Method for manufacturing a junction

The present invention relates to a method for manufacturing a junction with a controlled dopant (concentration) profile comprising (or consisting of) the steps of:
- forming a first semiconductor material comprising a first dopant having a first concentration and thereupon
- forming a second semiconductor material comprising a second dopant, having a second concentration thereby forming a junction, and
- depositing by Atomic Layer Epitaxy or Vapor Phase Doping at least a fraction of a monolayer of a precursor suitable to form the second dopant on the first semiconductor material, prior to forming the second semiconductor material, thereby increasing the second concentration of the second dopant at the junction.

FIG. 2b
Description

TECHNICAL FIELD OF THE INVENTION

[0001] The present invention relates to a semiconductor device comprising a homojunction or a heterojunction with a controlled dopant (concentration) profile and a method of making the same. For example, the present invention can be suitably applied in the manufacturing of a bipolar device for BiCMOS technology or of a photovoltaic device having a controlled dopant (concentration) profile at the emitter-base interface.

BACKGROUND OF THE INVENTION

[0002] In the npn (pnp) bipolar transistor, the emitter layer consists of n-type (p-type) semiconducting material that is deposited on top of the epitaxially-grown base structure. The emitter itself is either polycrystalline or monocrystalline. A monocrystalline emitter is preferred from the point of view of device integration because it allows for a reduction of parasitic resistance and enables band gap engineering of the emitter stack in the perspective of optimization of the transistor performances. In both cases, high dopant concentration (above 1E20 at/cm3) is required in order to achieve low-resistance emitter layer.

[0003] Nowadays the fabrication of a bipolar transistor is performed in a BiCMOS process flow, which means that the thermal anneal that drives the dopants from the emitter layer into the base layer also serves as a junction activation anneal for the CMOS part of the device. This step, which consists of a spike anneal occurring after the deposition of the emitter layer, is usually fixed by the optimization of the CMOS part of the process flow and provides a relatively high thermal budget which might adversely impact on the bipolar device characteristics.

SUMMARY OF THE INVENTION

[0004] The present invention provides a method for controlling the dopant concentration profile at the emitter-base interface of a bipolar transistor.

[0005] More particularly, the present invention provides a method for controlling a dopant overshoot (or a dopant concentration peak) at the emitter-base interface of a bipolar transistor.

[0006] Furthermore, the present invention provides a method for improving the control of the doping profile at the emitter-base interface of a bipolar transistor (when compared to methods described in the art).

[0007] The present invention provides a method for controlling the in-diffusion depth of the dopants at the emitter-base interface of a bipolar transistor upon a rapid thermal treatment.

[0008] More particularly, the present invention provides a method for improving the control of the in-diffusion depth of the dopants at the emitter-base interface of a bipolar complementary metal-oxide-semiconductor (BiCMOS), upon applying the activation anneal of the complementary metal-oxide-semiconductor (CMOS) flow (when compared to methods described in the art).

[0009] The present invention provides a method for forming a highly doped semiconductor layer in a bipolar transistor having a dopant concentration exceeding (or above) the dopant solid solubility.

[0010] According to one aspect of the present invention, a method is provided for manufacturing a junction with a controlled dopant (concentration) profile comprising (or consisting of) the steps of:

- forming a first semiconductor material comprising a first dopant having a first concentration and thereafter;
- forming a second semiconductor material comprising a second dopant, having a second concentration thereby forming a junction, and
- depositing by Atomic Layer Epitaxy or Vapor Phase Doping at least a fraction of a monolayer of a precursor suitable to form the second dopant on the first semiconductor material, prior to forming the second semiconductor material, thereby increasing the second concentration of the second dopant at the junction.

[0011] In the context of the present invention, a controlled dopant (concentration) profile refers to a steep (or abrupt or box-shaped or sharp) (concentration) profile of the second dopant at the junction in the as-deposited structures/layers.

[0012] More particularly, in a method of the present invention, the second concentration of the second dopant is increased locally (or an overshoot is created) at the junction. Otherwise stated, the second dopant (concentration) profile at the junction is controlled by steepening the second dopant (concentration) profile at the emitter-base junction.

[0013] In a method of the invention, the first semiconductor material can be a monolayer (or a single layer), or can comprise multiple layers, each of them being epitaxially grown.

[0014] In a method of the invention, the first concentration of the first dopant in the first semiconductor material can be comprised between (about) 10^{18} atoms cm^{-3} and (about) 10^{19} atoms cm^{-3}, preferably lower than 1x10^{20} atoms cm^{-3}.

[0015] In the context of the present invention, a fraction of a monolayer of a precursor refers to the deposition of less than one monolayer of said precursor on the surface (of a semiconductor material), whereby said surface is not fully covered with said precursor (i.e. incomplete coverage of the surface). Furthermore, it is to be understood that clustering of said precursor does not occur in said fraction of said monolayer.

[0016] In the context of the present invention, one monolayer (or one ML, or one single atomic layer) of a pre-
cursor refers to the deposition of said precursor on the surface (of a semiconductor material), whereby said surface is fully covered with said precursor. Furthermore, it is to be understood that clustering of said precursor does not occur in said monolayer.

[0017] Preferably, in a method according to the invention, the first semiconductor material and the second semiconductor material have the same composition, thereby forming a homojunction.

[0018] Preferably, in a method according to the invention, the first semiconductor material and the second semiconductor material have different compositions, thereby forming a heterojunction.

[0019] Preferably, in a method according to the invention, forming the second semiconductor material comprises

- performing a sequence consisting of
- epitaxially growing a layer of a second semiconductor material and thereupon
- depositing by Atomic Layer Epitaxy a monolayer of a precursor suitable to form the second dopant
- repeating the sequence at least twice, thereby incorporating the second dopant in substitutional sites in the second semiconductor material.

[0020] Preferably, in a method according to the invention, the second concentration of the second dopant in the second semiconductor material is higher or equal to 1x10^20 cm^-3.

[0021] Preferably, in a method according to the invention, the second dopant is a n-type dopant.

[0022] Preferably, the n-type dopant is arsenic (As) or phosphorus (P).

[0023] Preferably, the precursors suitable to form the n-type dopant are arsine (AsH3) or phosphine (PH3).

[0024] Preferably, in a method according to the invention, the first dopant is a p-type dopant.

[0025] Preferably, the p-type dopant is boron.

[0026] Preferably, in a method according to the invention, the second semiconductor material comprises Si, Ge or combinations thereof.

[0027] Preferably, in a method according to the invention, the second semiconductor material is an emitter region of a bipolar transistor.

[0028] Preferably, in a method according to the invention, the first semiconductor material comprises Si, Ge or combinations thereof.

[0029] Preferably, in a method according to the invention, the first semiconductor material is a base region of a bipolar transistor.

[0030] Preferably, a method according to the invention further comprises a rapid thermal treatment (or rapid thermal anneal (RTA) or spike anneal).

[0031] In a method of the invention, said rapid thermal treatment is performed after the step of forming a second semiconductor material.

[0032] According to one aspect of the invention, said rapid thermal treatment is performed after the step of forming a second semiconductor material, at the same time (or simultaneously) with the activation anneal of the CMOS device.

[0033] The present invention provides a method for controlling the in-diffusion depth of the dopants at the emitter-base interface of a bipolar transistor upon a rapid thermal treatment.

[0034] In the context of the present invention, the in-diffusion depth (or electrical junction depth or (in-)diffusion length) of the dopants refers to the depth to which said dopants are diffused into the base region upon performing a rapid thermal anneal.

[0035] In a method of the invention, said rapid thermal treatment is performed using any means known in the art, more preferably by rapid thermal anneal, by laser anneal, or by flash anneal.

[0036] Preferably, the temperature of said rapid thermal anneal (or spike anneal) is comprised between about 1050°C and about 1200°C for about 0 seconds (of soaking time), more preferably about 1100°C for about 0 seconds (of soaking time).

[0037] Preferably, when said rapid thermal treatment is performed by laser anneal or by flash anneal, the exposure time is of the order of sub-milliseconds.

[0038] Preferably, the rapid thermal treatment is a typical HDD (highly doped drain) activation anneal used in CMOS technology.

[0039] Preferably, an in-diffusion depth of Arsenic (As) into the first semiconductor material is lower or equal to 15nm upon (performing) the rapid thermal treatment.

[0040] According to another aspect, the present invention relates to the use of a method as above described for the manufacture of a bipolar CMOS (BiCMOS) device.

[0041] In still another aspect, the present invention relates to the use of a method as above described for the manufacture of a photovoltaic device.

BRIEF DESCRIPTION OF THE DRAWINGS

[0042] Fig. 1a represents schematically the emitter-base heterojunction (Si/SiGe) of a bipolar transistor, wherein the emitter is n-type heavily doped and the base is p-type doped (before performing a rapid thermal anneal).

[0043] Fig. 1b represents schematically the emitter-base heterojunction (Si/SiGe) of a bipolar transistor, wherein the emitter is n-type heavily doped and the base is p-type doped, having an overshoot (or concentration peak magnitude) of the n-type dopant (As) present at the emitter-base metallurgical junction (before performing a rapid thermal anneal). Said overshoot of the n-type dopant (As) may then be used as a reservoir of n-type dopant (As) for adjusting the concentration profile of said dopant, during (or upon performing) a subsequent rapid thermal anneal (i.e. diffusion of said dopant into the base region).

[0044] Fig. 2a represents schematically the emitter-
In the context of the present invention, an abrupt (or box-shaped) dopant concentration profile at the emitter-base interface is steep (i.e. abrupt/box-shaped). Preferably, the dopant concentration profile at the emitter-base interface is steep (i.e. abrupt/box-shaped). Upon performing a rapid thermal anneal said slope is less steep (or less abrupt) and shows a kink (such as represented e.g. in fig. 2a, 2b, or in fig. 5a, 5b (curve 3)) due to the diffusion of the dopant into the base region.

One inventive aspect relates to a semiconductor device comprising a homojunction or a heterojunction with a controlled dopant (concentration) profile and a method of making the same.

Another inventive aspect relates to a method for manufacturing a bipolar device (suitable for BiCMOS technology) having a controlled dopant (concentration) profile at the emitter-base interface and a controlled in-diffusion depth for a (pre-determined) rapid thermal treatment compatible with the conventional CMOS flow. Preferably, the dopant (concentration) profile at the emitter-base interface is steep (i.e. abrupt/box-shaped).

Yet another inventive aspect relates to a method for manufacturing a photovoltaic device having a controlled dopant (concentration) profile at the emitter-base interface. Preferably, the dopant (concentration) profile at the interface is steep (i.e. abrupt/box-shaped).

Another aspect of the present invention relates to a method for forming a highly doped semiconductor layer for a photovoltaic device (e.g. an emitter layer) having a dopant concentration exceeding the dopant solid solubility.

Another aspect of the present invention relates to a method for forming for forming a highly doped semiconductor layer for a photovoltaic device (e.g. an emitter layer) having a dopant concentration exceeding the dopant solid solubility.
In case of a npn bipolar transistor, the emitter region comprises a p-type heavily-doped semiconductor material and the base region comprises a n-type doped semiconductor material (the emitter layer being deposited on top of the surface of the epitaxially-grown base structure).

The base region can comprise multiple layers, each of them being epitaxially grown. For the purpose of illustration, the direction of growth is e.g. indicated by the arrow in the upper (right) corner of Figure 1a (and Figure 1b).

Different embodiments of the invention disclose a base region comprising Si and/or SiGe. Optionally, the concentration of Ge has a flat (constant) profile. Alternatively, the concentration of Ge has a ramped profile towards the top surface (of said base region), or a ramped profile towards the substrate.

In a particular embodiment of the invention a base region is disclosed having a 2-step Ge profile. More specifically the base region comprises a layer of SiGe with a first Ge concentration (SiGe1 in e.g. Figure 1a and Figure 1b), thereupon a second SiGe layer with a second Ge concentration (SiGe2 in e.g. Figure 1a and Figure 1b) and a base cap layer of Si. Preferably, the second Ge concentration is lower than the first Ge concentration.

The emitter region comprises a heavily-doped semiconductor material which can be either polycrystalline or monocrystalline. A monocrystalline emitter is preferred from device integration point of view since it allows a reduction of parasitic resistance and enables band gap engineering of the emitter stack. Throughout the description, a heavily doped semiconductor material is defined as a semiconductor material having a dopant concentration above (about) 1x10^{20} at/cm^3. The heavily doped emitter is required in order to achieve low-resistance emitter region.

Figure 1a (and figure 1b) shows schematically a Si/SiGe heterojunction bipolar transistor before applying (rapid) thermal treatment (or anneal). The optional (epitaxially grown) Ge peak in the emitter region is designed to improve the device operation by increasing the base current without degradation of the high-frequency performance.

Figure 2a (and figure 2b) represents schematically the Si/SiGe heterojunction of the bipolar transistor of Figure 1a (and figure 1b, respectively) after applying a rapid thermal treatment (or anneal). As shown in Figure 2a (and figure 2b), the junction is electrically activated (upon applying said rapid thermal treatment) and the emitter-base n-p (electrical) junction occurs in the layer SiGe2.

For a good performance of the heterojunction bipolar transistor, several requirements need to be fulfilled: (a) a high doping level in the emitter region (to reduce the emitter resistance), typically above 1x10^{20} cm^{-3}; (b) a sharp (i.e. abrupt, or steep) doping (concentration) profile at the emitter-base interface (e.g. in figure 1a and figure 1b); (c) a good control over the location of the electrical emitter-base junction (i.e. control of the electrical junction depth, given by the quality of the deposition process control), preferably positioned in the SiGe layer with low Ge content (e.g. SiGe2 in figures 2a and figure 2b, i.e. the electrical emitter-base junction preferably not being spread over the whole base thickness). In case of a base region with a ramped Ge profile, the in-diffusion depth should be reproducible (i.e. electrical emitter-base junction positioned at a fixed Ge content). A typical thickness of the base Si cap layer is about 7-15nm, which means that the (electrical) junction depth should be lower than 15nm, preferably lower than 7nm, the depth being measured from the metallurgical junction.

When the fabrication of a bipolar transistor is performed in a BiCMOS process flow, the (rapid) thermal anneal that drives the dopants from the emitter layer into the base region also serves as a HDD (Highly Doped Drain) activation anneal for the CMOS part of the device. This step, which consists of a spike (i.e. rapid thermal) anneal occurring after the deposition of the emitter layer/region, is usually fixed by the optimization of the CMOS-process flow and provides a relatively high thermal budget. A typical spike anneal for CMOS flow is a rapid thermal treatment (or anneal) at a temperature higher than 1050 °C, e.g. at 1085 °C.

The thermal budget of the spike anneal determines the in-diffusion depth of the emitter dopants and the position of the electrical emitter-base junction, which has a direct impact on the device characteristics. The method of the invention allows to control the effect of a high thermal budget activation anneal on dopant in-diffusion.

In general, forming a perfect sharp (i.e. box-shaped) dopant (concentration) profile at the emitter-base interface region is hampered by the lack of abruptness of the transition region between the emitter layer and the substrate (i.e. base cap), especially for highly-doped layers with e.g. arsenic introduced by an in-situ doping process in a chemical vapor deposition chamber.

The difficulty of realizing abrupt (i.e. steep) transitions (or concentrations) profiles originates both in the poor surface adhesion of the dopant (e.g. As, P, B) and the strong surface segregation of the dopant during growth. The segregation effect results in an incorporated bulk concentration lower than that the surface concentration by several orders of magnitude. These combined effects lead to a ‘corner-rounded’ (or a undershoot) of the concentration profile at the emitter-base interface in the as-deposited structures (illustrated in Fig 1a), instead of the intended box-shape (i.e. steep) profile (as illustrated in Fig. 2a).

The invention discloses a method for manufacturing a junction with a controlled dopant (concentration) profile comprising:
- forming a first semiconductor material comprising a first dopant having a first concentration and thereupon
- forming a second semiconductor material comprising a second dopant having a second concentration, thereby forming a (physical/metallurgical) junction, and
- depositing by Atomic Layer Epitaxy or Vapor Phase Doping at least a fraction of a monolayer of a precursor suitable to form the second dopant on the first semiconductor material, prior to forming the second semiconductor material, thereby increasing locally the second concentration of the second dopant at the (physical/metallurgical) junction.

[0077] In various embodiments of the invention the term "controlled dopant (concentration) profile" refers to steep (i.e. abrupt/box-shaped) (concentration) profile of the second dopant at the junction in the as-deposited structures/layers. This can be achieved by increasing locally the second concentration (or creating an overshoot) of the second dopant at the junction. In line with the above, steepening the second dopant (concentration) profile at the emitter-base junction means controlling (or creating an overshoot in) the second dopant (concentration) profile at the junction (i.e. at the metallurgical junction, before the step of performing the rapid thermal anneal, and subsequently, at the electrical junction, after having performed the rapid thermal anneal).

[0078] In different embodiment of the invention, the first semiconductor material and the second semiconductor material are made of the same material and have the same composition, thereby forming a homojunction.

[0079] In other embodiments of the invention the first semiconductor material and the second semiconductor material are made of different materials or have different compositions, thereby forming a heterojunction.

[0080] The method of the invention may comprise additional steps in between forming a first semiconductor material comprising a first dopant and forming a second semiconductor material comprising a second dopant. In case of a BiCMOS process flow, the emitter growth is in all cases the emitter layer/region overlying a lithographic step for emitter window definition. Howev-

[0081] The method of the invention allows the control of the dopant (concentration) profile at the emitter-base interface. Locally a dopant containing layer (of high dopant concentration) is provided that is used as a dopant reservoir for the in-diffusion during the subsequent (rapid) thermal treatment (or activation anneal).

[0082] Vapor Phase Doping (VPD) is a Chemical Vapour Deposition (CVD) process wherein dopant atoms chemi-sorb on a heated substrate and subsequently, at the electrical junction, after having performed the (rapid) thermal anneal.

[0083] Preferably, the precursors are diluted in hydrogen gas (H₂), or in an inert gas, such as nitrogen gas (N₂) or argon (Ar).

[0084] The precursors used in manufacturing are mostly diluted in hydrogen (i.e. mixtures of the species suitable to form dopants and H₂).

[0085] Forming a dopant containing layer has to be performed at a temperature lower than the corresponding dopant desorption limit for the n-type dopants (As, P) and, respectively, lower than the dopant in-diffusion limit for the p-type dopants (B). The dopant desorption limit is defined as the temperature at which the dopants start to desorb from the substrate. The dopant in-diffusion limit is defined as the temperature at which the dopants start to diffuse into the substrate.

[0086] Typical examples of n-type dopant precursors are arsine (AsH₃) and phosphine (PH₃). Advantageously, forming an arsine/phosphine containing layer is performed at a temperature lower or equal to the dopant desorption limit. In case of arsine, the dopant desorption limit is 600 °C. The dopant desorption limit put also a constraint on the deposition temperature of the epitaxial overgrowth of a semiconductor material as referred to elsewhere in the description.

[0087] A typical example of a p-type dopant precursor is diborane (B₂H₆). Advantageously, forming a diborane containing layer is performed at a temperature lower or equal to the dopant in-diffusion limit.

[0088] When the dopant deposition step from the gas phase in the Vapor Phase Doping process occurs epitaxially on the substrate and when the amount of dopants (or dopant dose) can be atomically controlled (typically at lower temperatures then usual VPD), the technique is also known as Atomic Layer Epitaxy (ALE). Atomic Layer Epitaxy is a chemical vapour deposition (CVD) process wherein dopant atoms chemi-sorb on a heated substrate through the thermal decomposition from a gaseous precursor (e.g., AsH₃, PH₃, B₂H₆). In the case of n-type doping, the chemisorption mechanism is self-limiting resulting in one single atomic layer (i.e. one monolayer) of dopant atoms (illustrated in Fig. 3). In the case of p-type doping, the self-limitation can be observed only at very low temperature, of the order of 100°C.

[0089] In the case of n-type doping (e.g. with As) the deposition is self-limited to 1 monolayer (ML). Below 1 ML, the deposited dose is determined by the duration of the exposure to the gaseous precursor (AsH₃), as shown in Figure 3 in the region labeled with ‘(1).’

[0090] Atomic Layer Epitaxy can be applied for in-situ doping of a semiconductor material. In this case, a layer of a semiconductor material (e.g. Si, Ge or SiGe) is epitaxially grown on top of a dopant layer already formed as illustrated in Fig 4.

[0091] The self-limitation of ALE to 1 monolayer of dopant is an additional advantage, since the dopant atoms can all be incorporated in substitutional sites during the
epitaxial (over)growth of the semiconductor material. The growth processes are non-equilibrium processes which can be performed below the surface diffusion temperature of the dopants (related to the kinetics of the deposition process). In this way, very high active levels of doping can be obtained, above the dopant solid solubility. When the chemisorption is done on a Si (100) surface, the saturation dose (i.e. the dose of one monolayer) corresponds to a surface concentration of about 6.8x10^{14} atoms/cm².

[0092] The basic sequence that combines a dopant deposition step followed by the epitaxial overgrowth of a semiconductor layer can be repeated several times (or cycles). Each time, the overgrown semiconductor layer provides a fresh surface which allows the formation of a new dopant layer. This process is represented schematically in Figure 4.

[0093] Embodiments of the invention disclose depositing at least a fraction of a monolayer of a precursor suitable to form a dopant at a pressure between about 0.1 Pa and about 1 atm (101 kPa). The reaction chamber can be, for example, an epitaxial reactor, a low pressure chemical vapor deposition (LPCVD) chamber, a reduced pressure chemical vapor deposition (RPCVD) chamber, an atmospheric pressure chemical vapor deposition (APCVD) chamber or a ultra high vacuum chemical vapor deposition (UHVCVD) chamber, or a gas source molecular beam epitaxy chamber (GSMBE).

[0094] In specific embodiments of the invention a method is disclosed to improve the steepness of the doping profile at the interface between the emitter and the base region of a bipolar transistor (when compared to methods described in the art). Secondly, the method allows a good (or improved) control of the in-diffusion depth of the dopants at the emitter-base interface of a bipolar CMOS, upon applying the conventional activation anneal of the CMOS flow (when compared to methods described in the art).

[0095] Since the as-deposited dose can be varied with continuous values between 0 and 1 ML, ALE can be tuned to fit the profile steepness at the (emitter-base) interface and, at the same time, the diffusion length in the base (upon rapid thermal anneal).

[0096] The bulk of the emitter can be grown either by conventional in-situ doping techniques (e.g. Chemical Vapour Deposition (CVD) or by performing multiple cycles of ALE.

[0097] The emitter region can comprise multiple layers, each of them being epitaxially grown.

[0098] The sequence of dopant deposition (ALE) and epitaxial overgrowth of a semiconductor material such as Si, Ge, SiGe is repeated several times (Fig. 4). Because the overgrown layer provides a fresh surface for the dopant atoms, the dopant dose can be increased to any arbitrary value, provided that a sufficient amount of cycles is performed. Due to the layer growth, the thickness of the structure increases with the number of cycles.

[0099] If the exposure time is short enough during the ALE step, the substrate surface is not saturated by dopants. By an adequate choice of the exposure time, it is possible to tune the as-deposited dose at the required value (see e.g. figure 3 in the region labeled with (1)).

[0100] If ALE is followed by a (rapid) thermal treatment (or anneal), the dopant atoms will be activated in the semiconductor material. The maximum active dopant level that can be achieved is determined by the solid solubility limit at the anneal temperature. In the case of n-type dopants, without the deposition of a capping layer (or overgrown semiconductor material) immediately after the ALE step, most of the adsorbed atoms will desorb during the anneal step at temperatures higher than 550 °C -600°C. Therefore the semiconductor material must be grown/deposited at a temperature lower than the desorption temperature, to act as a protective cap layer with minimal alteration of the as-deposited dopant dose.

[0101] In Fig. 5a (and fig. 5b), secondary ion mass spectrometry (SIMS) measurements of the As concentration in the emitter layer are shown for 4 samples in the neighborhood of the physical interface between the emitter region (left hand side of the figure) and the base region (right hand side of the figure) (said transition region between the emitter region and the (base cap of the) base region indicated on top of said figure and depicted with the dashed line rectangle on said figure). In the as-deposited sample with the ALE (curve 3), the problem of the corner-rounded profile (curve 1) is solved, obtaining even a dopant concentration peak, with a magnitude of 6.2E20 at/cm³. This magnitude of the concentration peak corresponds to 1 ML of As, but can be tuned/controlled towards lower values, upon the requirements of a particular device, by depositing a fraction of a monolayer of arsenine. The possibility to control the dopant overshoot (or concentration peak magnitude) is a particular advantage of the invention.

[0102] As a positive effect of ALE, the As concentration in the region (between -5 nm to -10 nm in said figure) of the overgrown layer close to the ALE peak (curve 3) is more uniform, compared to the profile of the sample without ALE (curve 1). Without being bound to theory, it is believed that the small dip in dopant (As) concentration at -14 nm is most probably due to the presence of Ge in the emitter or to a calibration issue of the SIMS measurement due to the presence of Ge.

[0103] After a spike anneal at 1085°C, the dopant (concentration) profile of the sample using ALE (curve 4) shows deeper in-diffusion compared to that of the sample without ALE (curve 2). The difference is due to the high amount of dopant (1 ML) that is available from the ALE, that acts as a reservoir of dopant atoms during the drive-in anneal. As indicated above, this amount of dopant can be reduced to a fraction of a monolayer in order to adjust the in-diffusion depth upon needs.

[0104] Fig. 6a (and fig. 6b) represents the results of TCAD simulations of an emitter grown using the (multiple) ALE.

[0105] Figure 6a shows the ALE peaks (1) (grey) to (5)
(dashed black) with increasing magnitude. Figure 6b shows the corresponding in-diffusion depth after a spike anneal at 1085°C for the ALE peaks (1) to (5).

The simulations show that a proper tuning of the magnitude of the ALE peak close to the emitter/base interface allow to control the in-diffusion length after (or upon) the (rapid) thermal anneal.

The higher the ALE peak magnitude (i.e. the distance measured from the top of the (grey) peak (1) to the top of the (black-dashed) peak (5) in Fig 6a the higher is the in-diffusion depth (measured in microns on the x-scale) in the direction indicated by the arrow in Fig 6b (i.e. from the grey curve (1) to the black-dashed curve (5)). Upon anneal, the other ALE peaks in the bulk emitter region are leveled off at the same bulk concentration in the emitter.

The present invention can be applied in different areas of semiconductor device manufacturing. While the invention is described in conjunction with a bipolar transistor and more particularly to a bipolar CMOS (BiCMOS) device, it will be apparent to those ordinary skilled in the art that the benefits of this invention can be applied to other applications. Another possible application is growing thin highly doped semiconductor layers on a substrate. The method of the invention can be used e.g. to form thin n+ Si layer for photovoltaic applications or to control the dopant (concentration) profile at the emitter-base junction in a photovoltaic device.

It is to be understood that although preferred embodiments, specific constructions and configurations, as well as materials, have been discussed herein for devices according to the present invention, various changes or modifications in form and detail may be made without departing from the scope of this invention as defined by the appended claims.

Claims

1. A method for manufacturing a junction with a controlled dopant profile comprising the steps of:
   - forming a first semiconductor material comprising a first dopant having a first concentration and thereupon
   - forming a second semiconductor material comprising a second dopant, having a second concentration thereby forming a junction, and
   - depositing by Atomic Layer Epitaxy or Vapor Phase Doping at least a fraction of a monolayer of a precursor suitable to form the second dopant on the first semiconductor material, prior to forming the second semiconductor material, thereby increasing the second concentration of the second dopant at the junction.

2. The method according to claim 1, wherein the first semiconductor material and the second semiconductor material have the same composition, thereby forming a homojunction.

3. The method according to claim 1, wherein the first semiconductor material and the second semiconductor material have different compositions, thereby forming a heterojunction.

4. The method according to any of claims 1 to 3, wherein forming the second semiconductor material comprises
   - performing a sequence consisting of
     - epitaxially growing a layer of a second semiconductor material and thereupon
     - depositing by Atomic Layer Epitaxy a monolayer of a precursor suitable to form the second dopant
     - repeating the sequence at least twice, thereby incorporating the second dopant in substitutional sites in the second semiconductor material.

5. The method according to any of claims 1 to 4, wherein the second concentration of the second dopant in the second semiconductor material is higher or equal to 1x10^{20} cm^{-3}.

6. The method according to any of claims 1 to 5, wherein the second dopant is a n-type dopant.

7. The method according to claim 6, wherein the n-type dopant is arsenic (As) or phosphorus (P).

8. The method according to any of claims 1 to 7, wherein the first dopant is a p-type dopant.

9. The method according to claim 8, wherein the p-type dopant is boron.

10. The method according to any of claims 1 to 9, wherein the second semiconductor material comprises Si, Ge or combinations thereof.

11. The method according to any of claims 1 to 10, wherein the second semiconductor material is an emitter region of a bipolar transistor.

12. The method according to any of claims 1 to 11, wherein the first semiconductor material comprises Si, Ge or combinations thereof.

13. The method according to any of claims 1 to 12, wherein the first semiconductor material is a base region of a bipolar transistor.

14. The method according to any of claims 1 to 13, further comprising a rapid thermal treatment.
15. The method according to claim 14, wherein upon the rapid thermal treatment an in-diffusion depth of As into the first semiconductor material is lower or equal to 15nm.
