm surges all contribute to increased salt intrusion in the South-West coastal region of Bangladesh; constituting the majority of The Bengal Delta. Salinisation affects both rural and urban coastal communities through changes in livelihood, contamination of water sources, reduced agricultural productivity, and declining trends in ecosystem services. Furthermore, salinization adds a huge public health burden both upon individual health (hypertension may just be the tip of the iceberg) and population level social and economic development.

Recent research has explored broad impacts of salinization in this region, however, we lack a concise summary of the evidence required for the formation of much needed meaningful solutions. This paper is a critical systematic review to assess and condense salinization's impact on life, livelihood and wellbeing of coastal populations. Different community based adaptation options will be discussed and conclusions will be drawn from a systematic literature review, recent field work and results from several ongoing project experiences.

P-2212a-17

The Implications of Climate Change on Water Quality and Ecosystem of Nasser Lake, Egypt

M. Rashed (1)
(1) Aswan University, Faculty of Science, Aswan, Egypt

Climate change can affect water resources and its water cycle. Through it climate change can affect the quantity and quality of water resources available to meet human and environmental demands, affecting water availability and quality for flora and fauna, lower minimum flows in rivers, drinking water intake, energy production (hydropower), thermal plant cooling and navigation. High Dam Lake is one of the largest man-made Lake in Africa, It includes Lake Nasser which extends for about 330 Km in Egypt. Lake Nasser water is a major source used for drinking, irrigation and domestic purposes in Egypt. Aquatic ecosystems of the Lake region support delicate, deeply interconnected webs of life which are highly adapted to the physical, chemical and biochemical characteristics and cycles of the lakes themselves. Warmer water temperatures affect physical, chemical, and biological processes. It reduces dissolved oxygen concentrations, which are a critical aquatic ecosystem requirement. Changes in rate of chemical reactions in the water column, sediment-water interface, and water-atmosphere interface are also expected. The present study aims to monitoring climatic change on Lake Nasser through the past 20 years (since the year 1991). The monitoring includes the physicochemical parameters (Temperature, pH, conductivity, dissolved oxygen, CO2 and Nitrate and other chemical parameters) in Lake water and sediment , and fish since the year 1991 to the year 2014. The obtained results indicated that as the Lake water temperature increases from the year 1991 to the year 2013, dissolved oxygen decreased from 10.8 to 6.1 ppm. Also, other parameters affected by temperature.

P-2212a-18

Impact of future global climate and land use and land cover changes in Amazonian run-of-river hydropower plants

J. Tomasella (1) ; D. Rodriguez (1) ; RRDCS. Von (1) ; GS. Mohor (1) ; JJL. Siqueira (1) ; LG. Lopes (1)
(1) INPE, CCST, Cachoeira Paulista/SP, Brazil

Brazilian strategic interest in Amazonia includes the development of hydropower to satisfy the country´s growing energy needs and new waterways to boost regional trade and economic development. Of the total amount invested in the Amazon until 2020, 37% will be allocated in the constructions of hydropower dams, which correspond to 45% of planned energy expansion during the period. Due to environmental constraints, hydropower dams under construction in Amazonia are run-of-river (ROR) type plants, thus is, with a limited storage reservoir to minimize the area of natural forest to be flooded. Although it is widely recognize that ROR plants dramatically reduce environmental local impacts compared to traditional large dams, they are subject to seasonal river flows. Considering that the Amazon Basin is characterized by high interannual variability, and have been recently affected by the occurrence of extreme droughts (for instance, 2005 and 2010), it is clear that the generation capacity of ROR plant could potentially be seriously compromise during extreme events. Besides this, IPCC scenarios indicate that climate change can seriously impact the hydrological regime South American rivers, which might also affect the distribution of biomes in South America due to the synergistic combination of impacts due to both land cover (deforestation, forest fires and fragmentation) and global climate changes. Therefore, the aim of this study was to critically assess how different global climate change scenarios associated with regional land-use and land-cover changes caused by deforestation could affect the power generation of run-of-rive power plants under construction in Amazonia. Power generation was analyze in the following ROR hydropower plants: Estreito, on the Tocantins River Basin, Santo Antônio dam, in the Madeira River Basin, Serra da Mesa in the Tapajós River Basin.

To achieve this goal, we calibrated the MHD-INPE hydrological model for the period 1970-1990 using hydrological, meteorological and soil data from different sources from Brazil, Bolivia and Peru. We analyzed the ability of the model to simulate the present hydrological regime when climate model simulations were used as input. Climate change projections produced by different climate models were used in the hydrological model to generate scenarios with and without regional land-use and land-cover changes induced by forest conversion to pasture for the period from 2011-2099. Finally we assessed the impacts of climate change on annual energy production based on the differences in the power duration curve - PDC produced by each scenario. The PDC of each scenario was estimated using hydraulic head and efficiency of each plant constrained by the minimum flow, under which the plant cannot operate, and the plant installed capacity. The use of PDCs allow to analyze the impacts not only of the annual average discharge, but also the effects of seasonal changes of climate. Despite of the differences among climate projections, results show that the climate change projections lead to a decreasing annual energy production and an increasing idle time at hydropower plants. Even when it is not possible to conclude about which projected climate scenario is the more appropriated, this work suggests to assess climate change impacts on energy production through an exploratory analyses, evaluating the robustness of the plant design under several plausible scenarios.

P-2212a-19

Impacts of climate change in epicontinental water systems of Mexico

P. Valdespino (1) ; J. Alcocer, (2) ; G. Vilaclara, (3) ; O. Escolero, (4) ; LI. Falcón, (5) ; M. Mazari, (6) ; J. Ramírez-Zierold, (7) ; M. Merino-Ibarra, (7)
(1) Posgrado en Ciencias del Mar y Limnología, Mexico DF, Mexico; (2) FES Iztacala, UNAM, Edo. de México, Mexico; (3) Posgrado en Ciencias del Mar y Limnología, UNAM, Mexico, DF, Mexico; (4) Instituto de Geología, UNAM, Mexico DF, Mexico; (5) Instituto de Ecología, UNAM, Mexico DF, Mexico;

(6) Instituto de Ecología, UNAM, Mexico, DF, Mexico; (7) Instituto de Ciencias del Mar y Limnología, UNAM, Mexico, DF, Mexico

Continental aquatic systems in Mexico exhibit a high vulnerability to climate change. In particular, variation in the patterns of precipitation and drought associated to climate change threatens both: a) the availability and quality of freshwater in the vast arid extension of the country (North and Center Mexico) and b) the population and infrastructure in the Southern region o the country, were heavy rains cause severe flood events. Aquifer overexploitation is also a crescent problem, associated to a fast growing population in the central highlands and to potential pollution in the karstic Yucatan peninsula, where groundwater is the only source of freshwater.

The effects of climate change on Mexican inland waters are mainly related to five processes: 1) changes in the water level of the systems and associated ecological impacts, 2) changes in the thermal structure and mixing regimes of lakes and reservoirs, 3) increased trophic state and intensification of hypoxia, 4) eutrophication and toxic algal blooms, and 5) increased respiration that turns the metabolic balance towards net heterotrophy. In particular, the processes implied in driving system shifts from sinks to sources of atmospheric carbon in tropical inland waters are discussed, although the data to build these analyses are still scarce and heterogeneous. We outline that research on tropical cyanobacteria metabolic treats may provide relevant elements to understand the increasingly threat of noxious phytoplankton blooms.

Here we highlight the research lines that need to be reinforced in order to create the strategies for preservation and management of freshwater in a sustainable way: 1) carbon, nitrogen and phosphorus fluxes should be estimated in ecosystemic to basin scales, and should be incorporated into long term studies of water quality, 2) pollutant assessment as well as water treatment programs must increase significantly (only 37% of the Mexican municipalities have water treatment plants), and 3) systematic monitoring programs should be included in country-scale planning.

Diverse social issues (e.g. inequity, corruption, security and drug dealing) threaten the possibility of coping with the challenges that climate change involve for continental aquatic systems in Mexico.

P-2212a-20

Analysis of groundwater level historical data to detect climate change impact in France

JF. Vernoux (1) ; JJ. Seguin (1)
(1) BRGM, Orleans, France

The level of groundwater bodies depends for many of them on the infiltration of meteoric water and will therefore be necessarily impacted by climate change if it causes a change in the infiltration system (intensity, period). To assess and monitor the impact of this change, a dedicated groundwater monitoring network is necessary. As this impact is currently unclear, the implementation of such a network involves an analysis of existing groundwater level data series.

The study was based on Mann-Kendall trend detection tests from groundwater level data and a comparison of trends between groundwater level data and climate data (precipitation, temperature, potential evapotranspiration). Trend detection tests were carried out on 377 piezometers of the french national groundwater quantitative monitoring network for which we had a data series of at least 25 years. In the end, 70 have a significant trend, 44 down and 26 up. Piezometers showing significant trend mostly concern aquifers with predominant annual hydrologic cycle. But most of aquifers in France have longer hydrologic cycles and statistical tests are not relevant because the data are autocorrelated and we do not have at our disposal long time series which are required for such tests. A sketch of spatial structuring trends has been identified, with rising levels for chalk aquifer in the Artois-Picardie basin and the center of the Seine-Normandy Basin and lower levels for chalk and Jurassic limestones aquifers in eastern Seine Normandy basin. Trends upward or downward may in some cases be influenced by groundwater pumping without that one can be demonstrated. The break tests show that the behavior change corresponds to the years in which water levels are significantly higher or lower than average or to the years that precede or follow these events. Finally, a tool for lumped hydrological modelling (Gardenia) was used to test the sensitivity of the groundwater level variations to potential evapotranspiration (PET). The results show that these variations have a relatively small impact on the groundwater levels, especially compared with model uncertainties.

In conclusion, this study shows that we cannot demonstrate a significant impact of climate change on groundwater levels because of too short time series but it reinforces the need to set up a monitoring network dedicated to the impact of climate change on groundwater. In order to set up that network, about 40 aquifers were selected with following creteria : unconfined aquifer, recharge likely to be impacted by climate change, large piezometric fluctuations, aquifer weakly impacted by withdrawals, aquifer to preserve for the future. To select piezometers for each aquifer, the main criteria was a low anthropogenic impact.

P-2212a-21

The Management of Traditional Hand Dug Wells

ALD. Wamba (1)
(1) Association AFVMC – Aide aux Familles et Victimes des Migrations Clandestines, Administration, Douala, Littoral, Cameroon

The population of Cameroon is about 22 millions of habitants. The country has at least 120 billion m3 of useable groundwater resources unevenly distributed. The proportion of Cameroon's population with access to clean water was estimated at 57.8 per cent in 2005. It was 40 per cent for rural areas.Groundwater Management provides information on the distribution of groundwater resources and the feasibility of the water supply technology through the building of traditional Hand Dug Wells (HDWs).Our objectives are to show how a successful management of HDWs are economically-viable for the water supply and for the sustainable development of communities.

The methodology of fieldwork involves three stages: the decision to establish a new, or renovate and existing Hand Dug Wells (HDWs) in the village, the construction/installation of the HDWs and Its management.The materials required:- Guided interviews/seminars/workshops with key informers (officers of the administration and NGOs, builders of HDW's technology, representatives of farmers and pastoral associations, professional diggers of HDWs, land committees, farmers, rural councilors and village chiefs).- Group discussions (focus groups to help identify key issues for field work and for the discussion of the preliminary results of research).

The analysis are:

The idea of common ownership of the HDW is a reality for more impactful stakeholders' engagement:

1) In local municipalities:

-the economical development of rural areas;- the availability of potable water for the population;- the reduction of water diseases;- the improvement of the hygiene and sanitation within the population;-the development of agriculture/irrigation/breeding

2) In associations of women interested in the management of HDWs:

-the availability of potable water to reduce the burden of fetching water dedicated to women and children;-the improvement of the hygiene and sanitation in houses;-the development of agriculture/irrigation/breeding;

3) In associations of youth interested in the management of HDWs:

-the learning of the duplication of the construction/management of Hand Dug Wells for the future and for the sustainable development of the locality;-the availability of job opportunities in the construction/management of Hand Dug Wells

The results are:

-the monitoring and the management of the HDWs by the rural communities;-the training of diggers, builders and users of HDWs;-the sustainability of HDWs;-the availability of water;-the supply of remote/ rural areas with water

Conclusion

Our conclusion includes the village subsistence -level cropping- with groundwater use for the cultivation of vegetable gardens and seedlings to the improvement of food security at local scale.

Recommendation

We recommend that the technology of building HDWs been developed further in many countries in Africa to improve the availability of water because significant findings and outcomes of the management of HDWs are in its replication:-by the learning of the construction/ management of Hand Dug Wells in primarily/secondary schools/associations of youth/universities;-by organizing workshops to train many trainees/teachers/diggers/ builders in the construction/management/technology of Hand Dug Wells(HDWs).

P-2212a-22

Glacier retreat from a regional point of view: Characterization of glacier area changes over the Southern Central Andes Region

N. Zazulie (1) ; E. Briche, (2) ; M. Rusticucci (3) ; GB. Raga, (4)
(1) University of Buenos Aires, Deparment of Atmospheric and Oceanic Sciences, Buenos Aires, Argentina; (2) UMI-IFAECI 3351/CNRS-CONICET-UBA, Buenos Aires, Argentina; (3) University of Buenos Aires, Atmospheric and Ocean Sciences, Buenos Aires , Argentina; (4) Universidad Nacional Autónoma de Mexico, Centro de ciencias de la atmosfera, Mexico DF, Mexico

In the region known as the southern central Andes of Argentina and Chile (between 30° and 37°S), some of the highest peaks are found. Glaciers are present in the high Andes from which originate several of the main rivers that flow through Chile to the Pacific and through Argentina to the Atlantic. Because of the temperate climate in the foothills on both sides of the Andes, this region is inhabited by the majority of the Chilean population as well as the largest fraction of the population in western Argentina. It is located in the transition between the region where the maximum precipitation over the Andes is observed and the desert regions of northern Chile. In this transition region, winter precipitation (mainly snow) associated with extratropical systems is sporadic in space and time and the melting of the yearly snowpack is the main source of summer river flow. Under these circumstances, mountain glaciers play an important role in the hydrological system of the region as they serve as a natural reservoir that can buffer the impact of dry seasons on socioeconomic activities in the region. Under a climate change context, the consequences of this phenomenon over glaciers are well observed at a global scale. Nevertheless a regional study of glacier variations over the Southern Central Andes Region has not yet been carried out.

We have selected images from the Landsat satellite from different years in the period 1989-2014. These images were obtained from the United States Geological Survey website. They have a spatial resolution of 30x30 m and they are ortorectified and georreferenced with the global reference system WGS84 and projected with the projection system UTM (Universal Transversal Mercator). All the images were obtained during the end of the ablation season, from the end of March to the beginning of April, when the seasonal snow has already melted. A false color composition that distinguishes ice surfaces was used. A supervised classification was applied with the purpose of making glacier evolution maps of the entire region. Changes are studied in terms of total glaciated areas and in individual glacier area.

Although some years have shown small advances, a general decrease in the total glaciated area was found. Both the altitudinal and latitudinal dependence was explored. Every latitudinal band has shown different rates of changes which imply that environmental factors other than latitude may play key role in determining the difference in the observed changes. Futherthermore, a number of glaciers were identified and studied as independent units which allows to consider other environmental factors, such as morphological characteristics of the different glaciers. As an example, the glacier Juncal del Sur (33°06'S, 70°07'W) situated in the Aconcagua river basin near the metropolitan area of Santiago de Chile has lost more than 25% of its total area between 1989 and 2014. Another glacier with accumulation zone at similar altitude, the Maipo volcano glacier (34°09'S-69°48'W) has reduced its total area by less than 20% in the same period. Even though the glaciers are situated within the same region, the second glacier belongs to a protected area. These factors are key when analyzing different behaviors within the same region.

2212b - Climate change and freshwater – 2: Shaping the Future

ORAL PRESENTATIONS

K-2212b-01

Water security: Global challenges, global responses?

F. Berkhout (1)
(1) King's College London, Geography, London, United Kingdom

Röckstrom et al. (2009) suggest using consumptive water run-off (or blue water use) as a proxy for global freshwater use. Assuming an upper limit of ~12 500–15 000 km3 year–1 of accessible blue water resources, they suggest that consumptive uses above a threshold of 4000–6000 km3 year–1 would represent a significant risk to ecosystems, moisture feedbacks and freshwater/ocean mixing. Given that consumptive use is now at about 2600 km3 year–1 the authors conclude that there appears to be some room for manoeuvre, although there continues to be a trend of rapidly growing consumptive water use at the global scale. An Anthropocene or planetary boundaries framing of global sustainable development problems suggests a global governance of planetary boundaries. But there are questions about whether the planetary (or global) scale is really the appropriate scale at which to govern many of critical global resources and environmental services, including water. Water is typically governed at the level of the river basin and ecosystem. Moreover, while for some global environmental problems, like stratospheric ozone depletion, global governance appears to have been, in large part, successful, there are questions about whether such global coordination can be achieved in other cases. While global governance regimes now exist in many environmental domains, including climate change, achieving an alignment of interests leading to a common understanding of the problem and effective action at the global scale has often proven elusive. Water security emerges at many different and connected scales, from the local to the global. There are important legal, regulatory and voluntary dimensions of global water governance that contribute to water security across these scales. These include norms about rights to water, trade in virtual water, technical and other standards for water use and quality, as well as international transfers of knowledge, technology and finance to support water security. The paper argues that much of the task of governance will need to be focused on fostering transitions in water use, starting at the local level.

Shaping the future of freshwater: towards a collective effort to enhance our understanding and capacity to model change

H. Savenije (1) ; A. Montanari (2) ; C. Cudennec (3)
(1) IAHS, Delft Technical University, Delft, Netherlands; (2) IAHS, Bologna University, Bologna, Italy; (3) IAHS, Allenvi, Agrocampus Ouest, Rennes, France

A large part of the Earth surface may still be in pristine condition, but humans have already had significant impacts on many hydrological processes relevant to society.

Humans have changed the face of the Earth dramatically over time and in doing so introduced substantial changes in the water cycle. Climatic change is one of these impacts, but effects of land use change on: erosion, the character of floods, droughts, and the partitioning and distribution of moisture fluxes are often more strongly noticeable at human scales.

In fact, the limited transferability of water in space and time implies that water withdrawals from natural resources take place where and when water is needed, thereby causing a direct perturbation to all water bodies relevant to society, and therefore to society itself. The current trend of population dynamics and the current status of water systems are such that this impact will not be sustainable in the near future. Therefore mitigation actions are urgently needed, and planning thereof needs to be based on improved interpretations of the impact.

Until recently, hydrologists mainly concentrated on catchments where human perturbation was limited, so as to improve the understanding of pristine hydrology. Nowadays, the urgency to mitigate the global water crisis through improved water management calls for research that attempts to bridge water and social sciences. To reach this target, new science is needed aimed at improved interpretation and modeling of the integrated human and water system. The question is how to build operational models that fully account for the interactions and feedbacks between water resources systems and society. This scientific challenge and the ambition to improve freshwater management in a changing environment together form the pillars of the science initiative «Panta Rhei», promoted by the International Association of Hydrological Sciences. Panta Rhei focuses on three targets, namely: to improve understanding; to enhance predictive capabilities; and to support societal planning. Two years since its inception, Panta Rhei already counts 30 working groups, involving about 300 scientists, who are developing innovative theories and modeling approaches to address the above challenges. In doing so, Panta Rhei is catalyzing a global and collective effort to assist societies to mitigate the global water crisis.

Water management planning is influenced by many natural and human factors that interact at basin scale. A multidisciplinary approach is therefore required to both understand and well represent the main characteristics of the water system before analysing its sustainability under global change and suggesting efficient adaptation measures. The complexity of the interactions and thus the challenge in modelling increase with the size of the river basin. This talk presents the main results of the research project R2D2-2050 "Risk, water Resources and sustainable Development within the Durance river basin in 2050" (Sauquet et al., 2014). The Durance River, one of the major rivers located in the Southern part of the French Alps, supplies water for competing human uses (irrigation, hydropower, drinking water, industries and more recently tourism and ecological services) within and out of the drainage area through an extended open channel network. The project R2D2-2050 aimed to assess whether the current water management – especially operating rules for the three main reservoirs – would need changing under future conditions taking into account evolutions in both climate and socio-economy.A multi-model approach was carried out to simulate regional climate, water resources, irrigation needs, water supply for domestic purposes, water transfers and reservoir operations. A model of water management similar to the operational tool used by the French hydropower producer EDF was also developed to simulate water released from the reservoirs on present-day conditions under constraints imposed by ecological flows and water levels in summer for recreational purposes. Four territorial socio-economic scenarios have been also elaborated with the help of stake holders to project water needs in the 2050s for the area supplied with water from the Durance River basin.

Results suggest:

- an increase in pressure on diminished water resources,
- a decrease in energy produced by the main dams mainly due to reduced annual inflows,
- a decrease in biological richness for intermittent rivers,
- a full compliance with water needs for priority uses downstream from the reservoir but less flexibility for hydropower management during winter peak energy demand if current water management rules are unchanged,
- more frequent restrictions on water abstraction reducing the demand to be met for sub-basins with no reservoir,
- socio economic scenarios as the most important source of uncertainty influencing the sustainability of the present-day allocation rules.

Those conclusions will be compared with previous findings from similar impact studies on other large French river basins (Seine (Habets et al., 2013); Garonne (Hendrickx and Sauquet, 2013)).

A citizen science approach to managing freshwater resources in the tropical Andes

W. Buytaert (1) ; B. Ochoa-Tocachi, (2) ; Z. Zulkafli, (1) ; B. De Bievre (3) ; M. Saravia Lopez De Castilla (3)

(1) Imperial College London, Civil and Environmental Engineering, London, United Kingdom; (2) CONDESAN, Quito, Ecuador; (3) CONDESAN, Lima, Peru

The tropical Andes are a hotspot of environmental change. The combination of global climate change, local land-use change, demographic growth, and increasing water demand is putting extreme pressures on water resources. This is of particular concern to rural upland communities. They are facing a double challenge of maintaining their own livelihoods with dwindling natural resources, and at the same time supporting downstream ecosystem services such as a well buffered stream flow and good water quality.

This challenge is complicated further by the acute lack of data on the hydrological functioning of Andean catchments. The factors that control their hydrological response are extremely variable in space and time, including meteorological forcing, land cover types, soil properties and geology. This makes it very difficult to predict accurately the impact of human activities such as land use, and watershed investments. Such predictions are essential for policy-making and sustainable ecosystem management.

In order to tackle the issue of hydrological data scarcity in the tropical Andes, we set up a citizen science initiative, implementing a network of hydrological monitoring of upland catchments in a pairwise fashion. Using a trading-space-for-time approach, the initiative aims to use these data to improve predictions about the impact of land-use changes and other ecosystem management practices on the hydrological response. Currently, over 25 catchments

are being monitored for precipitation and stream flow in 9 sites located in Venezuela, Ecuador, Peru, and Bolivia. The sites are supported by local stakeholders and communities in a participatory approach that otherwise would be impractical or prohibitively expensive.

Because of the technical challenges of monitoring hydrological variables in remote mountain areas, we set up a web-based infrastructure to support local technicians and stakeholders. Additionally, using open data standards such as those of the Open Geospatial Consortium, the data can be pooled efficiently for regional-scale analysis, as well as processed and visualized efficiently. Lastly, the datasets can be coupled to web-based hydrological models using rich and interactive interfaces. Such setups, which we refer to as "environmental virtual observatories", can support water and land users at different scales of decision-making, from community level to national governance entities, and at different levels of technical and scientific skills.

In our presentation, we will report on the effort of setting up a citizen science approach to monitoring freshwater resources in the tropical Andes, and how this can be used to support local management efforts. We will discuss our successes, as well as the remaining challenges in the technological, hydrological, and social science domains.

Science-policy interface to foster scientific development and uptake by policy makers for the purpose of water management in the context of climate change and climate change adaptation strategies development

F. Martini (1)
(1) Onema, Vincennes, France

Water resources challenges exacerbated by global change including climate variability can affect water security and human well-being. To globally face this situation, there is a need to develop evidence-based policy incorporating accurate information related to predicted global changes.

But water and climate change research outputs are insufficiently reaching water managers today. And there's a lack of places where water managers can express the scientific information they need to develop their adaptation strategies.

A science-policy interface (SPI) answers this challenge by enhancing science-based policy development and fostering dialogue between researchers and water managers. It first facilitates the expression of policy requirements of scientific knowledge for specific management decisions, and a common understanding of these needs. It identifies existing scientific knowledge fulfilling policy needs and influences development of research agendas to match future policy needs. It finally allows a mutual understanding and long-lasting dialogue between scientists and policy makers.

Three science-policy interface experiences studied at international, European and national levels led to identify some recommendations to set a sustainable science-policy interface helping to face the challenges of water and climate change.

The 6th World water forum recommended initiating an international networking platform for researchers and water managers in order to facilitate communications in relation to the IPCC and other UN conventions. The objective of such a water SPI is to provide relevant scientific inputs to help governments and water managers develop effective decisions and climate change adaptation strategies, considering the uncertainty related to the impact of climate change on water resources. A mapping of existing SPI mechanisms over the world initiated this investigation.

From 2010 to 2012 a science-policy interface for the water framework directive (WFD) has been operated by the European commission and France. This SPI intended to support WFD implementation by helping provide and if needed produce adequate scientific information.

With a view to improving the uptake of science by policy makers involved in water management decisions in the context of climate change, and conversely the comprehension by scientists of the needs of policy makers, Onema organized on 3 February 2015 a seminar between scientists and policy makers. This event allowed them to share their knowledge and views on scientific needs, and raise recommendations on science-policy dialogue enhancement.

Those three experiences led to consolidate some main principles to set and maintain a science-policy interface which allows a better evidence-based water policy development under climate change.

Establish a sustainable Community of practices (CoP). The CoP is a consistent group of stakeholders of the water sector: scientists, water managers, knowledge brokers, politicians, journalists, civil society, ensuring a multidisciplinary approach. It should engage stakeholders from all the scales of the water management (and around the world). It ensures the operating of the SPI.

Appoint Knowledge Brokers and form them. They are skilled experts dedicated, trained, and resourced to engage in the SPI. They assist policy makers in formulating scientific and technical questions, enhance the scientific knowledge transfer to the policy makers and contribute to keep research aligned with policy needs.

Improve Communication and Tools. Communication may be encouraged and improved at all levels through the creation of a platform in which the CoP can share information and network. Recent research findings and request for collaborators with particular expertise for future research projects can be shared there. Policy makers can there access scientific information digested into policy briefs and other publications, seek experts' scientific opinion, and communicate their research needs to scientists.

"Water crisis and tensions in Europe and in the Mediterranean by 2050: future scenarios?"

MA. Martin (1) ; S. Fernandez (2) ; M. Lang (3) ; J. Verdier (4) ; PL. Viollet (5)
(1) Académie de l'Eau, Water management, Paris, France; (2) IRSTEA, Umr geste, Strasbourg, France; (3) IRSTEA - Lyon, Research unit on hydraulics and hydrology, Lyon, France; (4) AFEID, Montpellier, France; (5) SHF, Paris, France

All around the world, water resources management is facing numerous challenges. The predicted effects of greenhouse gas emissions are of particular concern with regard to future droughts, which frequency and intensity are expected to increase. Despite the many uncertainties reflected in various future studies conducted in France, a general trend of decline emerges in the long term (2050-2070) with a 10 to 40 % decrease of the annual average river flows. Due to the decrease in snowy surfaces, rivers could also evolve from a nival (snowmelt dominated) regime to a pluvial (rainfall) regime, with lower flows during the summer - when crop evapotranspiration is at its maximum. Studies carried out on aquifers, suggest, under a business-as-usual scenario, an acceleration and intensification of the level of exploitation or of the degradation of the quality of many of them. Challenges and risks are particularly high in the Mediterranean countries, with a tendency towards an increased concentration of their population along coasts or within deltas, having direct and significant implications for drinking water supply and sanitation.

Foresight studies on water - related issues. The issue of scale is usually not discussed as such when conducting foresight studies. The watershed is certainly a relevant unit for surface hydrology. It does not, however, necessarily allow grasping groundwater, nor the territorial basis upon which public action is deployed. Greater emphasis should also be given to other scales such as water supply and water demands. On one hand, quantification is important in order to ensure the consistency of a given scenario, but it must be done a posteriori and not a priori. On the other hand, possible disruptions are difficult to model. Their probability of occurrence can certainly be quite well modeled, as long as a wide range of temporal uncertainty is acknowledged. What happens after any type of disruption is, instead, often qualitatively and quantitatively unpredictable.

Issues related to the status of global change. Climate

change is usually represented as a "driving force" of the system at stake, that legitimizes foresight debates, since it should lead to a decrease of water resources (on an annual or seasonal average),that could be very intense locally, and to a greater variability of the resource in space and time. While the water and climate nexus was brought to the international political agenda, the concept of adaptation also emerged, a concept to be differentiated from mitigation. Water issues are also to be framed in terms of adaptation, while having in mind that mitigation measures can significantly reduce adaptation costs.

Future issues. In Europe and in the Mediterranean basin, major issues are related to future tensions over water resources management and to likely induced disruptions. Possible answers to this should take into account the relations between climate change and the evolution of water uses, at an adequate time horizon (2050); it should also integrate hydrological and climate studies as well as social sciences approaches or results. Such is the aim of the international conference «Water Tensions in Europe and in the Mediterranean basin: water crisis by 2050?» organized by SHF, AFEID, the Water Academy and UISF, to be held at Paris (7-9 October 2015). Three cardinal themes have been identified: 1/Analysis of past and present "crises" and tensions on water resources. How, by whom and when, these past events have been classified as «crises» of «tensions»...? How were they governed, evaluated, explained? How may these analyses help in managing the future? 2/Forecast of the evolution of surface water and groundwater regime by 2050, and consequences associated in terms of water scarcity and water quality deterioration. The issue of uncertainty linked to the identified spatial scales shall be studied as well. 3/Methodological issues for prospective studies. How to build relevant analysis scales in prospective studies, how to relate them to water flows and territories? How to recognize and clarify uncertainties related to prospective studies and how to make more explicit the social and political dimensions that are inherent to prospective analysis? How to tackle water crises and their consequences? What kind of ruptures are to be considered? What can be expected from "new" technologies?

O-2212b-04

The importance of protecting and restore freshwater ecosystems for sustainable development and building resilience to climate change

S. Widforss (1) ; K. Lexen (2)

(1) Stockholm International Water Institue, International Processes, Stockholm, Sweden; (2) Stockholm International Water Institue, World water week & international processes, Stockholm, Sweden

According to OECD (2012), the global demand for freshwater is projected to increase by 55 % between 2000 and 2050. Freshwater ecosystems such as wetlands, lakes and peatlands are the most essential of ecosystem services providing for food security, income, health and resilience to climate change induced impacts. Safely managed water resources are necessary for human wellbeing, for protecting communities from climate induced vulnerability and risk. (Millennium Ecosystem Assessment 2005) Stress on already exposed water recourses has implications on local communities relying on the sources for their human security and livelihood; it will impair the ability to overcome inequalities, and enhance economic development (UN Water 2014). Women are at a higher risk of being negatively affected by hydro-climatic disasters, and to the exposure of water- and sanitation related diseases. Freshwater interlinks sustainable development strategies with effective mitigation action. Wisely managed water strengthens climate adaptation capacities and protects livelihoods. Freshwater ecosystems harness the potential for reduced climate vulnerability, while being vital for resilient, prosperous communities, and this should be acknowledged in global policies. Further, bridging the gap between policy and practice; facilitating the integration and application of local expertise from indigenous communities, is necessary in order to build relevant capacity.

P-2212b-01

Climatic Change in the Amazon Estuary: perception of changes and impact on production by traditional population

O. Almeida (1) ; S. Rivero, (2) ; N. Vogt, (3) ; CM. Alvez-Valle, (4) ; Y. Dou, (5) ; S. Thomas (1) ; N. Moreira, (6) ; A. Saldanha, (7) ; V. Zeidemann (8)

(1) UFPA, NAEA, Belem PA, Brazil; (2) UFPA, Economics, Belem PA, Brazil; (3) INPE, Sao Jose dos Campos, Brazil; (4) UFJF, Ecology, Juiz de Fora, Brazil; (5) Waterloo University, Geography, Waterloo, Canada; (6) IFPA, Aqualtic, Belem PA, Brazil; (7) Emater, Pesca, Belem PA, Brazil; (8) Federal University of Pará, Economic Graduation Program, Belém, Pará, Brazil

The studies on climate change in Amazonia have focused on the impact of changes on the regional climate (Coe et al 2002, Costa et al., 2013, Costa et al, 2007, Sampaio et al., 2007, Oliveira et al 2013) or on the relationship of climate change and reduction of biomass (Phillips et al. 2013) and more recently on the interactions between human activities (such as deforestation), climate change and the water system (Melack et al 2013). This paper aims to analyze the perception of traditional estuarine population in relation to climatic events in the Amazon and assess the potential for adaptation to climate change in this population.A semi-structured questionnaire was applied with 239 families in two communities in the municipality of the state of Pará Abaetetuba Perceptions of climate impacts vary according to the activity and the type of weather event to be evaluated. In general the product dries on the tree or fall and, according to the interviewees, can reduce yields by up to 46%. Regarding the fishing activity the answers were not as uniform as for the acai. In general, 54-58% report that high temperature affects the shrimp and fish (respectively) reducing their catch. The shrimp seem to be more susceptible to temperature and most of the informants said that the reduction occurs in the range 10-20% of production. The perception that temperature affects fishing fish is low (23% of total). The impact of rain, however, was remarkable for fishing. Most of the respondents say that increased rainfall and reduces fish and shrimp production (78% and 81%, respectively). In this case, around 50% said that production is reduced between 10-20% while 20% say that the reduction is around 50%. The tide seems to have huge impact on fisheries. In this case, the respondents said that when the tides were higher there was a large reduction in fish and shrimp production (92 and 95%, respectively). Surprisingly while 65% of respondents said that there was no way to reduce the impact of high temperatures on shrimp farming and fishing, the rest (45%), for the most part, believed that reducing deforestation would be a way to alleviate the impact. The population of the estuary is subject to a continuous process of adaptation. The cycle of the sugar cane mills encouraged the planting of sugar cane (from 1920 to 1987, Anderson 1991) resulting in deforestation of lowland forest. In 1987 in end of the cycle, the population began the cycle of palm hearts, cutting down much of the native palm heart trees and finally with the rising price of açaí fruit they began a process or maintenance of forest with enrichment of açaí forests or replanting açaí trees in areas previously cleared. In 1984 with the construction of Tucuruí hydroelectric dam, there were huge drop in fish catch (Juras et al., 2007) downstream of the dam to which the population also had to adapt. These experiences resulted in a higher capacity of adaptation by local population. However, with the major limitations of possible activities in the várzea and the high dependence on fishing and açaí this population need to be aware of the impacts.

P-2212b-02

WEBRESNAT: A Geoenvironmental Tool of GHG Emissions on Natural and Anthropogenic Aquatic Environments

R. Barreto (1) ; E. Santos (1) ; F. Justino, (1) ; V. Pereira, (1) ; M. Freitas, (1) ; L. Pinguelli, (1)

(1) International Virtual Institute of Global Change - IVIG, Centro de Tecnologia, UFRJ, Rio de Janeiro, RJ, Brazil

Concentration of natural greenhouse gases (GHG) in the

atmosphere have increased because of anthropogenic activities, but information on their emissions are still scattered in the scientific community. Hydroelectric dams have become the subject of speculation that their reservoirs are contributing to the intensification of the GHG effect. In 2006, IPCC decided to discuss a specific section to the issue of artificial wetlands where hydroelectric reservoirs are totally relevant. Research conducted primarily by COPPE / UFRJ in Brazil have shown that these systems have emissions, particularly CO2 and CH4. However, studies show that depending on the construction, operation, climate, soil and wetland biome type, hydropower reservoirs emit less or similar to various natural environments (wetlands, peat, rivers and estuaries). Thus, owning a GHG emissions database hydroelectric reservoirs and natural aquatic environment (wetlands, rivers, lakes, estuaries, etc.) are essential so that we can have a review of this issue and to make comparative studies. However, by 2012 it had no information about the existence of a database with this focus. As a result, the IVIG/COPPE from Brazil created WebRESNAT (http://webresnat.ivig.coppe.ufrj.br), in order to make available to researchers information about greenhouse gas emissions (CH4 and CO2) in hydroelectric reservoirs and natural aquatic environments worldwide. The study consisted of developing a database system based on GIS (Geographic Information Systems), whose objective was to collect, develop and disseminate information to assist in the analysis of the GHG and various geo-environmental parameters in hydroelectric reservoirs and natural environments through an online portal. The next steps will be oriented to the expansion, refinement and further details of the portal, using interactive maps that allow the user to view different aspects of specific areas and phenomena in question, as well as the lines of your interest, the different scales and varying degrees of detail. After its development, will become a very useful tool for the research community, because with it you can promote interactions, intercomparisons, collaborations and joint analyzes.

P-2212b-03

Integrated Modeling in support of Transboundary Water Cooperation in Central Asia: Ili-Balkhash watershed

A. Baubekova (1)
(1) Industrial Trading Group, Ecology, Astana, Kazakhstan

There is a concern that the Lake Balkhash can repeat the fate of the Aral Sea. Balkhash is the second largest lake in Central Asia and it has environmental, social and economic value for Kazakhstan. The loss of the Lake will lead to the deterioration of the climate change consequences in the region. An increase of the average air temperature by 1.3°C during the century that country is already facing is two times higher than the global warming value. This results in massive desertification and soil degradation, which will negatively impact on economy and living conditions in the region.

In order to verify this assertion an integrated model of the transboundary Ili - Balkhash watershed was done. Climate change and socio-economical changes were assessed for the level of influence on the lake system. Climate Change analysis was processed in Astana with the support of Laboratory of Energy, Ecology and Climate of Nazarbayev University Research and Innovation System. A Bayesian statistical model was used in order to make probabilistic forecast of climate change in the regional scale (Tebaldi et al. 2005). The analysis of socio-economical changes was based on the use of GIS techniques and remote sensing as well as literature review. Nine main scenarios were developed including climatic, economic and combined sets. An initial scenario showed that the Lake Balkhash is actually drying and current system is unstable. The best or 4.5 scenario that provided favorable conditions for the water regime has showed the only positive result and increase of water level. But this scenario is not realistic as finding of this study indicated the rapid economic growth in the near future due to population increase. Therefore combined p4.5 scenario was found more feasible. Under this scenario lake volume gradually fell but did not exceed the minimum level. The worst scenario (r8.5) showed the complete loss of the lake in fifteen years. Despite the fact that this last scenario is based on the maximum values and implies dramatic changes in the climate conditions and economic activities it is still possible to happen. Therefore countries were recommended not only to examine current watershed management strategy and come to consensus on the Ili river water use limits but also to reconsider energy strategy and consumer behavior of the local population.

P-2212b-04

Comparison of climate change impacts on the recharge of two karst systems computing different modelling approaches

Y. Caballero (1) ; B. Ladouche, (1) ; S. Lanini, (1) ; JJ. Seguin (2) ; JB. Charlier, (1) ; L. Cadilhac, (3) ; JC. Maréchal (1) ; C. Pagé (4)
(1) BRGM, Water division, Montpellier, France; (2) BRGM, Orleans, France; (3) Rhone-Mediterranean & Corsica Water Agency, Groundwater division, Lyon, France; (4) CERFACS, Toulouse, France

Karst systems constitute aquifers in which infiltration and groundwater flows are generally complex processes and are characterized by limited knowledge in terms of geometry and structure. Nonetheless, they often represent interesting groundwater resources, some of them being subjected to intensive exploitation and others non exploited due to their poor understanding. In the future, it is likely that climate change impact on water resources will increase the interest for such a kind of aquifers due to their strong infiltration and storage capacity, in a broad context of higher water scarcity.

The Lez and the Lison karst systems in Southern and Eastern France, respectively, provide 2 examples of such systems of several km² under two contrasted climate conditions, the first one being heavily exploited. This study presents a comparative climate change assessment on both karst systems. Nine climate scenarios corresponding to the Fourth assessment report of the IPCC (SRES A1B scenario), downscaled using weather-type methods by the CERFACS, have been applied to various recharge modelling approaches, as standard analytical solutions of recharge estimation and soil-water balance models. Results are compared and discussed in order to assess the influence on climate change impacts of i) the climate conditions (geographic location), ii) the groundwater exploitation and iii) the modelling approach.

P-2212b-05

Balancing water uses and availability under human- and climate-induced changes at the 2050 horizon

J. Fabre (1) ; D. Ruelland (1) ; A. Dezetter, (2) ; B. Grouillet, (1)
(1) CNRS, HydroSciences Montpellier, Montpellier, France; (2) IRD, Hydrosciences montpellier, Montpellier, France

Over the past decades, human and climatic pressures on water resources have been increasing in the Mediterranean region, and the area could experience higher water stress over the 21st century. This study aims to assess water stress by 2050 in Mediterranean river basins facing increasing human and climatic pressures, and to compare the impacts of a wide range of possible future socio-economic and climate trends.

A modeling framework integrating human and hydro-climatic dynamics and accounting for interactions between resource and demand at a 10-day time step was developed and applied in two basins of different scales and with contrasted water uses: the Herault (2 500 km2, France) and the Ebro (85 000 km2, Spain) basins. Natural streamflow was evaluated using a conceptual hydrological model. A demand-driven reservoir management model was designed to account for streamflow regulations from the main dams. Urban water demand was estimated from time series of population and monthly unit water consumption data. Agricultural water demand was computed from time series of irrigated area, crop and soil data, and climate forcing. Environmental flows were accounted for by defining streamflow thresholds under which withdrawals were strictly limited. Indicators comparing water supply to demand at strategic resource and demand nodes were computed. This framework was calibrated and validated under non-stationary human and hydro-climatic conditions over the last 40 years before being applied under four combinations of water use and climatic scenarios to differentiate the impacts of human- and climate-induced changes on streamflow and water

balance. Climate simulations from the CMIP5 exercise were used to generate 18 climate scenarios at the 2050 horizon (from nine climate models and two Representative Concentration Pathways). Two water use scenarios were considered: water uses of the 2000s and a trend water use scenario at the 2050 horizon, based on demographic and local socio-economic trends. The sensitivity of water stress to variations in the main drivers of water demand and availability under the trend water use and climate change scenarios was tested to assess the efficiency of potential adaptation measures.

Temperature projections show a clear increasing trend, particularly marked in the summer. Projections for precipitation are more uncertain and differ among the 18 scenarios considered. However, a decrease in spring and summer precipitation is expected in both basins. These climatic trends should result in changes in natural discharge: while scenarios diverge in fall, winter and spring, all 18 scenarios result in a decrease in summer low flows. Simulations revealed a significant increase in total water demand under anthropogenic and climate trends in 2050 in both basins. Results also show that projected water uses are not sustainable under climate change scenarios. While anthropogenic drivers could influence variations in water demand more than climate change, in the Herault basin the impact of climate change could be more determining than water use changes for the balance between water uses and availability. In some areas of the Ebro basin water use changes could have a larger impact than climate change on water stress. The combination of the trend water use scenario and climate change scenarios could also have a high impact on the respect of minimum environmental flows in both basins. Finally, water stress showed little sensitivity to individual variations in the drivers of water demand.

This study points out the areas most vulnerable to human- and/or climate-induced changes by 2050 in two Mediterranean basins. In both basins a combination of adaptation measures leading to a large decrease in water demand and an optimized management of water availability will be necessary in order to supply enough water to satisfy demand while limiting anthropogenic pressure on water resources to sustainable levels.

Revising the planetary boundary for freshwater use

D. Gerten (1) ; J. Heinke, (1) ; A. Pastor (2) ; J. Jägermeyr (1)
(1) Potsdam Institute for Climate Impact Research, Potsdam, Germany; (2) Wageningen University, Wageningen, Netherlands

The nine planetary boundaries represent thresholds for key earth system processes which, if crossed due to collective anthropogenic activities, may move the earth out of the Holocene status with potentially desastrous consequences for human societies. While the concept and quantitative basis of planetary boundaries has recently undergone a comprehensive update (Steffen et al., Science, 2015), some boundaries still require a more robust quantification, especially in terms of the upscaling of regional patterns to the planetary scale.

This presentation shows a way to improve the assessment of the planetary boundary for human freshwater use, and the proximity to this boundary given current and potential future water demand and use. Our core concept is to account for the environmental flow requirements of riverine ecosystems as local limitations to human water use, which serve as a basis for a geographically explicit 'bottom-up' estimation of the planetary boundary. Our pilot assessment indicates that respecting the environmental flow requirements yields a planetary boundary value that is potentially lower than suggested earlier. Different estimation methods to assess environmental flows suggest a boundary between 1,100 and 4,500 km3 consumptive water use per year (original estimate from Rockström et al., Nature 2009: 4,000 km3 per year). Thus, humanity's current consumptive water use (~1,600 km3/year, ~90% of which are for irrigation), let alone water withdrawal (~3,600 km3/year), already exceeds the lower end of this range that reflects strict rules on environmental flows. Moreover, local tolerance limits (specified in terms of the ecological flow requirements) are already exceeded in many places, such as in parts of southern Europe, southern Asia, the Near and Middle East, and in the western USA. Our assessment is based primarily on high-resolution simulations with a dynamic global vegetation and water balance model, LPJmL.

Building upon these results, the presentation also elaborates on how the definition and quantification of the freshwater boundary can be improved further, for example by including «green» water conributions, process linkages with the planetary boundary for land-system change, and also water ethical considerations.

P-2212b-07

"Garonne 2050": an innovative participatory prospective study on the base of a strategy of adaptation to global changes for the Garonne river basin

F. Goulard (1)
(1) Agence de l'eau Adour-Garonne, Toulouse, France

With its "Garonne 2050" study, the Adour-Garonne Water Agency, which covers the south-west quarter of France, carried out a forward-looking analysis of needs and resources, primarily taking into account the impact of climatic change. Although there remain considerable uncertainties about precipitation, by 2050, rising temperatures will result in a substantial increase in evapotranspiration in this region, what means less available water.

The study took place over a period of three years (2010 to 2013) combining a forward-looking methodology with the participation of the stakeholders (mainly water users) and simulations used to calculate the approximate amounts of water to be mobilised and costs involved for the agency managing the river basin .

The principal challenge for 2050 is that natural flow will be halved during the low-water period which itself will be earlier and longer (May to November). At the heart of possible scenarios for adapting to such changes, the key factor is the societal choice that will be made in response to the two-pronged question: what flow of water do we want in our rivers in the summer? And what are we able to do about it? Thus, the result of the simulation indicated that if we wanted, by 2050, to compensate for this natural hydrological reduction to maintain today's Target Low Water Flows (DOE) and preserve uses, biodiversity, aquatic recreational activities and landscapes during the summer period, then the total deficit, to be made good over the year, is around 760 Mm3/year (or to be more precise, a value between 480 and 1,200 Mm³ given uncertainties). As a comparison, summer surface water usage for irrigated agriculture in this basin currently amounts to around 400 Mm3 and water stored in hydroelectric reserves in this same area amounts to 1,200 Mm3.

Models of five initial exploratory scenarios were created and submitted for consultation. In this way, it was possible to reduce the scope of the strategic debate to three main water management scenarios.

One of the important conclusions of this study is that in a region that is both highly agricultural and attractive from a demographic point of view, it will be extremely difficult to secure uses and maintain a low-water flow as it is today with the natural hydrological context of the future.

However, without impacting the management of energy or completely sacrificing an activity like irrigated agriculture, it is almost impossible to maintain an acceptable low-water flow, without relying on additional storage. Other problems connected with the quantitative management of the water resource have not been sufficiently detailed in this study, which may lead to an under-estimation of the tensions at stake and the problems to come. These include pollution, of course, but also soil erosion and effects on biodiversity, river morphology and so on; all essential factors impacted and impacting the volumes of water available for various uses. Finally, since the study did not specifically look into questions of governance, its main aim is to highlight the scope of the debate, which can no longer be avoided in the Adour-Garonne basin. In addition to the efforts that are now necessary for each sector of activity, the study picks up on an important question: the way we arbitrate and reconcile between different uses and, therefore, the question of access, which will be increasingly strategic, to the water resource, an essential asset of a region of over 65,000 km2 which will accommodate over 5 million inhabitants in 2050.

That is why the Adour-Garonne water agency organizes in continuation of this study, a regional conference with controversies, beyond the river basin committee, by integrating questions of choices of lifestyle of the citizens...

Longuevergne (12) ; E. Martin (13) ; T. Morel (14) ; F. Regimbeau (10) ; D. Thiery (15) ; JM. Soubeyroux (16)

(1) CNRS, UMR 7619 Metis, université Pierre et Marie Curie, Paris, France; (2) Mines-Paristech, Geosciences, Fontainebleau, France; (3) ANTEA group, Hydrogeology, Orléans, France; (4) UPMC, Umr metis 7619, Paris, France; (5) BIPE, Issy-les-Moulineaux, France; (6) BRGM, Eau, Montpellier, France; (7) CNRS - University of Strasbourg, Lhyges, Strasbourg, France; (8) BRGM, Water Environment & Ecotechnologies, Orléans, France; (9) ONEMA, Paris, France; (10) Météo-France, Dclim/avh, Toulouse, France; (11) Géosciences Rennes, Cnrs, Rennes, France; (12) CNRS, University Rennes 1, Geosciences rennes, Rennes, France; (13) Météo France, Cnrm-game, Toulouse, France; (14) CERFACS, Toulouse, France; (15) BRGM, Eau, Orléans, France; (16) Météo-France, Dclim, Toulouse, France

Although nowadays groundwater resources are mostly affected by increasing water abstraction, they will have to face the impact of climate change. Even in a temperate climate as the one in northern France these two drivers will have strong impact on the aquifers. Evolution of groundwater resource is most often studied based on evolution of the rainfall infiltration that is assumed to be the aquifer recharge, although river-aquifer and multi-layer aquifer exchanges are also part of the recharge and can only be estimated using a hydrogeological model. Moreover, providing a change of the piezometric level is usually not found to be meaningful by stakeholder as a 1 meter variation can have different impact depending on the hydrogeological context. Therefore, in this study, to provide greater insight into the impact of groundwater, two new indicators are used: the evolution of the extension of groundwater-fed wetlands and the frequency with which a crisis piezometric head is exceeded. The crisis piezometric levels are used locally by stakeholders and as soon as the observed piezometric heads fall below these levels, actions are taken to preserve the water resource.

For the present study, the local crisis piezometric heads were extended to the whole studied basins, the Seine and Upper Rhine Graben basins.

The results show that the two basins under study are not affected in the same way by climate and groundwater abstraction changes. The Seine multi-layer aquifers are projected to suffer from

a substantial decrease in rainfall infiltration (about 20%), while the decrease is lower in the Upper Rhine Graben aquifer (about 6%).

In 2050, the extension of groundwater-fed wetlands is expected to lose about 900m2/km2, while the crisis piezometric heads are expected to be exceeded about 40% and 26% of the time on average on the Seine and Upper Rhine Graben aquifers, respectively. The reduction of the groundwater abstraction has a large impact locally but is not efficient enough to overcome the impact of climate change, although the impact is more sensitive on the Upper Rhine Graben than on the Seine,

and particularly on the extension of wetlands and low flow. Sensitivity to the parameters that drive the river-aquifer exchange was found to be second order compared to the uncertainty due to the

climate model in the Upper Rhine Graben, although these parameters have a considerable impact on present-day estimation of the aquifer balance. The two indicators are found to be highly useful to discuss the impact of climate change on groundwater with stakeholders.

In order to be able to extent such studies to the whole aquifers of France, and to have a survey of such impact as soon as new downscaled projections are available, the AquiFR project is bringing together hydrogeological applications used by stakeholder in a common plateform that will be based at Météo-France.

P-2212b-09

Monitoring and Evaluation of water of Quality of Taal lake, Philippines

F. Martinez (1) ; I. Galera, (2)

(1) De La Salle University dasmarinas, Physical Sciences Department, College of Science and Computer Studies, Dasmarinas City, Philippines; (2) De La Salle University dasmarinas, Psd, dasmarinas, Philippines

The study is an update on the physico-chemical properties of Taal Lake for local and government officials and non-government organizations to determine if there is a change in the quality of water in relation to climate change and environmental effects. A total of nine (9) water quality parameters were monitored and analyzed. The study shows that Taal Lake's surface temperature, pH, total dissolved solids, total suspended solids, color, and dissolved oxygen content conform to the standards set by the DENR while phosphate, chlorine, and 5-Day 20°C BOD are below the standard. T-test result shows that there is no significant difference in the overall average of the two sites at Taal Lake ($P > 0.05$). Based on the data, the lake is safe for primary contact recreation such as bathing, swimming, and skin diving and can be used for aqua culture purposes.

P-2212b-10

Integrated Climate and Land Use Change on Downstream Ecosystem Service in the Ta Chin River Basin, Thailand

S. Monprapussorn (1)

(1) Srinakharinwirot University, Geography, Bangkok, Thailand

Ecosystem provides goods and services that sustain all life on planet earth. The services provided by ecosystem and their components are highly crucial for human well-beings such as provisioning of food, water and habitat, regulating carbon sequestration and providing recreational resources. Economies and livelihoods in developing countries heavily depend on ecosystem service. Climate change is expected to be major cause for changing in ecosystem services in variety of ways. Land-use and land-cover change (LULCC) involves several processes that are central to the estimation of climate change and its impact on ecosystem. It is, therefore, very important that integrated climate and LULCC change framework scenarios will enhance the current and future knowledge of ecosystem services. The area of study is located in downstream portions of the Ta Chin river basin where the river Ta Chin passes through the heart of province and flows into gulf of Thailand. It consists of many tributaries networks which connecting the ecosystem of lands and seas make it as a suitable place for fishery and aquaculture.

This paper aims at exploring potential impact of climate and LULCC change on ecosystem services in downstream areas of the river basin. Three Land-use change scenarios were developed; business as usual scenarios (BAU), high economic growth (HEG) and green growth (GG) scenarios and integrated to different climate scenarios (RCP 4.5 and RCP 6.0). For a case study, downstream ecosystem service in a changing climate and LULCC will be quantified baseline and projected change in provisioning of habitat and water supply. The interaction of socioeconomic development and changing climate on runoff, streamflow and precipitation will be studied. The scenarios shows that habitat loss is expected to occur in a basin in according to urban/resident sprawl (HEG scenario). Projection also reveals the increase in extreme precipitation in rainy season that might dominate runoff than recharge. Altered service of ecosystem leads to substantial effect on local livelihood. The results found that integrate climate smart land-use planning needs to be taken into consideration. It will reduce vulnerability and increase more efficient in water resource planning and resilience of local communities.

P-2212b-11

Salinity intrusion in the Mekong delta of Vietnam: Challenges and Solutions

H. Nguyen (1) ; S. Tyler, (1)
(1) Institute for Social and Environmental Transition – Vietnam, Hanoi, Vietnam

Mekong delta is located in the South of Vietnam, where salinity intrusion has been observed for many decades (Nguyen et al, 1999). As with many deltas, the Mekong delta is a□ected by both river floods and tidal inflows. Before 1980, salinity impacted 1.7-2.1 million ha of a total 3.5 million ha of agricultural areas of the Mekong delta every year during the dry season. In the 1980s and 1990s, a number of salinity control projects were implemented, including the construction of closure dams and sluice gates in the navigation canals connecting the branches of the delta. However, fresh water intakes along key estuary branches are a□ected each year by high salinity (Nguyen, 1999; Le A. T., 2006; Chu, T. H., 2012). As a result, these intakes have to be closed for anywhere from a few weeks to two months each year to prevent salt intrusion. (Nguyen and Savenije, 2006; Chu, T. H., 2012).

In recent years, stronger ocean tides and saline intrusion as a result of sea level rise are changing Mekong river flow in the dry season. Saline intrusion has started to influence river water near Can Tho city which is 65km far from the costal line and it impact to almost of sectors such as agriculture, aquaculture, infrastructure, water supply and local livelihood (ISET, 2013). According to the climate change scenario of the Ministry of Environment and Natural resource of Vietnam, the Mekong delta will be impacted significantly by sea level rise and salinity intrusion in the future (MONRE, 2012). The close proximity of measured saline intrusion to the cities and provinces in the Mekong delta and the vulnerability of residents to that intrusion have made this an issue of concern for people in the region. The combination of land subsidence, sea level rise, upstream dams and extractions, and tidal flows are projected to produce rapidly increasing salinity levels. With an unusually high reliance on surface water for industrial, residential, and agricultural use, the regional stakeholders quickly recognized the need to respond to the situation. To further complicate matters, daily fluctuations provided a strong impetus to monitor levels as could provide real-time data to ensure that citizens, water utilities, public health agencies, farmers, and local industries were informed.

This paper introduces a new model of real-time salinity monitoring system, which has been installed, and maintaining in the Mekong delta. Without the ability to halt the salinization process, the paper presented a strong example of resilience planning. It enabled adaptive management at a household and institutional level. It brought multiple stakeholders together, including city and national departments within government, and also involved collaboration with telephone companies to deliver SMS alerts. In addition, it focused on a pressing, but not immediate challenge, a category for which it's difficult to generate interest or commitment. This paper also reviews scientific information related to salinity intrusion as well as the perspectives of scientists, key local stakeholders, and local communities in order to assess the likelihood for salinity intrusion in the Mekong delta and, based on that, review possible options for the next steps of planning and decision making.

P-2212b-12

Impacts of climate change in the Bolivian Altiplano

PL. Pacheco Mollinedo (1) ; AL. Gonzales Carrasco (2) ; J. Molina (3) ; A. Veizaga (1)
(1) Agua Sustentable, Climate Change Adaptation, la Paz, Bolivia; (2) Agua Sustentable, Climate change, La Paz, Bolivia; (3) Universidad Mayor de San Andrés, Instituto de hidrología e hidraulica, La Paz, Bolivia

Introduction
The biggest impacts of global climate change will be felt mostly in developing countries, specifically smallholder farmers like in the case of the Bolivian Altiplano. The vulnerability of the people living in the Bolivian Altiplano comes in various ways; one is the location, the high altitude given semi-arid climatic conditions and the recurrence of ENSO natural phenomena.

The impacts of climate change on water resources in the Altiplano will have consequences on the availability of the resource and its growing demand to meet the requirements of drinking water and irrigation for agriculture.

The focus of the study is the Mauri and Desaguadero river basin, located in the Bolivian highlands part of the binational (Bolivia-Peru) TDPS hydrological system (Titicaca, Desaguadero, Poopó and Coipasa salt lake). The Mauri and Desaguadero rivers provide irrigation water to more than 24.000 ha. of crops.

The aim of this study is to assess the impact of climate change on the historical availability and requirements of water in a basin of the Bolivian Altiplano as a base line to build future scenarios to construct a participatory integrated adaptation Plan for the basin.

Methods
For this topic, three specific studies (water availability, water rights and water requirements) are considered combining field work with participation of stakeholders in the area and office work to process the data acquired.

Water availability
This procedure implies the collection and process of hydrological data (1965-2012), defining the curves of discharge of hydrometric stations in the basins Mauri - Desaguadero and Lake Titicaca, and obtaining series of daily flows, monthly averages and annual averages validated.

Water Rights
To have a view of the local management of water in the basin, a mapping rights study was developed, it allows to spatially visualize the water rights in relation with the customary rules applied to the social organizations of users. The methodology consists on interviews to stakeholders, workshops with communities and processing work. The most important tool is the GIS to process the information (Villarroel et al., 2014).

Water requirements
The water requirements methodology for crops and wetlands begins with the collection of productive information, weather information and the information about social management of water.

The main irrigated crops in the area are alfalfa (Medicago sativa), potato (Solanum tuborsum), barley (Hordeum vulgare), oats (Avena sativa), wheat (Triticum aestivum), native grasses, introduced grasses and quinoa (Chenopodium quinoa). A considerable area of wetlands is also important for the requirements in the basin.

Results and discussions
A hydrological database (1965-2012) of 21 stations located throughout the TDPS system was generated to use it in flow calculation. The results in the model showed that during the period 1990 - 2012 a significant reduction of the annual average flow is observed for the stations in the Mauri and Desaguadero Rivers. The reduction on the average flow of the Desaguadero river is caused by the contributions of Titicaca Lake, rainfall reduction and increased water usage in the upper side of the watershed (Molina et. Al. 2014).

The common law is that, in practice, grants, regulates and guarantees the rights of access to water for the residents of the area. Likewise, customary law is backed by positive law in different standards starting with the new Constitution of Bolivia that recognizes the habits and customs in water management.

After looking at the results of this study, it is important to consider that if the availability of water decreases and the water requirements increases, a deficit of water will be a fact.

P-2212b-13

Influences of Climate Change on Freshwater Water Resources Availability in a Basin Located in Asian Monsoon Region

W. Sun (1) ; J. Yu, (1)
(1) Beijing Normal University, College of Water Sciences, Beijing, China

The influences of climate change on fresh water resources availability in Chinese Jinjiang Basin located in Asian monsoon region were assessed using the Block-wise use of the TOPmodel with the Muskingum-Cunge routing method (BTOPMC) distributed hydrological model. The ensemble average of downscaled output from sixteen GCMs (General Circulation Models) for the medium CO2 emission scenario in the 2050s was adopted to build regional climate change scenario. The projected precipitation and temperature data were used to drive BTOPMC for predicting hydrological changes in the 2050s. Results show that evapotranspiration will increase in most time of a year. Runoff in summer to early autumn exhibits an increasing trend, while in the rest period runoff shows a decreasing trend, especially in spring season. From the viewpoint of fresh water resource availability, it is indicated that it has the possibility that water resources may not be sufficient to fulfill irrigation water demand in the spring season and one possible solution is to store more water in the reservoir in previous summer.

P-2212b-14

Uncertainties in establishing hydrological impacts of climate change: what do we really know?

M. Tumbo (1)
(1) University of Dar es Salaam, Institute of Resource Assessment, Dar es Salaam, Tanzania, United Republic of

The success of climate impact assessment studies is partly dependent upon the uncertainties in the reliability of the future climate estimates derived from one or more GCMs or RCMs but also depend upon the ability of the hydrological model to represent the catchment responses to climate variations and change. Thus, both hydrological and climate model uncertainties propagate through the entire assessment process and are not always easy to isolate. This study of the Great Ruaha River basin in Tanzania is based on the use of regional estimates of mean runoff, groundwater recharge and three flow points on flow duration curves (FDCs) to constrain ensemble outputs from the Pitman monthly model using Monte Carlo parameter sampling. The constraint bounds were quantified from gauged data available for 26 sub-basins together with assumptions about the spatial variations in hydrological response using limited physical sub-basin property and climate data. The results are encouraging in that the simulated FDC ranges bracket the observed curves at two gauging stations downstream of many ungauged sub-basins that are important sites for water resources development decision making. The established hydrological model (GW-PITMAN) with behavioural parameter sets has been utilized to simulate the effects of climate change projections on stream flow as given by three (3) GCM/RCM combinations using the RCP 4.5 emission scenario for the near future period 2031-2060. The RCM projections of change in monthly precipitation and potential evapotranspiration were estimated using the delta change approach where future climate conditions are compared to a reference period 1976-2005. Preliminary results based on three GCM_RCM combinations (NCC_RCA4, MPI-ESM_CRCM5 and MIROC5_RCA4) clearly indicate a shift in mean discharge. There are notable changes in both high and low flows. In all three GCM-RCM combinations, low flows are lower than the historical flow conditions, while high flows are higher than historical flow conditions. The high flows correspond to the projected increase in precipitation where initial results indicate a clear tendency across the RCM to increased precipitation in the wet season and decreased precipitation in the dry season with an overall annual increase in precipitation. A comparison of the uncertainty arising from the hydrological model and GCM-RCMs combination has been established based on the upper and lower bounds of the simulated historical and future stream flows. Figure 8.2 the upper and lower bounds for the three GCM-RCM shows an overlap between the historical and future predicted uncertainty.

2213 - Ecological feedbacks to climate change

How biodiversity mediates feedbacks from terrestrial ecosystems to climate change

S. Lavorel (1)
(1) CNRS, Laboratoire d'Ecologie Alpine, Grenoble, France

Climate change impacts ecosystems in multiple ways, in interaction with other global change drivers such as land use change, nitrogen deposition or biological invasions. These joint impacts may vary from radical shifts such as switches in vegetation types or loss of top predators to more subtle reorganisation of community composition and interactions across trophic levels. While their understanding has progressed tremendously over the past decades, many uncertainties still remain about their implications for earth system dynamics. This uncertainty is all the more critical as cascading impacts of biodiversity for the earth system have recently been recognised as one of the two highly integrated emergent system-level phenomena that are connected to all other planetary boundaries (Steffen et al. Science 2015).

Biodiversity affects ecosystem functioning and land surface properties through multiple mechanisms. These are often underpinned by so-called functional effects, which reflect the fact that the morphological, structural, biochemical or life history characteristics of organisms directly determine their effects on ecosystem properties, as well as their responses to global change drivers. In this presentation I will first review the diversity of functional mechanisms through which biodiversity affects ecosystem properties, and especially biogeochemical cycling. This review will emphasise the role of interactions among the functional characteristics of organisms and global change drivers, and between the functional characteristics of different groups of organisms that interact as part of ecological networks. Second I will summarise the available evidence across scales for such effects and highlight main uncertainties and gaps in terms of knowledge and data. Lastly I will outline how some recent research terrestrial modelling efforts have started to incorporate functional diversity and its role in the response and effects of vegetation on biogeochemical cycling.

K-2213-02

Responses of marine ecosystems to climate change and ocean acidification

W. Cheung (1)
(1) University of British Columbia, Fisheries Centre, Vancouver, Canada

Changes in temperature, oxygen level, acidity and other ocean properties directly affect marine ecosystems through shifts in biogeography, phenology, productivity and trophic interactions. This paper synthesizes our latest understanding on the extent to which climate change and ocean acidification are affecting global marine ecosystems structure, functions and services and the resulting vulnerability. As shown by analyzing global marine biogeography records and fisheries data, ocean warming has already been altering marine species assemblages in the past four decades. Moreover, mapping of vulnerability of almost 1000 species marine fishes in the global ocean based on their exposure to climate stressors and biological sensitivity and adaptive capacity indicates that most of the studied marine fishes become highly vulnerable to climate change under high greenhouse gas emission scenarios. Such findings corroborate with results from simulation modelling of global shifts in distributions of marine fishes and invertebrates, highlighting the large climate risks of regional ecosystems, particularly in the tropics, in terms of decreases in biodiversity and key ecosystem services such as fisheries. Scope of adaptation to these changes may not be sufficient to substantially reduce these risks, particularly in sensitive ecosystems. These evidence demonstrates the multi-facet responses of marine ecosystems to climate change, identify hotspots of vulnerable ocean regions to climate change, and highlights the need for ongoing interdisciplinary efforts between marine biologists, ecologists, oceanographers are needed to further reveal the multi-scales (spatial, temporal and

organizational) responses of marine ecosystems to climate change, ocean acidification and interactions with other human stressors.

O-2213-01

Ecological emergence of thermal clines in body size

E. Edeline (1) ; G. Lacroix (1) ; C. Delire (2) ; N. Poulet (3) ; S. Legendre (4)

(1) Institue of Ecology and Environmental Sciences, Paris, France; (2) GAME/CNRM, CNRS/Météo-France, Paris, France; (3) French National Agency for Water and Aquatic Environments (ONEMA), Vincennes, France; (4) CNRS, UMR 7625 Ecologie & Evolution, Paris, France

The unprecedented rate of global warming requires a better understanding of how ecosystems will respond. Organisms often have smaller body sizes under warmer climates (Bergmann's rule and the temperature-size rule), and body size is a major determinant of life histories, demography, population size, nutrient turnover rate, and food-web structure. Therefore, by altering body sizes in whole communities, current warming can potentially disrupt ecosystem function and services. However, the underlying drivers of warming-induced body downsizing remain far from clear. Here, we show that thermal clines in body size are predicted from universal laws of ecology and metabolism, so that size-dependent selection from competition (both intra and interspecific) and predation favours smaller individuals under warmer conditions. We validate this prediction using 4.1 million individual body size measurements from French river fish spanning 29 years and 52 species. Our results suggest that warming-induced body downsizing is an emergent property of size-structured food webs, and highlight the need to consider trophic interactions when predicting biosphere reorganizations under global warming.

O-2213-02

From cut twig to satellite – understanding the full response of phenology to climate change

A. Menzel (1)

(1) Technische Universität München, Ecology and Ecosystem Management, Freising, Germany

Phenology (the timing of seasonal natural events such as plant growth or animal migration) is now commonly used as indicator for evaluating responses of ecosystems to climate change. More than 500 papers are published annually that include 'phenolog*' in their title and many of them are related to anthropogenic change. Recent phenological changes have been reported across the globe, continents, ecosystems, habitats and taxa, predominantly as mean temporal changes ('trends') or as relationships to temperature and other drivers ('responses'); they have been summarized in various meta-analyses as well as in the IPCC WG II contributions to the AR4 and AR5. Although it has been well known during the 20th century that phenological events are triggered predominantly by climate, it was only in the late 1990s that phenology emerged as a key asset in identifying fingerprints of climate change in natural systems, when significantly advancing spring events were identified on larger scales mirroring recent warming.

Since then, phenological research has made considerable advances but is now at a crossroads of understanding its full climate change response and associated variability. Especially, other drivers of phenology than forcing by spring temperature, such as chilling and photoperiod preventing too early spring development and thus damage by late spring frosts, precipitation, snow, nutrients, ambient CO2 concentration or management effects have come to the fore. In addition, more emphasis has been given on reproductive phases and autumn changes in the last decade. The reported variability in observed trends and responses has been related to geno- / phenotypes, microclimate in stands, provenances and origins, species, species traits and phylogeny, regional climates and methodological considerations.

The timing of leaf development strongly regulates earth-atmosphere interactions and thus climate feedbacks, e.g. via biogeochemical cycles and impacts on the global energy balance, as well as biotic processes, such as pollination, agricultural and forestry production, and human health (via allergenic pollen). Thus, a full explanatory understanding of phenological drivers, accurate predictions and development of adaptation options are emerging topics which also need a full acknowledgement of the observed variability in trends and responses. In data-intensive analyses of observations, the inherent variability may facilitate the correct identification of all drivers, whereas in novel experimental approaches, the observed variability may call for a higher number of species, treatments and replicates. Variability may yield to more plasticity and resilience to climate change and thus phenological responses will drive the fitness and adaptation capacities of species. In this review, I summarize the current knowledge and recent insights into observed changes in phenology from satellite data to multispecies records, describe observed spatio-temporal variability linked to species traits and regional climates and highlight the role of additional drivers other than spring climate recently derived from cut twigs. Only a full consideration of variation in these responses will allow a complete understanding of ecological, cultural and socioeconomic consequences of these phenological changes mirroring climate change, driving impacts in the biosphere and feeding back to the climate system.

Effect of climate and site factors on exotic plant invasion in West Virginia, USA

R. Gazal (1) ; M. Burkowski, (1) ; K. Gazal, (2)

(1) Glenville State College, Department of Land Resources, Glenville, WV, United States of America; (2) West Virginia University, School of natural resources, Morgantown, WV, United States of America

Global climate change is known to contribute to the proliferation of non-native invasive plants worldwide. Moreover, human-caused soil disturbance favors the growth of invasive plants, which negatively impacts the productivity of forest ecosystems. This study aims to examine the distribution of invasive plants in West Virginia and identify the site and climatic factors that contribute to exotic plant invasion. In 2007-2008, the U.S. Northern Research Station's Forest Inventory Analysis Program (NRS-FIA) surveyed the presence and extent of 20 invasive plants in West Virginia. Approximately 20% of permanent forested plots in 46 of the 55 counties were surveyed. The non-native plants were chosen based on range, invasiveness, and level of landowner interest. We generated maps and performed geospatial analysis using Geographic Information System (ArcGIS v.10). The most abundant invasive species was multiflora rose, (Rosa multiflora) which was present in 48% of the forested plots and 77% of the inventoried counties. Japanese stiltgrass (Microstegium vimineum) occurred in 52% of WV counties and was recorded in 24% of the sample plots. Nearly 25% of the sample plots containing Japanese stiltgrass had 25 to 70% cover. Autumn olive (Elaeagnus umbellata), tree-of-heaven (Ailanthus altissima), and garlic mustard (Alliaria petiolata) were present in 18, 14, and 10% of the forested plots, respectively. Each of West Virginia's ecoregions contains large number of invasive species with the Northern Ridge and Valley and Southern Unglaciated Allegheny Plateau sections containing the highest amount of 85% (n=17). Among the 46 counties, Hardy County contained the largest number of invasive plants surveyed at 65%, while Lewis County held 50%, and Ritchie and Hampshire Counties contained 45%. Logistic regression analysis of site and climatic factors ($p > 0.05$) reveals that the occurrence of Japanese stilt grass and garlic mustard is indirectly related to elevation and temperature while forest cover and road density are directly related to the presence of Japanese stilt grass and tree-of-heaven, respectively. Understanding invasive species and the environments where they exist is essential to gauge their impact and control their spread in West Virginia. Key site factors (elevation, aspect and slope), disturbance regime (land use types, amount of timber removal, degree of urbanization, fire occurrences and road density) and climate factors (temperature and precipitation) contribute to rapid increase in the distribution and abundance of non-native invasive plants.

How soil microorganisms respond to and feedback climate change under non-extreme to extreme water fluctuations

JC. Lata (1) ; A. Kaisermann (2)
(1) iEES Paris (Institute of Ecology and Environmental Sciences – Paris), Community Diversity & Ecosystem Functioning (DCFE), France, France; (2) The University of Manchester, Faculty of life sciences, Manchester, United Kingdom

The response of soil to water fluctuations is poorly understood which result in high uncertainties about the effects of climate change and the associated feedbacks. Through several French national and regional research programs, different scenarios of drought–wetting (DW) intensities were simulated in microcosms and the dynamics of telluric microbial communities were followed to assess their stability in terms of diversity and function.

Thess studies highlighted a critical minimum moisture threshold below which microbial community stress was induced. Below this threshold, the wetting of dry soils induced (i) a large flux of CO2 (called the 'Birch effect'), which could be finely predicted from the intensity and duration of drought and wetting and (ii) erosion of bacterial diversity, leading to a structural instability in the following DW cycles. Despite an overall functional resilience, bacterial and fungal communities exhibited permanent modifications. Finally, the effects of DW events were also partially modulated by the soil physicochemical characteristics inherited from management practices.

These changes in microbial communities may be related to the size of soil pores, with more intense drying causing usually moist micropores to dry out. The stress of microbial populations less adapted to these disturbances, could result in (i) higher population turnover and intense competition for new available ecological niches and (ii) the establishment of physiological mechanisms such as the synthesis of extracellular protections. Upon wetting, this C would be immediately dissolved and mineralised. This is an alternative explanation for the increase in substrate availability and the CO2 flush that occurs after rewetting.

Taken together, the integration of climate change drivers investigated in this work could improve the modeling of C fluxes in soils undergoing DW cycles that feedback both atmospheric and soil C compartments. It also raises the issue of the existence of a tipping point in the decline of diversity beyond which an erosion or cut-off of the functions and services provided by ecosystems could be induced.

P-2213-03

Influence of climate changes on growth and initial development of tambaqui (Colossoma macropomum) larvae (Characiformes, Serrasalmidae)

MC. Portella (1) ; I. Guidini Lopes (1) ; TBDA. Silva (1) ; JT. Kojima (2) ; AL. Val (3)
(1) UNESP – Univ. Estadual Paulista, Centro de aquicultura da unesp, Jaboticabal, São Paulo, Brazil; (2) UNESP – Univ. Estadual Paulista, Faculdade de ciências agrárias, Jaboticabal, São Paulo, Brazil; (3) Instituto Nacional de Pesquisas da Amazônia, Manaus, Brazil

Introduction: The Amazon is the most diverse biome in the planet, hosting a number of plants, animals and microorganisms, being specially subjected to worldwide climate changes due to constant human activities affecting this biome. Amazonian species show important adaptation capacity, allowing them to explore challenging environments throughout the year. Larval development of fish is a very dynamic phase, marked by morpho-physiological changes during the organogenesis of the main systems. Therefore, initial phases are especially critical and the interactions with the environment define the adult individual. The aim of this study was to evaluate the effects of climate changes on the initial development of an important Amazonian fish species, the tambaqui – Colossoma macropomum.

Material and Methods: The predicted scenarios by the IPCC AR4 for climate change (Current CT, Mild B1, Moderate A1B and Drastic A2) were simulated in real time controlled microcosms – at the "Instituto Nacional de Pesquisas da Amazônia", Manaus – AM, Brazil – based on the current climate conditions. Ten 9-L tanks, equipped with recirculation system, containing 300 newly hatched larvae each were positioned in each microcosm. Larvae were kept for 16 days and periodically collected to perform biometrics and yolk consumption analysis. Yolk consumption, notochord length and standard length were analyzed by one-way ANOVA with Tukey post-hoc, and are presented as Means ± SE.

Results: Temperature, CO2 concentration, dissolved oxygen and water pH are shown in Table 1. Yolk consumption was not different among treatments throughout the five lecithotrophic days (mean areas on day 1 and day 5 of 0.7095 ± 0.007 mm2 and 0.2583 ± 0.016 mm2, respectively). Larvae submitted to the CT and A2 scenarios showed, by the end of the experiment, similar standard length (6.764 ± 0.170 mm and 6.877 ± 0.148 mm, respectively), but were significantly smaller ($P < 0.05$) than larvae in B1 and A1B (7.573 ± 0.141 and 7.804 ± 0.247 mm, respectively). During the first two days, high mortality was observed in all treatments (approximately 50%) due to an unknown cause, and by the end of the experiments, survival rates were calculated considering the initial density of the tanks. Survival rate in CT was 29.3 ± 0.3%, significantly higher ($P<0.001$) than in A1B (26.3 ± 0.7%) and in A2 (24.7 ± 1.0%). In the B1 scenario, the survival rate was intermediary (27.5 ± 0.6%).

Discussion: The causes of high mortality in the first two days of the experiment could not be identified. However, the stress of the transportation of the yolk-sac larvae (about 200 km) and the water quality differences from the water of transportation and the water in the microcosms must be considered, despite the use of a rigorous protocol of acclimatization. When exposed to higher temperatures (A2), the larvae energy demand to supply the increased metabolism is also higher. Considering that yolk consumption did not differ among treatments, it is assumed that the efficiency of this initial source of energy in the yolk-sac larvae may have been compromised at higher temperatures, subsequently resulting in smaller larvae and higher mortality. Treatments with intermediate temperatures (B1 and A1B, ranging from 29 to 30.5 °C) allowed better growth.

Conclusions: The predicted scenarios of future climate change by the IPCC for the end of the century, mainly the drastic ones, may affect the initial development of this Neotropical fish species, leading to high mortality rates.

Table 1. Mean values of temperature (temp, °C), CO2 concentration (ppm) in the air and water, pH and dissolved oxygen (DO, mg.L-1) in the tanks installed in each microcosm. Values are presented as Mean ± SE.

	Current	Bland	Moderate	Drastic
Room Temp	26.74 ± 2.08	28.72 ± 2.05	29.68 ± 2.01	31.70 ± 2.07

P-2213-04

Effects of Climate Change on Bird Migration in Iran

S. Sadeghi Zadegan (1) ; M. Mahmoudi (2)
(1) Department of Environment, Natural Environment Deputy, Wildlife Bureau, Tehran, Islamic Republic of Iran; (2) Shahid Beheshti University, Tehran, Islamic Republic of Iran

Climate change can directly affect birds through changes in temperature and precipitation. Drainage of wetlands is from the direct effects of climate change, which can indirectly affect bird's life. Around 70% of wetlands are seriously subject to dry or water loss. Even the rice fields, which defined as a wetland type, and very important for birds, are rapidly decreasing, converting to the other cultivations and uses. Birds in Iran are affected by climate change in various ways, such as distribution, abundance and migration behavior. Statistics and observations suggest that the birds are selected more northern altitude for wintering. As well, they arriving to wintering grounds later and leaving the area a bit earlier. A huge breeding colony of Greater Flamingos are disappeared in Uromiyeh Lake due to serious drainage this international wetland. The Siberian crane is a critically endangered migratory wetland bird numbering 3,000 individuals worldwide, which breed in arctic Russia and Siberia, which recent climatic conditions in these areas have seen rivers and lakes shrinking, causing wetlands to become more accessible to hunters. The western population of this species is dropped to only one single bird. Noting that climate change will put a lot of birds in danger of extinction In the future, we need activities to help birds to mitigate and adapt against changes. One way should be conserve local bird habitats, through the community based and grassroots programs and invested in on-the-ground projects involving Important Bird Areas.

The response of species and ecosystems to large and rapid climate changes in the past: information for conservation policy in an uncertain future

IC. Prentice (1)
(1) Imperial College London, Department of Life Sciences, Ascot, United Kingdom

Contrary to the impression given by some recent, high-profile reports, climate changes of similar magnitude and rate to those projected for the 21st century have occurred repeatedly in the geologically recent past, during and at the terminations of glacial periods. The causes and geographic patterns of these natural climate changes were quite different from those of contemporary climate change, which has two additional distinguishing properties: the fact that it is superimposed on a warm (interglacial) rather than a glacial base state, and the fact that it could – in the absence of mitigation – continue longer, and ultimately exceed the bounds of what the biota have experienced during several million years of Earth history.

Nonethless, the palaeoecological record can provide uniquely valuable evidence on how the biotic response to a fast-changing environment. Examination of the last glacial termination yields surprising (and in many ways encouraging) findings. Known extinctions were few, except among large mammals. Among hundreds of tree species known to have existed worldwide at the last glacial maximum, just one became extinct. A variety of responses allowed the great majority of species to persist, either in situ (through toleration or local habitat shifts), or by migration at remarkable velocities. These findings suggest a continuing role for conservation policies that focus on the maintenance and spatial continuity of habitats. They also suggest that the species most vulnerable to climate change may also be those that suffer most from other, non-climatic pressures.

Enabling transformative adaptation

M. Colloff (1) ; S. Lavorel (2) ; R. Wise (1) ; M. Dunlop (3) ; R. Gorddard (1)
(1) CSIRO, Land and water, Canberra, Australia; (2) CNRS, Laboratoire d'Ecologie Alpine, Grenoble, France; (3) CSIRO, Land & water, Canberra, Australia

The Transformative Adaptation Research Alliance (TARA) has developed an operational framework to study and support transformative adaptation, linking three novel concepts of 'adaptation services', the 'values-rules-knowledge (vrk) perspective' and 'adaptation pathways'. Adaptation services describes future options provided to people by ecosystems, recognising changing societal perspectives on ecosystem management and use. The vrk perspective focuses on the societal system and how we can free up constraints on the decision context for implementation. The adaptation pathways concept provides the means for planning and sequencing the actions required for transformative adaptation. Uniting these concepts allows the exploration of interactions between changing biophysical systems and co-evolving societal systems in order to enable deliberation, choice and decision-making.

K-2214-03

Biodiversity conservation under climate change: do we need a new approach?

G. Mace (1) ; M. Dickinson (2)
(1) University College London, Genetics, Evolution and Environment, London, United Kingdom; (2) Imperial College London, Grantham institute – climate change and environment, London, United Kingdom

Climate change is predicted to have major implications for species and ecosystems, acting as a driver of biodiversity loss in its own right and amplifying the effects of existing threats. It differs from other pressures, such as land-use change or over-exploitation, in the global extent and pervasive nature of its potential impacts on biodiversity. The potential magnitude of climate change impacts calls for a policy response, but the type of response and the species or regions to be targeted remains unclear. Predictions for wide-scale extinction and disruption of communities and ecosystems has led some to question whether traditional conservation practices, such as protected areas, will continue to be effective. Others have called for radical and interventionist strategies, such as moving species from their current locations to regions that are predicted to be climatically suitable.

We will provide some recommendations for conservation management under climate change based on the emerging science of integrated vulnerability assessment. This uses multiple sources of information, a greater understanding of the mechanisms and drivers of vulnerability, and identifies proxies and predictors for sensitivity and adaptive capacity.

Effective conservation policy and practice will need to embrace some change rather than aiming to preserve existing ecosystems with their component species. Distinctions between native and non-native species may become less relevant as species shift their geographic ranges. Global rather than regional or national targets or criteria for species or habitat protection or designation of protected areas may be more appropriate as species' ranges and abundances change. A focus on ecosystem function and resilience may be more appropriate than on maintaining species community composition. Traditional practices, such as protecting or restoring habitat within reserves, may support function and resilience by allowing existing systems to absorb the impacts of climate change. Improving permeability of the landscape or connectedness between reserves may be required to facilitate range shifts, either through spatial structuring of new reserves of by enhancement of natural linear features, such as rivers and hedgerows.

Uncertainty as to future climate may be, to some extent, irreducible and be incorporated into decision frameworks and interventions though adaptive management and scenario planning. Early applications of integrated vulnerability frameworks suggest that tropical regions may be centres of climate change vulnerability. Climate change, coupled with predicted increased in land-use

change in these regions, suggests that tropical zones may be future centres of biodiversity loss. Stemming loss is likely to require a co-ordinated international response, with transfer of expertise and financial assistance from high-income developed temperate nations to assist low-income tropical nations in increasing their level of human societal development in a sustainable manner.

K-2214-04

Powerful deliberate practices for enabling transformative adaptation

I. Fazey (1)
(1) University of Dundee, School of environment, Dundee, United Kingdom

Anticipatory and transformative adaptation in the face of climate change, including for biodiversity conservation and maintenance of ecosystem services, is an intentional process. It requires the facilitation of the enabling conditions for significant and qualitative societal changes well beyond minor or incremental adjustments. Yet there is currently little understanding about how such deliberate significant changes come about, and at the rates necessary to reduce the threat of climate change. This presentation will therefore examine the nature and role of powerful deliberate practices (the tools, activities and processes) for helping to create the enabling conditions for transformative adaptation and conservation of biodiversity. The presentation will do four things. First, it will explain the concept of transformative adaptation and the challenges involved in facilitating enabling conditions. Second, it will explain the kinds of research that is that can simultaneously help understand transformation while also accelerating transformation in practice. This necessarily involves: (i) integrating existing theory, such as social practice theory and social technical transitions to overcome epistemological and ontological differences; and (ii) the bridging and integration of different kinds of knowledge, including academic (episteme) and that of practitioners (phronesis). Third, it presents a new concept called 'powerful deliberate practices' as a way to overcome some of the challenges of working on transformation. This concept is important because its emphasis on: (i) 'powerful' highlights the need to understand which practices are most useful, for which circumstances, and why for adaptation and biodiversity conservation; (ii) 'deliberate' highlights the need for approaches that can directly contribute to change in the present rather than, for example, looking to poorly suited past cases of change as analogues for the contemporary issues; and (iii) 'practices' highlights the need to understand the complexities and subtleties of interventions for conservation and adaptation as a collection of tools, activities and processes in systems of wider, less conscious social practices. Finally, an example of Three Horizons will be used of a potential powerful deliberate practice. Three Horizons is a process used to facilitate dialogue between individuals with different values and mindsets to map out processes of transition and transformation. The approach is able to both deal with situations of high uncertainty and has been found to create radical transformations in how participants relate to the future and view themselves as credible actors in shaping change, and is thus relevant to diverse circumstances, including transformative adaptation and the management of ecosystem governance and change. In conclusion, a research agenda is needed to develop, integrate and understand the role of a suite of powerful deliberate practices to accelerate learning about the enabling conditions for transformative change. This will necessarily involve new transformative modes of research that are significantly and qualitatively different from many of those already being applied.

O-2214-01

Expanding the horizons of governance for adaptation pathways: illustrations from protected areas management

C. Wyborn (1) ; L. Van Kerkhoff (2)
(1) WWF International, Luc Hoffmann Institute, Gland, Switzerland; (2) The Australian National University, Fenner School of Environment and Society, Canberra, ACT, Australia

The concept of adaptation pathways is expanding our ideas of governance for adaptation to include wider social and institutional dimensions of organisation, decision-making and implementation. This is captured by the "values-rules-knowledge" construct. Drawing on recent work in adaptive governance and long-standing development studies literature and practice, we propose that we can combine this construct with complementary perspectives to develop a more holistic framework for governance in examining transitions to more sustainable and adaptive development pathways. This expanded framework incorporates culture and corruption, power and politics, resources and capacity, and process and vision. We present this framework, and demonstrate its application through retrospective application to research on public land management in Colorado, USA, and prospectively to a pilot study on the Pacific island of Palau, specifically the Protected Areas Network (PAN) Fund. These illustrations suggests that the framework can be used as a device to help us identify 'deeper', more structurally-embedded influences that shape values, rules and knowledge, that support or inhibit transformational change, as well as some of the practical implications. Importantly, it also has the potential to alert us to crucial 'blind spots' in our investigations and analyses of governance for adaptation in the face of global environmental change, as well as to identify opportunities for institutional innovation.

O-2214-02

Global scenarios that achieve multiple sustainability targets: challenges for IPBES and IPCC

P. Leadley (1)
(1) Univ. Paris-Sud, Lab. Ecologie, Systématique et Evolution, Orsay, France

Several global sustainability goals for the 21st century have been agreed upon or are being discussed in the context of global multilateral environmental agreements. These include keeping global warming to 2°C or less for the 21st century (UNFCCC objective under discussion), halting the loss of biodiversity by 2050 (Convention on Biological Diversity) and attaining these while simultaneously meeting human development goals under the UN post-2015 global development goals currently under discussion. Scenarios of future global development suggest that achieving these multiple targets simultaneously will require substantial societal transformations. Many of these transformations have not been fully explored in global scenarios, even though many studies have shown that these can play very large roles in achieving mutliple sustainability targets. This talk will review some of the key challenges facing IPCC and IPBES (International Science-Policy Platform on Biodiversity and Ecosystem Services) in developing the next generation of global scenarios of socio-economic development, using examples from the IPCC SSP scenarios, the Global Biodiversity Outlook 4, the UNEP Green Economy report and a wide range of published studies. This analysis suggests in that transformations of food systems, in terms of marine fisheries, aquaculture, agriculture, food transformation and food consumption can make major contributions to achieving a wide range of sustainability targets.

Guiding Agricultural Expansion to Spare Tropical Forests

A. Baccini (1) ; E. Dinerstein (2) ; M. Anderson (3) ; G. Fiske (4) ; E. Wikramanayake (2) ; D. Mclaughlin (5) ; G. Powell (3) ; D. Olson (2) ; A. Joshi (6)
(1) The Woods Hole Research Center, Woods Hole, United States of America; (2) Resolve, Biodiversity and wildlife solutions program, Washington DC, United States of America; (3) World Wild Fund, Washington, United States of America; (4) The Woods Hole Research Center, Woods Hole Research Center, United States of America; (5) World Wild Fund, Markets program, Washington, United States of America; (6) University of Minnesota, Conservation biology program, St. Paul, United States of America

Expanding commodity crop production in the tropics presents the dual challenge of enhancing food production while preserving tropical moist forests (TMF) ecosystems and the carbon that they store. Over the years, biologists

have prioritized biodiversity rich areas and made recommendations on conservation imperatives. Conversely, agricultural imperatives—and especially commodity crops—typically ignore biodiversity and carbon content values when converting new lands for expansion, even though the ecosystem services from the latter are vital to sustain the former. In this analysis we attempt to reconcile biodiversity, carbon storage, and agricultural imperatives by identifying low-carbon density land (LCDL) for large-scale commodity agricultural expansion in the tropical realm. Thereby protecting important and representative biodiversity while minimize CO2 emissions. Our rationale is based on the fact that LCDL are essentially degraded TMF that are usually stripped of the high carbon cover and forest-dependent biodiversity. Because degraded TMF can take decades or even centuries to recover and mature, these lands are of limited conservation value relative to intact forests. With techniques now available to improve soil fertility, drainage, and sustainability these degraded forests can be made suitable for agriculture, and provide opportunities to expand the commodity and industrialized agricultural footprint with minimal loss of biodiversity and CO2 emissions

Here, we propose a transparent approach for shifting agricultural expansion away from biodiversity and carbon rich TMF into degraded, low-carbon density lands, defined as lands holding less than 40 metric tons of Above Ground Carbon (AGC)/ha. Results show about 274 Million ha of low carbon density forests occur in the TMF tropical belt. After applying important safeguards, filtering for areas unsuitable for industrial agriculture, under formal protection, in indigenous reserves, or other biologically sensitive areas, about 125 Million ha are potentially available for tropical agricultural expansion for the next 25-50 years without further destruction of rainforests. About 65 Million ha of this LCDL estate is distributed in contiguous tracts larger than 5,000 ha and lies below 500 meters elevation, meeting the prerequisites for successful commercial-scale oil palm production. Nearly one third of all LCDL occur in Brazil; followed by India, Myanmar, Mozambique, Indonesia, Tanzania, and Democratic Republic of Congo, all holding more than 4 Million ha. The simplicity and transparency of this easily-monitored metric could prove useful to producers, governments, investors, and consumers and enhance good governance in tropical regions.

Treeline Dynamics with Climate Change in Nepal Himalaya

DR. Bhuju, (1) ; NP. Gaire (2) ; P. Rana, (3) ; UK. Thapa, (4) ; SK. Shah, (5) ; M. Koirala, (1) ; M. Carrer, (6) ; S. Bhandari, (1) ; B. Sharma, (7) ; A. Shrestha, (8) ; R. Ghale, (9) ; YR. Dhakal, (10)

(1) Central Department of Environmental Science, Tribhuvan university, Kathmandu, Nepal; (2) Nepal Academy of Science and Technology, Faculty of Science, Lalitpur, Nepal; (3) Nepal Academy of Science and Technology, Faculty of scinece, Lalitpur, Nepal; (4) Department of Geography, Environment and Society, University of minnesota, Minneapolis, United States of America; (5) Birbal Sahni Institute of Paleobotany, Lucknow, India; (6) Department of Land and Agro-forest Environment, University of padova, Padova, Italy; (7) GoldenGate International College, Department of environmental science, Kathmandu, Nepal; (8) Sanima Hydropower Company, Environment, Kathmandu, Nepal; (9) Karnali Integrated Rural Development and Research Center, Lalitpur, Nepal; (10) Tree Ring Society of Nepal, Kathmandu, Nepal

The imprints of climate change impacts have evidently been recorded from the natural habitats of the Himalaya. Available climatic data show a rapid increase in the average annual temperature in Nepal Himalaya compared to other regions. Nepal's rich tree diversity emanating from varied climate within a narrow geography of extreme topographic range (Alt. 60 m to >8000 m asl) provides opportunities for multi aspect tree-ring research. The high altitude climatic treelines are sensitive biomonitors and bioindicators of past and recent climate change and variability as well as warning line to the climatic impacts on high altitude biota and livelihood. Science based empirical studies on the impacts of climate change in high-altitude ecosystems and their components are yet new approach in the Himalaya especially in Nepal.

We carried out a dendro-climatological study at the tree-line ecotones of seven high mountain protected areas of Nepal Himalaya from east to west, namely: Kanchenjungha, Sagarmatha (Everest), Langtang, Manaslu, Annapurna, Rara and Api-Nampa, with an aim to assess the impact of climate change in the tree-lines. Two to three sites were selected in each protected area. Vertical transect plots (10-20 m x 100-250 m wide) were laid down in each treeline site covering different aspects of mountain slopes. In addition to ecological details, more than 1200 tree core samples from major treeline species, viz. Abies spectabilis D. Don, Betula utilis D. Don and Rhododendron campanulatum D. Don were collected. Using the ecological and dendrochronological tools, climatic response on radial growth and regeneration, recruitment and dynamics of the these species were analyzed.

The position of tree-line in the east (Lat. 27.7155 N) was higher (Alt. 4150 m asl) in the west (Alt. 3800 m als; Lat. 29.8750 N). The size parameters such as tree density, basal area, diameter at breast height, height and age decreased with increasing elevation revealing dynamic nature of tree-lines though it presented some spatial heterogeneity. High regeneration of A. spectabilis as compared to B. utilis was observed in most of the sites. The population age structure of these species showed both stand densification as well as upward shifting of tree-line in many sites. The tree core analysis showed that in most sites, B. utilis appeared first which was later displaced by A. spectabilis. High regeneration of A. spectabilis in recent years compared to that of B. utilis indicated that the tree-lines in Nepal Himalaya are changing along with the species composition and dominance.

The upward shift of A. spectabilis was clearly observed, the shifting rate ranged from 1.1 m to 3.6 m per year. An invariant positive correlation among the site chronologies was also noted, indicating that there prevailed some common climatic factors limiting the growth and dynamics of the trees. Tree growth-climate and regeneration-climate relationship showed that warm winter and moist summer favoured the regeneration of A. spectabilis, while pre-monsoon (March-May) climate enhanced the radial growth. Growth of B. utilis in most of the sites was mainly limited by moisture stress during pre-monsoon months just before the main growth period. Population structure and climate growth response indicated that both the species had species specific response to climate change. Hence, a wider difference is anticipated in the population attributes of the species as climate continues to change in the future. These shifting also have implications on the poor mountain people whose livelihood depend on marginal rangeland just above the tree-lines.

P-2214-03

A Perspective on Conservation of Sub-Tropical Grassland in Eastern Himalaya

D. Das (1)

(1) ATREE, Bengalure, India

The matrix of riverine grasslands and grassland-forest mosaics in the Ganges and Brahmaputra river valleys in the eastern Himalayan foothills are some of world's tallest and most productive .These tall grassland forest mosaics are the last remaining examples of subtropical tall grasslands in the Indian subcontinent, and contain some of the highest densities of tigers, rhinos, and ungulates in Asia. These grasslands mosaic are maintained by a suite of disturbance processes including flooding, fire, and grazing. Manas National Park, a world heritage site and a tiger reserve with an area of 519 sq. km, situated in the North bank landscape of Assam. A socio-political change in the North bank landscape led to a disruption of management practices in the Park. These changes lasted over 15 years, and as a result, fire regimes and grazing practices changed. Wild populations of herbivores and carnivores suffered huge declines due to lack of protection. Coupled with changes in river flow, these changes have led to significant alteration in the grassland community in both local and regional level. Recent observations have shown an increase in the spread of species that are dominant in drier ecosystems, as well as occurrence of tree species in areas previously occupied by grasslands, changing savanna grasslands to woodland. This dynamism is probably driven by the interacting effects of environmental variation, changing management regimes, human interactions, and ecosystem feedbacks. The system probably experiences fluctuating species composition and wide variation in population dynamics of plant species, but none of this has been clearly documented.

P-2214-04

Commodifying Nature, Where we were mistaken with Ecosystem Service Classification

A. Dhungana (1)
(1) Center for Climate and Environment Research, Policy and Economics Research Unit, Lalitpur, Nepal

Economic theory driven ecosystem valuation has been the fundamental areas for the Ecosystem Service (ES) and Payment for Ecosytem Services research in the last decade. The Classification of ES by MEA 2005, has diverted the whole research community to think Nature as a Commodity and the research community for this whole decade spend their huge effort in the monetary valuation of Nature, but still we are far away from the solution within nature-human-development nexus. The major problems in this classification was with the cultural service, weighted in similar fashion with other three provisional, supporting and regulating service. Our empirical Study has shown that, with all those three services, cultural service was interconnected and no way can be treated as a separate class. Besides, the complexity of natural process like hydrological cycle, nutient cycle and climate cycle, which were categorized in regulating and supporting services needed research on the long term nature, and it can no way be monitised like other economic goods, and hence resulted in the failure to measure and manage it for the transformative solutions in our societies. The economic theory like utility and welfare theories in no way could justify the interlinkage of nature and economy.

P-2214-05

Maintaining Habitat Connectivity for Vulnerable Ungulate to Mitigate the Impacts of Climate Change in Isfahan Province, Iran

S. Fakheran (1) ; S. Malakoutikhah (1) ; A. Soffianian (1) ; J. Senn (2)
(1) Department of Natural Resources, Isfahan university of technology, Isfahan, Islamic Republic of Iran; (2) Swiss Federal Institute for Forest, Snow and Landscape Research, Wsl, Zurich, Switzerland

Climate change is predicted to have substantial negative impacts on biodiversity for a wide variety of taxa across many regions of the world. The combined effects of climate change, habitat fragmentation and land use change is the most important conservation challenge we face. Maintaining connectivity is the most recommended strategy for conserving species in onset of climate change. In this study, we identified and evaluated migration corridors for two vulnerable ungulate species, the wild sheep (Ovis orientalis isphahanica), and the goitered gazelle (Gazella subguterrosa) between Mooteh and Ghamishloo wild life refuges in Isfahan province, Iran. Migration of goitered gazelle and wild sheep between these wildlife refuges is related to seasonal change in environmental conditions. To identify migration corridors, two connectivity models were used, Least-Cost Corridor (LCC), and Circuit Theory. Using LCC, two corridors were selected for each target species. The first least-cost corridors for the species included habitats of highest quality (lowest resistance) which stands for the minimum costs for movement. Theses corridor for giotered gazelle covered about 158 km2 (7.5% of the total area) and the one for Wild sheep covered 151 km2 (7.2% of the total area). Although the identified corridors in this study are currently used for round migrations between Mooteh and Ghamishloo wildlife refuges, they are most likely to be served as one way migration corridors from Ghamishloo to Mooteh protected area assisting the species to shift their ranges in response to climate change in an immediate future. Climatic conditions in Mooteh compared to Ghamishloo in terms of annual rainfall (249.16 mm in Mootieh in compared to 180.9 mm in Ghamishloo) and minimum average temperature (-8.5C in Mooteh compared to -1.6 C in Ghamishloo) indicates that Mooteh wildlife refuge will be used as a refugia to buffer these ungulates from the impacts of drought and climate change in this region.We conclude that protecting and incorporating of the remaining suitable migration corridors into the existing protected areas network of Iran is an urgent need in order to secure the survival of the migratory species. As the study area is not protected at present and is very likely to be developed in near future, it is very important identifying the areas with the easiest movement routes for future conservation which, if conserved, provide the easiest movement routes assisting species in the face of climate change and land use change. Improving connectivity is not only strategically smart, but a proven method of allowing wildlife to move in response to rapid environmental change.

P-2214-06

Impacts of Biodiversity Loss in the Carbon Stock and Evapotranspiration Fluxes Regulation in Brazilian Amazon

R. Ferraz (1) ; M. Simões (2) ; M. Equihual (3) ; O. Maqueo (3) ; N. Alaniz (4) ; P. Verweij (5) ; A. Alvez (6)
(1) Embrapa, Embrapa Solos, Rio de Janeiro, RJ, Brazil; (2) Embrapa, Embrapa solos, Rio de Janeiro, Brazil; (3) INECOL, Instituto de ecologia a.c, Veracruz, Mexico; (4) CONABIO, Comisión nacional para el conocimiento y uso de la biodiversidad, Mexico DF, Mexico; (5) Wageningen-UR, Alterra, Wageningen, Netherlands; (6) Universidade do Estado do Rio de Janeiro, Programa de pós-graduação meio ambiente (ppgma), Rio de Janeiro, Brazil

Biodiversity supports many ecosystem services that are very important for climate change mitigation and adaptation, according to the Convention on Biological Diversity (CBD) there are clear interlinkages between biodiversity and climate changes. There is a functional link between the tropical forest ecosystem biodiversity and their capacity for carbon uptake and storage as well as regulation of evapotranspiration flux. Nevertheless, land use changes and agriculture expansion reduce the ecosystems integrity modifying the functions related directly to the ecosystem services. The relationship between biodiversity loss and the ecosystem services in tropical forests, in face of the ongoing global climate change, has been quite accepted by the scientific community, but needs to be better quantified and understood. The objective of this paper is to present the methodological approach and preliminary results on the impact estimation of land use changes and ecosystem biodiversity loss in carbon stock and evapotranspiration fluxes regulation ecosystem services. In order to fulfill that goal, the carbon stock and evapotranspiration spatial models were correlated with an ecosystem integrity model, used as an indicator of biodiversity loss for the Brazilian Amazon. The methodological approach of this work consists in the generation of an "ecosystem biodiversity loss" spatial model based on probability distribution of evidence parameters (Bayesian theory - Lindley 1972). The modeling was based on learning process (dada-driven model) using the Expectation Maximization algorithm (Buntime 1994). Bayesian network has been established from an expert conceptual model that related different spatial data (Thematic maps and Remote Sensing data): (i) Biomass (MODIS/ USGS - NASA); (ii) EVI; (iii) LAI- Leaf Area Index (MODIS/ USGS - NASA); (iv) Tree Cover (MODIS/ USGS - NASA); (v) GPP- Gross Primary Productivity (MODIS/ USGS - NASA). The carbon stock ecosystem service was estimated from aboveground carbon stocks spatial model developed by Baccini et. al. (2004) within the Pantropical National Level Carbon Stocks Project held by the Woods Hole Research Center - WHRC, Boston University and the University of Maryland (MA, USA). The methodology was based on ground data, MODIS 500m imagery and GLAS LiDAR data. The evapotranspiration fluxes ecosystem service was estimated from MODIS Surface Resistance and Evapotranspiration (MOD 16), data developed by Numerical Terradynamic Simulation Group (NTSG), College of Forestry & Conservation - University of Montana (Mu et al., 2007). Preliminary results were promising, allowing the establishment of the probabilistic distribution spatial patterns of biodiversity loss, as well as a preliminary assessment of the relationship with the carbon stocks (aboveground biomass) and evapotranspiration fluxes. This work is part of the ROBIN Project - Role of Biodiversity in Climate Change Mitigation - sponsored by the European Union (FP7 Edict ENV. 2011.2.1.4 -1: Potential of biodiversity and ecosystems for the mitigation of climate change).

A theoretical analysis of a hypothetical auction program to pay for biodiversity in Peruvian Amazon nuts (Bertholletia excelsa) ecosystems

P. Flores Tenorio (1)
(1) La Trobe University, Department of Economics, Melbourne, Victoria, Australia

Peru is a megadiverse country with the second extension of forests in the Amazon basin. The design of efficient public policies for these territories is challenging due the fragility of public institutions and lack of economic valuation of important ecosystem services provided from old-growth forests.

This paper develops preliminary a dynamic system model and a theoretical analysis from the ecological economics perspective for a key non-timber forest product of the Peruvian Amazon basin: the Amazon nut (Bertholletia excelsa). Specially, we analyse the bioeconomic dimensions of two ecosystem services: pollination and the forest cover to provide habitat for flora and fauna.

The contribution of this paper is to present evidence that support the argument that decision makers from development countries have an excellent investment opportunity for conservation of biodiversity in indigenous lands with Amazon nuts.

P-2214-08

West Africa's most climate change vulnerable species: which, where and why?

W. Foden (1) ; J. Carr, (2) ; E. Belle, (3) ; N. Burgess, (4)
(1) Global Change and Sustainability Research Institute, University of the Witwatersrand, Gauteng, South Africa; (2) IUCN Global Species Programme, Cambridge, United Kingdom; (3) UNEP-World Conservation Monitoring Programme, Brussels, Belgium; (4) UNEP-World Conservation Monitoring Programme, Cambridge, United Kingdom

West Africa supports globally high levels of species richness and endemism but this exceptional biodiversity is subject to serious ongoing anthropogenic threats, particularly from land transformation and over-exploitation. Climate change is now recognised as a serious emerging threat to biodiversity due both to its direct impacts on species' health and habitats, and because some human responses are likely to exacerbate historical threats. In order to prepare sound climate change adaptation strategies for West Africa, it's necessary to understand how biological systems will be impacted. To address this need, we carried out climate change vulnerability assessments for almost all of the region's terrestrial and freshwater vertebrates, including mammals, birds, reptiles, amphibians and fishes (2,854 species). Using a trait-based approach, we worked with species experts to identify traits conferring high climate change sensitivity and low adaptive capacity for each taxonomic group, and then scored each species' degree of possession of these. Species' exposure to climate change was estimated using regional projections of future climate across their individual distribution ranges. Combining the resulting sensitivity, exposure and adaptive capacity scores, we categorised each species' overall climate change vulnerability. This allowed us to identify those facing highest risk from climate change, as well as the regions where such species are concentrated. Comparing the patterns of high climate change vulnerability with those of high threat from non-climate related factors allowed us to identify areas of greatest overall concern for West African species. By comparing these priorities with current protected area coverage, we highlight areas that are currently unprotected but in great need of protection, as well as the existing protected areas in which adaptation efforts should be prioritised.

P-2214-09

Pitfalls in reconciling greenhouse gas mitigation and biodiversity conservation

N. Fromin (1)
(1) Centre National de la Recherche Scientifique, Centre d'Ecologie Fonctionnelle et Evolutive, Montpellier, France

Current environmental policies urgently call for climate change mitigation strategies. Among these, biological sequestration of carbon (C) in soils through plant and soil management was identified as one of the most promising. Compared to other strategies such as oceanic sequestration or solar radiation management, biological C sequestration is cost effective, ecologically more attractive, relatively easily applicable, and has minimal side effects (Cusack et al. 2014). The potential for biological C sequestration in terrestrial ecosystems at the global scale is estimated between 1.7 and 2.4 GT C per year, which is roughly one fourth of the 9 GT C released annually to the atmosphere through human activity.

Biodiversity is often presented as critical to explain ecosystem processes, because more diverse organisms may exploit more efficiently the resources available in their environment. Yet, altering biodiversity might have strong functional consequences for C sequestration. The few meta-analyses dealing with biodiversity / ecosystem process relationships suggest, however, that protecting biodiversity is not necessarily the best way to optimize C sequestration in soils. Reciprocally, management strategies identified as favorable to C sequestration sometimes cause side effects on habitat structure and biodiversity. Because the conservation of biodiversity is also an internationally recognized priority in environmental policy, the potential for C sequestration management and its application must be assessed intimately with their consequences for biodiversity and sustainable development in the wider sense.

The proposed soil management strategies for increasing C sequestration include afforestation / reduction of deforestation, biofuel energy plantations, no-till or conservative tillage systems, nutrient management and the use of biochar. In this poster, I will present their respective potential for C sequestration, their feedbacks on biodiversity, but also their reliability, ecological risks, and their economic and social acceptance. The literature treating biological C sequestration increasingly referred to it as an 'ecosystem service' in its own right. However, as I will show, C sequestration is a complex process with strong scale dependent properties and interacting with other ecosystem functions in often non-linear ways. Therefore, I will argue that C sequestration cannot be evaluated in isolation of other ecosystem functions and should not be identified as an independent 'ecosystem service'.

Climate change impacts on the fisheries in the Himalayan Kingdom of Nepal

MA. Husen (1)
(1) Nepal Agricultural Research Council, Agricultural Research Station (Fisheries), Kaski, Pokhara, Nepal, Pokhara, Nepal

Besides land locked country, Nepal is home of more than 200 fish species. The resident of these species are rivers and lakes of this country. Rise of temperature with changes in precipitation have been effecting on the Himalayan river flow rate with un- expected floods and runoff. These increased flow rates have been altering the habitat of fish species. These will be affecting on the diversity of fish species in these river and lakes. The bank of rivers and lakes are known to home of many ethnic fishers and livelihood of these ethnic communities depends on its capture fishery. Thus, vulnerability of fisher community due to climate change is at high risk in this country. Proper adaption measures needed to combat the climate change and its hazards.

P-2214-11

Community Forest of Nepal: How it maintains ecosystem services and maintain sustainability?

B. Khadka (1)
(1) Yokohama National University, Yokohama, Kanagawa, Japan

Community forestry is a participatory forest management system in Nepal. Till date 17,000 community forest (around 1.2 million ha) forest is managing directly from the 1.5 million people.

Research shows that the environmental services provided by the Community forest such as provisioning services, regulatory services, cultural services, supporting services, biodiversity conservation, water purification and regulation, soil erosion protection, forest recreation and carbon storage are gaining some attention and need to protect the future of the forests linking commercial market and climate change adaptation and mitigation issues activity to conservation objectives from past 30 years. Moreover, selling forest environmental services for the coping with climate change should ensure through the effective payment system in securing forest environmental benefits and their role in effort to eliminate rural poverty and also helps further for climate change mitigation and adaptation. The government of Nepal is developing different policy and management plan how can get more benefit from the community forest such as Payment for ecosystem services, Carbon market, Reducing Emissions from Deforestation and degradation plus, ecotourism, green jobs from the forest etc which can make direct benefit to the community people and helps to cope with climate change.

This research explore how community forest maintains ecosystem services and maintains sustainability, resilience development for community?

P-2214-12

Sectoral contributions to the conservation of biodiversity

M. Kok (1)
(1) PBL Netherlands Environmental Assessment Agency, Bilthoven, Netherlands

In 2014, governments within the Convention on Biological Diversity (CBD) reviewed progress in the achievement of the goals and targets set in the Strategic Plan on Biodiversity 2010-2020, as a step towards halting the loss of biodiversity as envisioned in the 2050 Biodiversity Vision. Although there has been an increase in responses to stop the further loss of biodiversity, this progress is insufficient to attain most of the Aichi Targets by 2020, nor can under current trends a stabilization of biodiversity loss towards 2050 be expected. This is for a large part due to persistent increases in pressures. To be able to address these, biodiversity policies need to address primary production sectors. Developments in sectors such as food production and agriculture, wood production and forestry, energy production, water management and fisheries largely shape the world's current and future biodiversity, as they exert direct pressures on biodiversity.

Related to the Aichi targets on sustainable use we identify different pathways that could contribute to achieving the 2050 Biodiversity Vision. Pathways are combinations of technological measures and behavioural changes, for food production and wood production and consumption. Biodiversity goals in these pathways are realized as part of a broader set of sustainability objectives, including eradicating hunger, feeding an increased and more wealthy world population, providing universal access to modern energy, preventing dangerous climate change and controlling air pollution. The pathways were evaluated, using the IMAGE-GLOBIO integrated assessment modelling framework. The analysis shows that it is possible to couple improvements in the trend of biodiversity, reduce greenhouse gas emissions and improve the well-being of all people simultaneously, but that this requires substantial transformations in the sectors we researched.

Climate change impacts on global faunas: the causes and consequences of range shifts

E. Leyequien (1) ; J. Verboom (2) ; JA. Harvey (3) ; T. Essens (3) ; C. Vos (2) ; WF. De Boer (4)
(1) CENTRO DE INVESTIGACIÓN CIENTÍFICA DE YUCATÁN, Unidad de recursos naturales, Merida, Yucatan, Mexico; (2) WAGENINGEN UNIVERSITY AND RESEARCH CENTRE, Alterra, Wageningen, Netherlands; (3) Netherlands Institute of Ecology NIOO-KNAW, Department of terrestrial ecology, Wageningen, Netherlands; (4) WAGENINGEN UNIVERSITY AND RESEARCH CENTRE, Resource ecology group, Wageningen, Netherlands

Anthropogenic climate change has affected Earth's biota on all continental and ocean territories. Global and regional climatic changes affect the world's faunas, causing among others shifts in their geographic ranges, changes in their seasonal activities, species turnover, increasing the risk of extinction, of spread of diseases and of invasive species. Species' range shifts have been the focus of attention of climate change studies, and vast amounts of correlational evidence show that the geographic range of species around the world is shifting either in latitude or elevation in response to climate change. There is no doubt of the importance of correlational studies describing the connection between the range shifts in species and climate change, however a great challenge in ecology is to commute from a simple correlational claim to the understanding of the underlying causal mechanisms. Understanding species' range shifts relative to climate changes entails knowledge of the underlying causal mechanisms of the observed phenomena, to ultimately understand the future directions of global faunas under climatic changes. Mechanistic explanations of animal range shifts – or their absence – should account for ecological traits that strongly influence species' responses to climate change. For example physiological thresholds that determine climatic limits to species distributions, or biotic interactions (e.g., inter and intra-species competition) in which intricate web relations and feedbacks influence the distribution of animal species. Other example is species' dispersal limitations that may compromise their capability to disperse at rate that is sufficient to track the changes in suitable bioclimatic space, causing time lags and thereby leading to novel community structures and novel interactions. We propose a comprehensive framework linking mechanistic explanations to causal claims in explaining range shifts, present and future, under changing climate zones. First, we illustrate the mechanistic explanations underlying animal range shifts driven by climate changes using a series of case studies contrasting the northern and southern hemispheres. We discuss as well the resulting effects exerted by range shifts at different ecological levels, from micro-evolutionary processes through selection of phenotypes, to ecological communities and ecosystems; and identify consequential feedback loops. Our theoretical framework provides a synthetic robust broader approach that links hypotheses and underlying mechanisms to advance our understanding of climate change impacts on global faunas, and provides grounds for generalisations that can direct future research and lead to evidence-based solutions to climate change challenges.

Biodiversity implications of REDD+ policies: assessments in Brazil and in the Congo Basin

R. Mant (1) ; B. Bodin, (1) ; A. Mosnier, (2) ; A. Soterroni (3) ; FM. Ramos (3) ; AXY. Carvalho (4) ; G. Câmara, (5) ; J. Pirker (2) ; M. Obersteiner (2) ; D. Bokelo, (6) ; R. Ndinga, (6) ; A. Makoudjou, (7) ; P. Tonga, (6) ; V. Kapos (1)
(1) UNEP-WCMC, Cambridge, United Kingdom; (2) IIASA, Laxenbourg, Austria; (3) National Institute for Space Research (INPE), Sao Jose dos Campos, Brazil; (4) IPEA, Brasilia, Brazil; (5) National Institute for Space Research (INPE), São José dos Campos, Brazil; (6) COMIFAC, Yaounde, Cameroon; (7) COMIFAC, Yaoune, Cameroon

Brazil and the Congo Basin contain the largest remaining areas of tropical rainforest on earth. In both regions, there is interest in implementing policies to mitigate climate change through the Reduction of Emissions

from Deforestation and forest Degradation plus the conservation, sustainable management and enhancement of forest carbon stocks (REDD+) in order to mitigate climate change. Policies aimed at achieving REDD+ objectives will have major impacts on future land use and resulting land cover, both inside and outside forest areas, which in turn affect biodiversity. Countries in both regions have committed both to supporting the the achievement of the goals of the Convention on Biological Diversity (CBD), including the Aichi Biodiversity Targets in its Strategic Plan, and to addressing and respecting the safeguards developed by the UNFCCC to minimise social and environmental risks and enhance the benefits of REDD+ . Therefore, understanding how different policies may influence land use and biodiversity is essential to informed decision-making and identifying REDD+ policies that can help safeguard biodiversity.

We are assessing the potential impacts of REDD+ policies on biodiversity in Brazil and the Congo Basin by using an economic land use model (GLOBIOM), to project future land use and changes in land cover under different scenarios. The biodiversity impact of the different scenarios is then explored by assessing the locations of projected land use change in relation to ecological regions, nationally and regionally identified priority areas for biodiversity conservation and species ranges. The effect of potential differences between ecoregions in land use policies and their application are explored. The impacts on species depend on both their habitat requirements and their distributions relative to different types of land use change.

The different assessments of impacts on biodiversity can in combination inform both REDD+ and biodiversity policies. In Brazil, both the implementation, and the impacts, of the Forest Code differ between Amazonia and other biomes. This therefore has implications for the species living in the different biomes. Analysis of the impacts on threatened species of different assumptions regarding the implementation of the forest code can inform the classification of species threat status. It also allows an assessment of the compatibility of these different scenarios with achievement of Aichi Biodiversity Target 12 on reducing extinction of threatened species. In the Congo Basin two important future scenarios relate to the contribution of protected areas and forest concessions to reducing deforestation. The assessment results highlight that not only is the current network of protected areas unevenly distributed across the different ecological regions, but also the impact of their enforcement on deforestation varies between ecological regions. Expanding the network and strengthening the effectiveness of existing protected areas to support REDD+ objectives would also contribute to achieving Aichi Biodiversity Target 11.

Multi-Temporal cover patterns using Landsat TM in the Tapajós National Forest and its surroundings: a case study

L. Martorano (1) ; L. Lisboa, (2) ; C. Vettorazzi, (2) ; R. Muniz, (2) ; NES. Beltrão (3)

(1) s/nº, Agrometeorology, Belem, Brazil; (2) ESALQ, Piracicaba, Brazil; (3) UEPA, Belém, Brazil

Brazil's Tapajós National Forest (Flona Tapajós) — a designated Conservation Unit (CU) under the Sustainable Use Group created by Decree No. 73,684 (February 1974) — measures approximately 527,000 hectares (ICMBio, 2012). This CU has undergone constant changes in usage patterns and ground cover, especially in its surroundings, due to activities related to agriculture, livestock and timber harvesting. In June 2012, Federal Law No. 12,678 reduced the area of Tapajós Flona by approximately 4% of its original size. These areas began to be called buffer zones. According to Batista et al. (2013), this reduction may lead to possible threats in the maintenance of goods and services that Flona offers, provoking with the passing of years changes in the livelihoods of surrounding communities, thus increasing pressure on the protected area. Therefore, the aim of this work was to identify and map spatial distribution patterns of use and ground cover after the alterations in the landscape using data from spatio-temporal remote sensing sources. Satellite images from the TM sensor and the Landsat-5, from July and August of 1989, 2005 and 2009 were used. Digital processing was performed: atmospheric correction; geometric correction; mosaic; classification, post-classification and definition of use classes and land cover. We used the Geographic Information System (GIS) ArcGIS v.9.3 to construct thematic maps of the study-case, along with the following procedures: conversion of classified images to vector format for calculating the areas of thematic classes adopted this work; assembly and manipulation of geographic database and map algebra to detect changes between the years studied.In Flona Tapajós and its surroundings, between 1989 and 2005, the areas with Native Forest (NF), Regeneration (R), Recent Deforestation (RD) and Exposed soil (ES) that remained unchanged comprised respectively 62, 3, 2 and 2%. The altered areas (17%) underwent their most drastic changes in areas with NF (9%) and in 2005 were identified as R (2%), RD (3%) and ES (4%), while (2%) areas belonging to class RD had not been removed, reaching stage R 2005. The remaining 6% suffered conversion between ES and RD (Table 1). In the period 2005-2009, the areas with NF, R, RD and ES that remained unchanged comprised 61, 6, 3 and 6% (Table 2) respecitvely. It is noteworthy that 11% belonged to Water bodies in both periods. In the period 1989-2005 there was a 11% reduction in NF areas. In the second period, this reduction was approximately 1%. On the other hand, the area (R) made up only 4.4% in 1989 and grew to 7.6% in 2005, reaching about 11% of the area in 2009.Areas with RD represented 5% in 1989 and 7% in 2005 and 2009, indicating that the «Government Programme Zero Deforestation in the Amazon» shows evidence of consolidation in Flona Tapajós and its surroundings. This fits with the trend in ES, which went from 4% in 1989 to 19% in 2005 and 2009. It is noteworthy that, despite the reduced fragments located within Flona Tapajos, its environment, in particular its buffer zone, underwent a robust process of human disturbance. From the results, we concluded: Between 1989 and 2005 there was a higher percentage of loss patterns in the Native Forest than occurred from 2005 to 2009 and the patterns remained stable; the method of assessment of natural and non-natural landscapes can support the understanding of the observed dynamics of use and coverage. In addition, the assessment provides support for analysis of the effects of fragmentation in this landscape. The spatiotemporal dynamics in Flona Tapajós and its surroundings indicates the importance of legally protected areas for the conservation of goods and services offered by the people as part of the Amazon Forest Strategy. In integration with other information and analysis, these dynamics may uncover possible threats to the maintenance of goods and services that sustain the biodiversity of the region.

P-2214-16

Scenario analysis of the main drivers forces threatening the conservation of the Tapajós National Forest, Brazilian Amazon

N. Nascimento (1) ; L. Martorano, (2) ; NES. Beltrão (3)

(1) National Institute of Spatial Research, Terrestrial system sciences departament, São José dos Campos, SP, Brazil; (2) Embrapa, Agrometeorologia, Belém, Brazil; (3) State University of Pará, Applied Social Sciences, Belém, PA, Brazil

Several public policies were released in an attempt to integrate the Amazon to the other regions of Brazil in the 1960s. Amongst the main engagements on infrastructure, the government built ports, hydroelectric facilities, and opened highways such as the Transamazônica (BR 230), Cuiabá-Santarém (BR 163) and Belem-Brasilia (BR 316), triggering an aggressive process of landscape transformation and deforestation. At the same time, however, the government instituted legally protected areas in the region, such as the Tapajos National Forest (FLONA), in 1974. The road was extended in 2012 and is now part of a regional complex, between two major highways in the region. The Tapajós National Forest suffers influence of the Transamazônica highway (BR-230) in the South, and the Cuiabá- Santarém highway (BR-163) located in its Earsten side, which leads to Santarém and Itaituba. Despite all the pressures generated by its surroundings, the protected area has presented suitable conservation indicators. However, it is noteworthy that the west side of Pará concentrates the greatest number of projects, as the seven hydroelectric power plants, the Cargo Transhipment Stations (ETC), and also the paving of highways BR-163 and BR-230. Thus, the spatiotemporal analysis intends, not only to provide a description of changes over time, but also to point out future trends and identify higher-pressure areas. This study addresses efforts to investigate landscape changes in the Tapajós National Forest and its surroundings, which covers a total area of 19,627 km², including the municipalities of Belterra, Santarém, Aveiro, Rurópolis, and Placas. The

literature review supported the selection of change drivers.

Considering the infrastructure, we selected roads, municipal offices, land tenure (settlements, Conservation Units and Indigenous Lands) and localities. Biophysical elements included climate variables such as rainfall and annual water deficit, altimetry and slope. All variables were crossed with land use data made available by the project TerraClass (INPE) for 2008 and 2010. For each municipality was sought information on crop, livestock and plant extraction through production to subsidize economic data provided by the results of spatial analysis process. Data were spatialized by using the geostatistics analysis, modeling and scenario generation were operated in the DINAMICA software that provided a detailed analysis for each vector element of change in the landscape, in addition to its role in the spatial dynamics of the study area.

The results showed that amongst the variables used as landscape transformation vectors, the roads appear to be the main drivers of change in every scenario, which means a change in the forest with different production systems. Taking into account the total area analysed, sites from Rural Settlement present more probability for transitions. The remaining areas with most probability for transitions are those with the lowest declivity values, who use agricultural machinery on the yearly cultivation of soy and corn. The remaining transitions follow the deforestation pattern, known as fishbone, along the Transamazonica highway. Inside the National Forest, the road that connects the São Jorge Community to the Tapajós across the Forest, at the Km 67 on Highway 163, is a major anthropic pressure. The evidence to this fact is that in 2012 this community was no longer under the control of ICMBio. In the map, the yellow and red dots indicate the places with higher chance of changing in the year 2030. According to the map, there are two zones of concern: the South side of FLONA, for the settlements controlled by INCRA (National Institute of Colonization and Agrarian Reform); the West side, where the Santarem-Cuiabá road is being renewed. The South side is a major concern for biological conservation given the intense use of the soil by farmers from the Settlements. The altitude, intense rainfall rates, the areas for settlements, and the predicted scenario for the year 2030 are elements that strengthen the need of Integrated Crop-Livestock-Forestry Systems to relieve the pressure on the south side of the Tapajós National Forest. Based on the results, we conclude that the emancipation of the São Jorge Community entails a further loss in the total area of FLONA for 18 years scenario, therefore leading to a threat for this Conservation Unit. In addition, it is recommended that the ICMBio should have a more strict access control to the Tapajós River.

P-2214-17

On the need to integrate microclimates and thermal limits when forecasting warming tolerance of organisms

S. Pincebourde (1) ; J. Casas, (2)
(1) CNRS, Institut de Recherche sur la Biologie de l'Insecte (IRBI), Tours, France; (2) Université François Rabelais, Institut de recherche sur la biologie de l'insecte (irbi), Tours, France

The impact of warming on the persistence and distribution of ectotherms is often forecasted from their warming tolerance—inferred as the difference between their upper thermal limit and habitat temperature, which is usually taken as the macroclimate temperature. Ectotherms, however, are thermally-adapted to their microclimates, which can deviate substantially from macroscale conditions. Ignoring microclimates can therefore bias estimates of warming tolerance. We compared warming tolerance of a leaf miner insect across its ontogeny when calculated from macro- and microclimate temperatures. We used a heat balance model to predict experienced microclimate temperatures from macroclimate, and we measured thermal limits for several life stages (egg, larval stages 4 and 5, and pupae). The model shows a concomitant increase in microclimate temperatures and thermal limits across insect ontogeny despite they all experience the same macroclimate. Consequently, warming tolerance, as estimated from microclimate temperature, remained constant across ontogeny. When calculated from macroclimate temperature, however, warming tolerance was wrong by over 7–10°C depending on the life stage. Therefore, large errors are expected when predicting persistence and distribution shifts of ectotherms in changing climates using macroclimate rather than microclimate.

P-2214-18

Inferring the effect of climate change on dispersal-limited species in the Brazilian Atlantic rainforest with collection data and targeted field sampling

V. Tarli (1) ; P. Grandcolas (2) ; R. Pellens (2)
(1) Muséum National d'Histoire Naturelle, CNRS UPMC EPHE, Institut de systématique, evolution, biodiversité, umr 7205 isyeb, Paris, France; (2) Muséum National d'Historie Naturelle, CNRS UPMC EPHE, Institut de systématique, evolution, biodiversité, umr 7205 isyeb, Paris, France

Inferring the effect of global change is especially difficult in tropical biodiversity hotspots. These places shelter a large and poorly known part of the world's biodiversity, with many species that cannot track environmental changes due to their limited dispersal ability. Tropical hotspots are also submitted to the fastest man-induced environmental changes. Therefore, even strongly targeted field samplings cannot be fast and comprehensive enough to provide knowledge for taking management and conservation decisions. Sampling needs to be completed by data already obtained and accumulated for decades in Museum collections. Better than being simply supplementary, these data are often critically complementary, since they represent the only available information for parts of natural ecosystems that are already largely destroyed, allowing for composing more real models of species requirements and distributions. We carried out a study to understand the effect of climate change on one of the most remarkable hotspots of biodiversity, the Brazilian Atlantic rainforest, fragmented in thousands of remnants, and extending on more than 3000 km from Nordeste to Uruguay. Our goal was to evaluate the ability of dispersal-limited and poorly-known species to survive climate change and also to assess how much collection data from Natural History Museums complement a targeted field sampling. We focused on one model organism, the saprophagous insect genus Monastria Saussure, 1864 (Dictyoptera, Blaberidae) endemic of the whole rainforest hotspot, abundant but still poorly known, dispersal-limited and unable to track climate change.

We conducted a targeted field sampling by visiting 67 locations distributed all over the Atlantic rainforest in geographical and altitudinal extremes and including all forest physiognomies, and by also sampling "secondary" forests and areas with other land uses. This was complemented with specimens from collections from 13 Natural History Museums. We used the Species Distribution Model (SDM) MaxEnt to model present and future potential habitats based on sets of 19 Bioclim climate variables. For current climate, we used the data from 1950-2000 provided by Worldclim. The habitat modeled with collection data nicely overlaps in 89% that obtained with targeted field sampling. It covered almost the entire range of the 19 climate variables assessed with targeted samples, which shows how useful it can be to consider it.
